The Fifth Edition of *Essential Surgical Practice* is dedicated to a former Co-Editor of ESP, the late A. R. Moossa, MD (1939–2013), a truly great master surgeon and teacher, and a very close friend who will always be remembered by his Residents brought up within his unforgettable Residency Program at UCSD, California.

PART I: GENERAL SECTION

PART II: SPECIALIST GENERAL SURGERY

Preface

This edition is different from the previous ones in many respects. In the first instance I have recruited a new co-editor, Professor George Hanna, a long-term colleague and friend who is deeply committed to surgical training and education and shares my views on the extreme importance of passing on one's experience and practical clinical knowledge of surgical practice gained over many years to the next generation of surgeons. Between us we have decided to change the structure and content of *Essential Surgical Practice* directing it exclusively to trainees in higher surgical education in General Surgery. This decision reflects the changed scenario in higher surgical training over the past three decades, with the inevitable progress towards specialization in the various Surgical Specialties. Thus all the Specialty Sections included in previous editions (Neurosurgery Thoracic, Vascular and Urology) have been omitted as these are now distinctly separate from General Surgery, which by consensus includes the rest together with Trauma including Head Injuries.

This strategy has allowed us to provide a more detailed account of the various disorders and has enabled us to cover important surgical topics which were either not included in previous editions or were not covered in sufficient depth. We have for this reason recruited new authors, all of whom were carefully selected for their eminence in their respective fields. The 5th edition of *Essential Surgical Practice* is an almost complete rewrite in view of the considerable progress that has taken place in the past 10 years with respect to both pathology and management of the various surgical disorders. The same basic format of *Essential Surgical Practice* has been, however, retained, including highlights of core information for revision purposes and quick reference.

The 5th edition is a single volume with two sections: General section, Chapters 1–15, and Specialist general surgery, Chapters 17–31. *Essential Surgical Practice* will be available in two versions: hard copy and electronic. As with previous editions, both editors have between them written or updated a substantial part of the volume and have taken particular note of all the important recent advances relevant to the subject matter. We have however recruited authors as acknowledged experts for chapters covering topics beyond our clinical expertise, all of whom have provided excellent contributions which required virtually no editing by us.

We hope that the 5th edition of *Essential Surgical Practice* will be well received by the surgical tutors and chiefs of training programmes, and, what is more important to us, that the surgical trainees themselves, irrespective of country, find it a truly useful aid for their surgical education as this has always been our prime objective. Surgical trainees and young consultants are the torch bearers of our profession. In the final analysis, they must always remember that surgery is a craft specialty and that a good surgeon is one who attains fully operating proficiency – nothing less suffices – and, moreover, he or she has the duty of care to his or her patients since technical proficiency and accomplishment are not enough. In essence surgeons are the treatment but the outcome of patients is linked as much to the quality of execution of the operations as to the supportive care which surgeons provide before, during and after surgery.

Finally, we would like to thank our publishers for their assistance, support and especially for their forbearance in extending the deadline for completion a few times. We have no valid excuse for this other than our heavy commitments.

George B. Hanna

List of Contributors

Ahmed R. Ahmed BSc(Hons) FRCS (Gen)
Senior Lecturer in Bariatric Surgery, Imperial College London; Consultant Bariatric Surgeon, Clinical Lead - Bariatric Surgery, St Mary's Hospital, Imperial College Healthcare NHS Trust, Academic Division of Surgery, Department of Surgery and Cancer, London

Saba P. Balasubramanian MS PhD FRCS
Clinical Senior Lecturer and Honorary Consultant Endocrine Surgeon, University of Sheffield and Sheffield Teaching Hospitals NHS Foundation Trust

Jane M. Blazeby BSc MSc MD MBChB FRCS(Gen Surg)
Professor of Surgery, University of Bristol and Honorary Consultant Surgeon, University Hospitals Bristol, NHS Foundation Trust, Bristol

Ken Campbell MBChB FRCS(Ed) MD
Consultant Colorectal Surgeon, Ninewells Hospital, Dundee

Arup Chakraborty BSc MBBS MRCP EDIC
Registrar in Anaesthesia and Intensive Care, Princess Alexandra Hospital, Harlow

Raul Coimbra MD PhD FACS
The Monroe E. Trout Professor of Surgery, Executive Vice-Chairman, Department of Surgery; Chief, Division of Trauma, Surgical Critical Care, and Burns, University of California San Diego School of Medicine, San Diego

Richard W. Corbett
Academic Clinical Fellow, Imperial College Renal and Transplant Centre, Hammersmith Hospital, London

John A. Dewar
Consultant and Emeritus Professor of Clinical Oncology at Dundee University and formerly Head of Oncology at Ninewells Hospital, Dundee

John F. Dillon MBBS MD FRCP
Clinical Senior Lecturer, Gut Group, Medical Research Institute, University of Dundee, Ninewells Hospital and Medical School, Dundee

Neill Duncan MBBS MRCP
Renal Consultant, Imperial College Renal and Transplant Centre, Hammersmith Hospital, London

Sam Eljamel MBBCh MD FRCSEd FRCSIre FRCS(SN)
Consultant Neurosurgeon, Ninewells Hospital and Medical School, Dundee

Andrew Evans
Professor of Breast Imaging, Dundee Cancer Centre, University of Dundee, Dundee

Omar Faiz BSc(Hons) MBBS FRCS(GenSurg) MS
Senior Lecturer and Honorary Consultant Surgeon, St Mark's Hospital, Northwick Park, Harro and Academic Surgical Unit, Imperial College Healthcare NHS Trust, London

Edward Fitzgerald BA BM BCh MRCS(Eng)
Registrar in General Surgery, Royal Marsden Hospital, London

Jacob George MD MRCP
Division of Cardiovascular and Diabetes Medicine, Medical Research Institute, University of Dundee Medical School, Dundee

Priya George MBChB MRCOpth MRCP
Division of Cardiovascular and Diabetes Medicine, Medical Research Institute, University of Dundee Medical School, Dundee

Panayiotis Georgiou
NIHR Academic Clinical Fellow in General Surgery, West Middlesex University Hospital and Imperial College Healthcare Trust, London

Mohamad S. Hamady MD FRCR
Consultant Interventional Radiologist and Honorary Senior Lecturer, Department of Interventional Radiology, Imperial College Healthcare NHS Trust; and Department of Surgery and Cancer, Imperial College London

David Hoyt MD FACS
Executive Director, American College of Surgeons, Emeritus Professor of Surgery University of California San Diego School of Medicine, San Diego

Helgi Johannsson BMedSci MBBS MRCP FRCA
Consultant in Anaesthesia and Chief of Service - Theatres and Anaesthesia, St Mary's Hospital, Imperial College Healthcare Trust, London

Leslie Kobayashi MD FACS
Assistant Professor of Surgery, Division of Trauma, Surgical Critical Care, and Burns University of California San Diego Health Sciences, San Diego

Sacha Koch MD PhD
Consultant Surgeon, Ninewells Hospital and Medical School, Dundee

Onn Min Kon MD FRCP
Consultant Respiratory Physician and Honorary Senior Lecturer, Chest and Allergy Clinic, Imperial College School of Medicine, St Mary's Hospital, London

Paul Maddox BSc MCh FRCS(Ed) FRCS(Eng)
Consultant Surgeon, Department of General Surgery, Royal United Hospital, Bath

Vafa Mansoubi MBBS BSc (Hon) FRCA
Specialist Registrar, School of Anaesthesia, Charing Cross Hospital, Imperial College Healthcare Trust

Ian A. Zealley BSc MBChB FRCP FRCR
Consultant Radiologist, Ninewells Hospital, Dundee

PART I

General section

CHAPTER 1

Surgical biology and pathology

SIR ALFRED CUSCHIERI

Wound healing and repair

In earlier times the wound was assessed somewhat indirectly by studies of the breaking strength and collagen content. Today we look beyond these parameters to the behaviour of the individual cells in the wound since these are the prime movers in the healing process. Uneventful healing is dependent on their health and, in turn, this is determined by their microenvironment and a whole host of growth factors supplemented by growth-promoting and chemotactic substances produced primarily by platelets, lymphocyte cells and macrophages.

The elements of healing

Three distinct processes contribute to the process of wound healing.

Epithelialization

This is the process by which the surface covering of the wound is restored by a combination of cell migration and multiplication. The stimulus for epithelial repair is unknown. The loss of contact between cells undoubtedly plays a part. When an area is denuded of epithelium, the marginal cells divide and migrate across the bare area. The activity ceases when epithelial contact is re-established. There is also evidence that the loss of the epithelial cover is associated with a fall in the level of a local inhibitory hormone or chalone that is synthesized by the epithelial cells. Epithelialization proceeds most rapidly in a most highly oxygenated environment.

Contraction

This is the process by which the edges of an open wound gradually close together. It is a form of tissue migration that involves the entire thickness of the skin and subcutaneous tissues. It therefore proceeds most readily in areas where the skin is loose, such as the buttocks and the back of the neck. Contraction is the result of forces exerted by specialized fibroblasts in the wound. These cells have contractile elements in their cytoplasm known as myofibroblasts. The process of contraction is physiological and must be distinguished from the pathological process of scar contracture or cicatrization that causes distortion and limitation of movement.

Connective tissue formation

This is the process by which the main body of the wound is united. It plays a fundamental role in all but the most superficial injuries, and the strength of the wound following surgery is dependent on it. Connective tissue formation is the most important element of the three components, and many studies of wound healing are simply an examination of this component in isolation.

Types of healing

Although the elements of tissue repair are the same, open and closed wounds heal rather differently. When a surgical incision is closed with sutures or clips and heals without complication, it is said to heal by first intention. Union takes place by a combination of epithelialization and connective tissue formation. When an open wound is allowed to close naturally, union is accomplished by a combination of all three: wound contraction, connective tissue formation and epithelialization. This is known as healing by second intention or by granulation. These wounds heal from the bottom by abundant vascular connective tissue that has a granular appearance, hence the alternative name 'healing by granulation'.

Prior to the development of connective tissue, the closed wound is much more susceptible to infection than the open wound. For this reason, a heavily contaminated wound is often only partially closed. The deeper layers are secured but the subcutaneous tissues and the skin are left open. Once healing is established and granulation tissue has formed, the wound may be closed without fear of invasive infection developing. The technique is called delayed primary closure or secondary suture, and this type of healing is known as healing by third intention.

Phases of healing

In deeper wounds, the strength recovery is often an important attribute. Early studies demonstrated that this occurred in the phasic manner, typical of many biological processes. In the first few days, the wound has no recordable strength. Following this, strength increases rapidly. Finally, after a few weeks, the process slows down yet further increases in strength occur gradually. These features of strength recovery correlate well with observed changes in the wound, and healing is often considered as a three-phase event.

During the first few days, when the wound has no strength, little seems to be happening and this is called the lag phase. However, there is intense enzymic and leucocytic activity with breakdown and removal of devitalized tissue. A better term is the preparation phase, as the foundations for repair are being laid. During the next few weeks, the scene is dominated by the proliferation of cells and capillaries. Neutrophils and macrophages are prominent and fibroblasts lay down collagen in increasing amounts. In an open wound, this vascular fibrocellular tissue is recognized as granulation tissue. This is the phase of proliferation or fibroplasia. After a variable number of weeks, these wound activities slow down. Fibroblasts and capillaries are less evident and strength increases progressively. The third phase is one of maturation or differentiation that lasts for several months.

The organ of repair

During the phase of proliferation the new tissue in the wound can be thought of as a repair organ (Figure 1.1). Its delicate stroma and extensive capillary network provide both physical and nutritional support for its component cells. The function of this organ is connective tissue formation. The fibroblast is the key cell synthesizing collagen and intercellular ground substance. Its activities, together with those of the support macrophages, are dependent on a readily available supply of oxygen. As a result, cells and capillaries develop together as a unit and grow until the wound is filled. This new vascular connective tissue is most obvious in open wounds but it is also present between the edges of a healing, closed, incised wound. As time passes, the fibroblasts and the capillaries become much less prominent and a mature fibrous scar remains.

Dead space

Figure 1.1 Profile of a healing wound. It is a delicate system of cells and capillaries. New tissue grows from the 'vital' edge towards the central dead space. Direct measurements of PO_2 in this granulation tissue show a steady fall from the normal mature tissue level of around 45 mmHg to anoxic levels in the centre of the wound. Macrophages have a lower oxygen requirement than fibroblasts and are found at the free edge of the growing tissue. (After Silver, 1980.)

Wound strength

The recovery of strength has obvious clinical significance and has proved to be one of the most useful indications of the progress of repair. Early studies of wound-breaking strength showed that the apparently well-healed wound was still remarkably weak. Skin and scar tissue are complex viscoelastic materials that cannot be fully characterized unless tensile strength and extension (stretch) are recorded simultaneously. Plotted together, they describe a curve (load–extension) that reflects the ability of the scar to resist rupture (energy absorption, Figure 1.2). The findings are remarkably uniform, demonstrating only a 50–70% recovery of strength by the end of 6 months. It appears that total recovery is rarely achieved. Such low recordings need not cause alarm, for the absolute values are more than enough to meet the stresses imposed by everyday life.

Wound histology

Light microscopy shows a characteristic sequence of events (Figure 1.3). As time elapses after wounding, specific cell populations appear on the scene. Neutrophils predominate in the first day and monocytes peak about 24 hours later. By 5–6 days, fibroblasts are found in large numbers, and their presence is synchronous with the establishment of a microcirculation. Collagen is readily identified in increasing amounts after the fourth day.

A characteristic sequence of enzyme changes is also seen (Figure 1.4). When identified histochemically, these can be used to calculate the age of the wound in hours. Collagen is responsible for most of the strength of the wound, and scar weakness is associated with physical changes in the collagen. When the wound is examined by polarized light, normal collagen stands out as a clearly birefringent material. However, the wound scar does not exhibit this property during the first 6 months of healing. This lack of birefringence indicates a failure of organization at the molecular and small fibril level. Physical factors, e.g. fibre shape and weave, are important in determining the mechanical properties of skin and scar. These are best displayed by scanning electron microscopy. In unwounded skin, the collagen fibrils lie in well-organized bundles (Figure 1.5). In sutured wounds, the collagen fibrils lie in a relatively haphazard manner (Figure 1.6). As time passes, the collagen fibrils in the wound coalesce to form large irregular masses (Figure 1.7), remodelling being minimal. As yet, there is no evidence that the normal architectural network is ever restored.

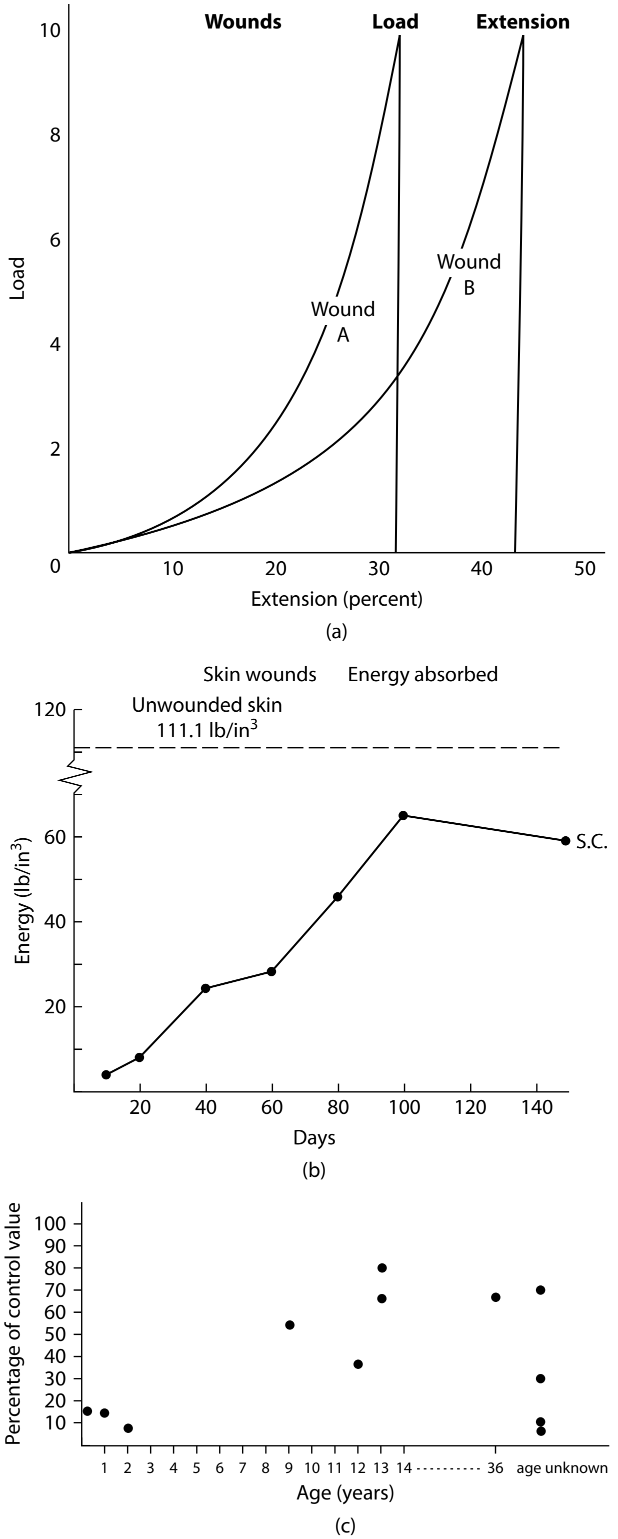

Figure 1.2 (a) Load–extension curves for wounds which break under the same load but differ in the degree of extension. Wound A is less pliable than wound B and is therefore easily ruptured. The ability to resist rupture (energy absorption) is measured by the area under the curve. (b) The ability of a wound to resist rupture expressed as its energy absorption. There is only a 50% recovery by 150 days. (From Forrester *et al.*, *J Surg Res* 1969;**9**:207–212, with permission.) (c) The tensile strength of human skin wounds expressed as a percentage of intact skin. In the first 2 year period, skin wounds are less than 20% of the control value, and even at 13 years there is still a marked weakness. (From Douglas *et al.*, *Br J Surg* 1969;**56**:219–222, with permission.)

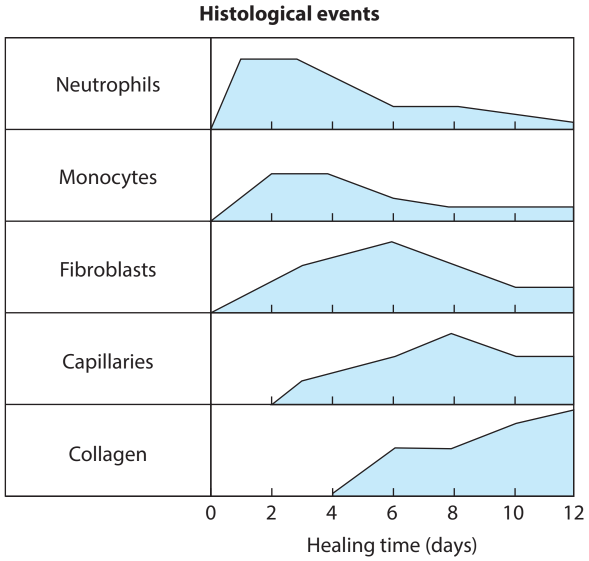

Figure 1.3 Characteristic sequence of events in the first few days of wound healing. Neutrophils and monocytes appear first. Collagen appears following the development of a functioning fibroblast–capillary system.

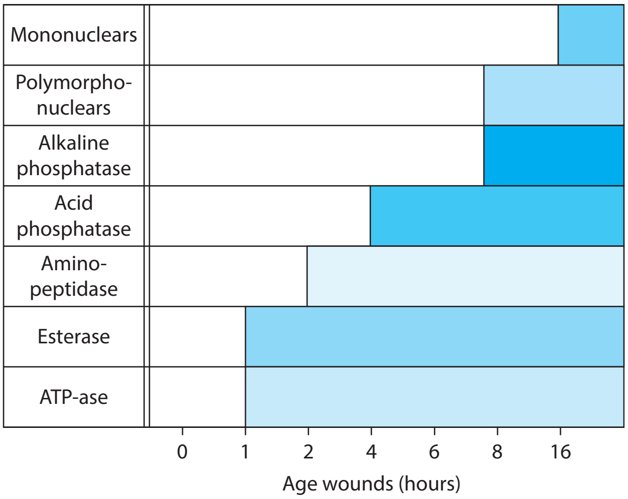

Figure 1.4 Schematic diagram showing the histochemical estimation of age of antemortem skin wounds. (From Rawkallio, *J Forensic Sci* 1972;**1**:3–16, with permission.)

Wound biochemistry

Of all the soft-tissue constituents of the body, only collagen has sufficient strength of its own to be responsible for the observed mechanical properties of unwounded tissue and firmly healed scar. The total amount of collagen rises rapidly in a healing wound and normal levels are usually attained within a few weeks. However, strength continues to increase long after the collagen content has returned to normal. Clearly, the quality of the collagen in the wound alters as time goes by.

Studies using radioactive tracer techniques have clarified the situation (Figure 1.8). The amount of collagen in the wound stabilizes after a few weeks but the rate of collagen synthesis and lysis remains high for considerably longer. This balance of synthesis and lysis may explain several healing defects. In keloid

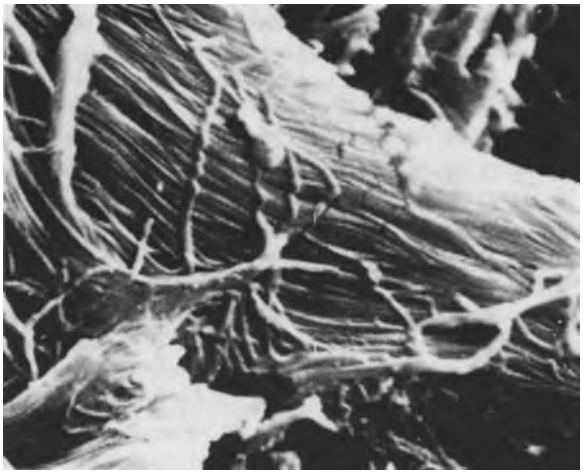

Figure 1.5 Scanning electron micrograph of part of a normal collagen fibre showing that it is made up of bundles of cross-banded fibrils (×9000). (From Forrester *et al.*, *Nature* 1969;**221**:373–374, with permission.)

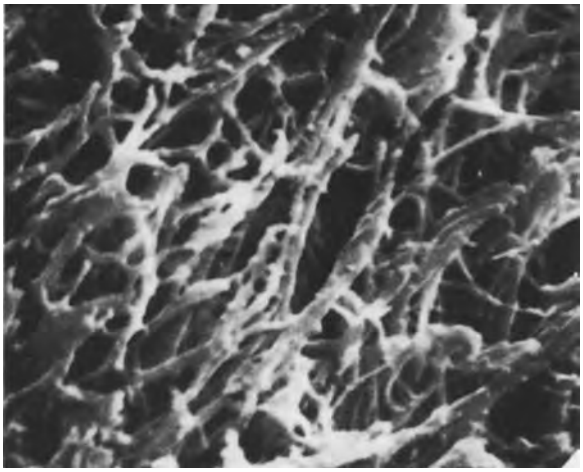

Figure 1.6 Scanning electron micrograph of a 10-day sutured wound showing the randomly orientated collagen fibrils. They show little tendency to aggregate. Cross-banding is not apparent (×9000). (From Forrester *et al.*, *Nature* 1969;**221**:373–374, with permission.)

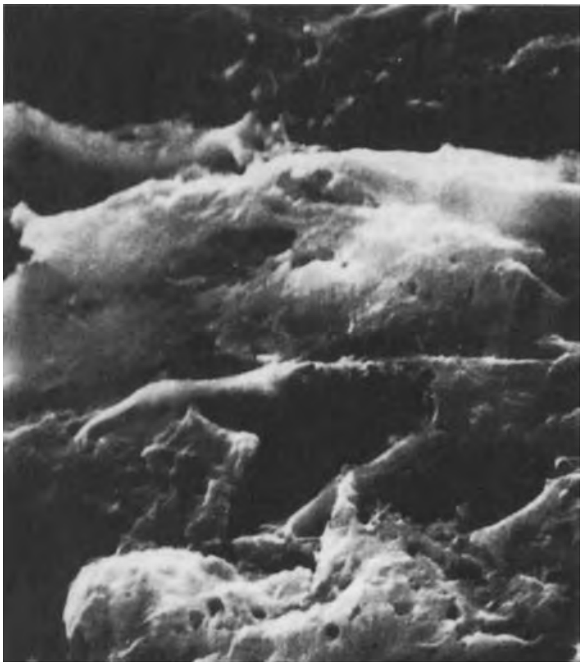

Figure 1.7 Scanning electron micrograph of a representative portion of a 100 day wound. The collagen fibrils have aggregated to form large collagen masses but normal fibre architecture has not been restored (×3150). (From Forrester *et al.*, *Nature* 1969;**221**:373–374, with permission.)

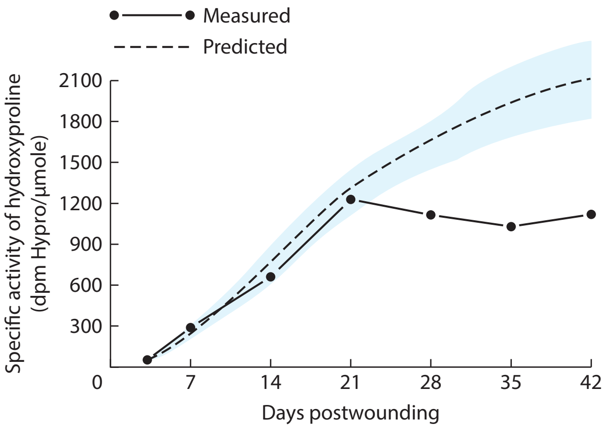

Figure 1.8 Comparison of scar collagen accumulation predicted from its rate of synthesis with that actually measured. Total collagen does not increase after 3 weeks, even though it continues to be synthesized and deposited at a rapid rate. Collagen is now being removed as quickly as it is formed (collagenolysis). The difference between the curves represents scar collagen turnover. (From Madden and Peacock, *Ann Surg* 1971;**174**:511–520, with permission.)

and hypertrophic scars, overproduction of collagen seems to be due to a relatively low rate of lysis. In scurvy, it is the synthesis of collagen that fails, and the wound weakens under the continued lytic process.

Collagen forms 30% of the total protein content of most animals. The collagen molecule is a rigid rod 300 nm long and 1.5 nm wide. Each molecule is composed of three polypeptide chains bound in a left-handed helix. The molecule itself is twisted the opposite way into a right-handed superhelix. The polypeptide chains of collagen are themselves remarkable. Over half of the molecule is composed of the three amino acids: glycine, proline and hydroxyproline. Both the carboxyl and amino ends of the molecule are non-helical and the entire structure is held together by hydrogen bonds. These bonds are relatively weak and the bulk of the strength of mature collagen is attributed to strong intermolecular and intramolecular covalent bonds. The individual amino acids are assembled in the endoplasmic reticulum of the fibroblast (Figure 1.9), beginning at the amino terminal and proceeding towards the carboxyl end.

A unique feature in collagen synthesis is that neither hydroxyproline nor hydroxylysine is incorporated directly into the collagen molecule. Instead, a proline-rich collagen precursor (protocollagen) is formed. Hydroxylation then proceeds under the influence of protocollagen hydroxylase. Requirements of the enzyme are oxygen, α-ketoglutarate, ferrous iron and ascorbic acid. Each of these may interfere with collagen metabolism but the only one of practical importance is ascorbic acid,

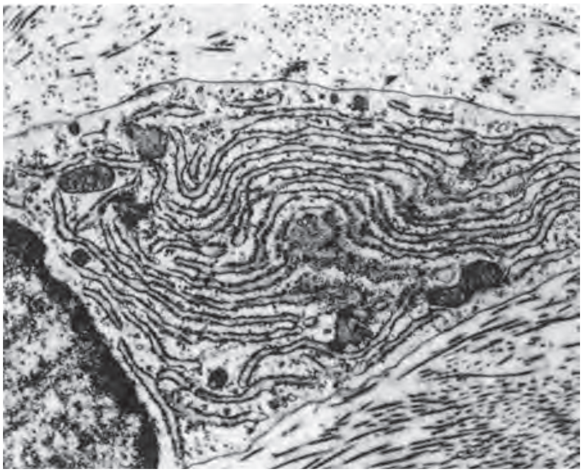

Figure 1.9 Electron micrograph of a normal fibroblast. Note the characteristic well-developed endoplasmic reticulum. The lining ribosomes, which are responsible for its rough appearance, are the active site of collagen synthesis. New collagen fibrils are rapidly excreted and are seen here surrounding the cell (×9000). (Courtesy of Professor Russell Ross, Seattle.)

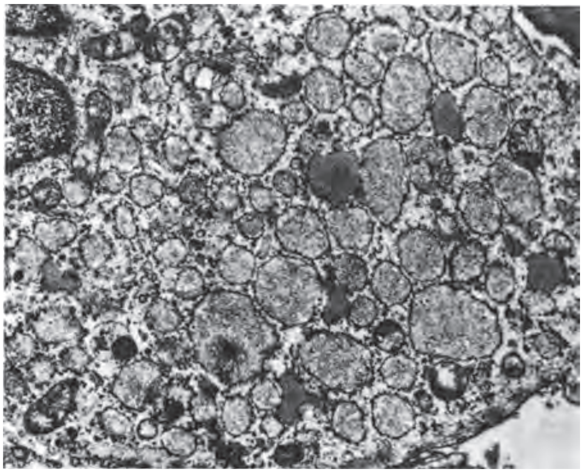

Figure 1.10 Electron micrograph of part of a scorbutic fibroblast. Note the typical distended endoplasmic reticulum. There is no sign of collagen but it will appear within 24 hours of providing ascorbic acid (×9000). (Courtesy of Professor Russell Ross, Seattle.)

deficiency of which delays collagen synthesis. The incompletely synthesized collagen cannot be excreted from the fibroblasts and distends their endoplasmic reticulum in a characteristic way (Figure 1.10). Several different genes direct synthesis and 13 distinct types of collagen have been identified in vertebrate tissues. Type I characterizes mature bone and skin. Type II is found in hyaline cartilage, and type III in cardiovascular structures, infant skin and the granulation tissue of healing skin wounds. Types IV and V are associated with basement membranes, and the others with a variety of tissues including cartilage and certain tumours. The significance of these different forms of collagen is not yet clear, but their existence does help to explain why cutaneous scar tissue behaves in a different way from the surrounding dermis. Scar collagen contains types I and III and differs in its degree of hydroxylation of lysine and glycosylation of hydroxylysine. The cross-linking pattern is also characteristic.

All connective tissues contain varying amounts of ground substance. This amorphous matrix between the cells and fibres contains protein–glycosaminoglycan complexes called proteoglycans. The fibroblast synthesizes collagen, glycosaminoglycans and fibronectin. The last component of the matrix is a large glycoprotein with important influences on both intercellular adhesion and cell-to-matrix adhesion. The functions of the proteoglycans and fibronectin are incompletely understood, but they appear to play a part in the organization and precipitation of collagen fibres. The ground substance has, in addition, important effects on the mechanical properties of mature tissue. The wound is a fibre–gel–fluid system and the mechanical properties of this complex material differ significantly from those of fibrous tissue alone.

Factors affecting healing

A number of factors influence the rate of wound healing. However, some have unpredictable effects. Thus, jaundice and uraemia adversely affect wound healing in animals but not in humans. The important factors influencing healing in clinical practice are age nutrition, vascular supply, sepsis, oxygen and wound dressing.

Age

Healing proceeds more rapidly in the young provided they are well nourished. The increased vigour of repair may explain why hypertrophic scars and keloids are more common in early life.

Nutrition

To a certain extent, wounds do not heal well in the debilitated and malnourished. However, several studies have documented the biological priority of healing wounds. Thus, patients have to be very severely protein depleted before healing is impaired. Ascorbic acid is required for the synthesis and maintenance of collagen. Following injury, body stores are rapidly depleted and a scorbutic state may be induced. When this happens, collagen synthesis is impaired with delayed healing. In older wounds in which collagen turnover is still active, scars have been known to reopen. Healing is also delayed by zinc deficiency.

Vascularity

Wounds heal well in areas such as the face where the blood supply is good, and vice versa. The most striking examples are found in ischaemic vascular disease of the lower limb. Both wound healing and the overall metabolic response to trauma are optimal when the environmental temperature is raised to 30°C. The combination of increased blood flow and warmth following sympathectomy has been shown to improve healing in patients with peripheral vascular disease.

A minimal inflammatory stimulus is required for healing to progress normally. If anti-inflammatory drugs, e.g. cortisone, are administered in the first few days after wounding, healing is likely to be delayed. Once healing is established, cortisone does not appear to interfere with the healing process. In practice, wounds do heal in patients receiving long-term steroid therapy, but the process is slow and more susceptible to complications.

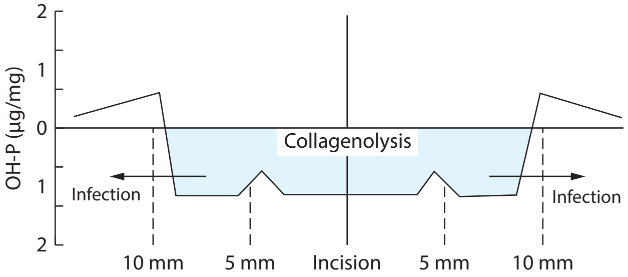

Figure 1.11 The chemically active zone of an incised wound extends for at least 5 mm on either side of the wound. Collagen lysis is prominent in the first week and is more marked when infection is present. The zero line is the concentration in normal abdominal wall. (After Adamsons *et al.*, *Surg Gynecol Obstet* 1966;**123:**515–521.)

Sepsis

Local infection is perhaps the most important cause of delayed wound healing and dehiscence. Collagen synthesis is depressed and collagenolysis increased, thereby enhancing the softening of the wound edges (Figure 1.11). This adversely affects the strength of the repair and makes cutting out of the sutures more likely.

Oxygen

Oxygen is crucial for wound healing. Direct examination of the granulation tissue growing into a wound chamber shows a number of regular features. The PO_2 falls steadily from the normal mature tissue level of around 45 mmHg (6.0 kPa) to levels close to zero in the centre of the wound. Fibroblastic activity is maximal up to 50–80 µm away from the nearest normally perfused capillary. At this point, PO_2 levels between 10 and 20 mmHg (1.3–2.6 kPa) are regularly recorded. Macrophages have lower oxygen requirements than fibroblasts and are found at the free edge of the growing granulation tissue. Even in these areas of very low oxygen tension, they are still able to ingest bacteria, but there is uncertainty about their ability to kill ingested organisms. Increased oxygen uptake is invariably associated with bactericidal activity since the process is mediated by the peroxidase system.

The delivery of nutrient oxygen to the wound is impaired by a number of local factors, such as tissue trauma and tight suturing techniques. More serious problems arise when wound capillary perfusion is impaired by systemic disorders. By far the most serious of these is the capillary shutdown associated with hypovolaemia. The wound, together with the splanchnic and cutaneous circulation, is the first to shut down in an attempt to maintain circulation to the vital organs. Similar effects are observed in states of increased blood viscosity and cardiopulmonary decompensation. Finally, there is evidence that increasing the oxygen supply to a wound induces greater collagen production (Figure 1.12), although it does not appear to affect the overall rate of healing.

Wound dressings

The undisturbed wound heals best, and dressings may therefore impair healing, especially of open wounds, by damaging the delicate new cells and capillaries on the wound surface. These wounds have to be packed with non-adherent materials that permit surface oxygenation and do not encourage bacterial overgrowth.

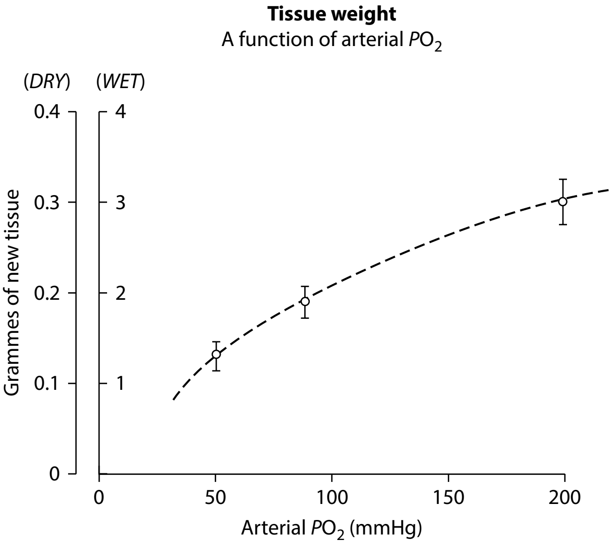

Figure 1.12 The amount of new tissue formed in a wound is considerably greater when arterial PO_2 is increased by changing the ambient oxygen from 14–20% to 45% for 25 days. (From Hunt, *Trauma* 1970;**10:**1001–1009, with permission.)

Wound failure

Although healing is a unified response to injury, failures tend to present in three quite distinct ways. Acute failures are wound infection and dehiscence. Chronic failure is the condition of pathological fibrosis resulting from the overproduction of scar tissue (hypertrophic scar, keloid).

Acute failures

Wound infection

This is the most common and troublesome disorder of wound healing. A primarily closed wound has no resistance at all to bacteria contaminating the surface during the first 6 hours (Figure 1.13). After this time, it becomes increasingly difficult to infect the wound, until at 5 days it is as resistant as the surrounding skin. Thus, an occlusive dressing is advisable only during the first few days unless there is an obvious nearby source of contamination, e.g. colostomy. *The main source of wound infection is endogenous from the patient's own bacteria at the time of surgery*.

The factors predisposing to wound infection include:

- local trauma from excessive retraction, extensive electrocoagulation, defective haemostasis
- the presence of foreign material; a single piece of sterile silk suture material doubles the chance of a contaminated wound becoming infected (Figure 1.14)
- diminished perfusion.

Wound dehiscence

This is always a catastrophe. At the least, the patient requires a second operation and hospital stay is prolonged. In specific

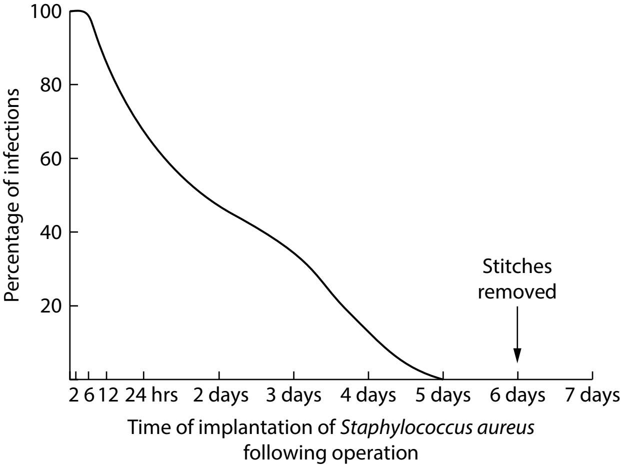

Figure 1.13 Vulnerability of a healing incised wound to surface contamination with micro-organisms. During the first 6 hours it has no resistance. Thereafter, it becomes increasingly resistant to invasion, and by 5 days it is as resistant as normal skin. (After DuMortier, *Surg Gynecol Obstet* 1933;**56:**762–766.)

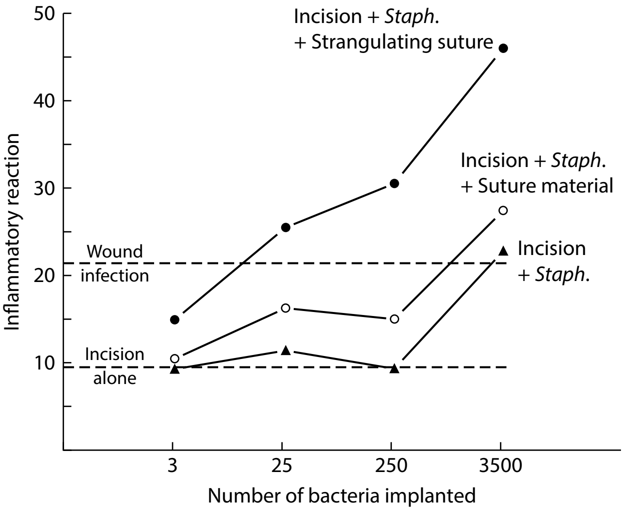

Figure 1.14 The presence of extraneous material in a wound enhances the likelihood of infection developing. The presence of one tied silk suture doubles the chance of a contaminated wound becoming infected. (After Howe, *Surg Gynecol Obstet* 1966;**123:**507–514.)

situations, particularly in cardiac and vascular surgery, it may prove fatal. In a high proportion of cases, wound infection precedes and determines the result. Wound dehiscence after laparotomy is a serious complication, occurs in 0.25–3.0% of laparotomies and has a reported mortality of 20%. Risk factors include anaemia [haemoglobin (Hb) <10 g], hypoalbuminaemia, malnutrition, malignancy, jaundice (debatable), obesity [body mass index (BMI) >35], sepsis, diabetes, male sex and elderly patients (>70 years). There is also an increased incidence after specific operations, e.g. emergency laparotomy and total colectomy. Although preoperative chemotherapy and radiotherapy are reported as risk factors, the evidence for this is by no means certain. Wound dehiscence is commoner with midline vertical wounds and when wounds are closed with interrupted sutures as opposed to continuous closure. The highest incidence is encountered in elderly patients with chronic obstructive airways disease, and in some reported series these patients account for 70%.

Ordinary, the condition becomes clinically manifest on days 7–9, although occasionaly wound dehiscence can occur after discharge from hospital. It is usually preceded by seepage of blood-stained serum from the wound for some hours before the actual dehiscence; otherwise, the diagnosis is obvious, with loops of intestine appearing in the depths of the wound or even prolapsing when the patient coughs or strains. Patients often develop some degree of hypotension.

The immediate management is by a sterile dressing and bandaging, therapeutic nasogastric decompression, intravenous fluid therapy and intravenous broad-spectrum antibiotics followed by immediate surgery unless the patient requires resuscitation. During operative closure, some advocate the use of deep tension sutures, although the value of these remains controversial.

Wound fibrosis

Abnormally contracting tissue is often a late consequence of injury or inflammatory disease and features a whole range of chronic fibrotic processes, from simple adhesions in peritoneum and tendon sheaths to interstitial fibrosis. Other troublesome examples are benign oesophageal stricture, mitral stenosis and hepatic cirrhosis. In primary closed wounds pathological fibrosis results in either a hypertrophied scar or keloid. Wound scarring is also increased in wounds that become infected before they heal. Attempts have been made to control this pathological fibrosis by specific antifibrotic treatment of the scar (β-aminopropio-nitrile, penicillamine, steroids and zinc) and non-specific methods aimed at diminishing the inflammatory process that precedes fibroblast activation.

The present methods of managing hypertrophic scars and keloids are imprecise and rely on compression, surgical excision and judicious use of corticosteroids (triamcinolone).

Blood and haemostasis

Although the cardinal function of blood and an effective circulation is the provision of adequate tissue perfusion for the supply of oxygen and for export of waste products, the cellular component and the plasma fraction of blood subserve several other functions, some of which involve the participation of the monocyte–macrophage system.

Blood groups and histocompatibility antigens

Blood groups

The most important is the ABO system. The surface antigens A and B are coupled to ceramide, a lipid component of the cell membrane of the erythrocyte. Both are derived from substance H as a result of the activity of two specific transferases coded by the respective allelic genes A and B on chromosome 9. Blood group O individuals do not possess either of these transferase enzymes and thus carry substance H unchanged. Antibodies to antigen A or B are present in the plasma when the respective antigen is

Table 1.1 ABO blood groups

Phenotype (group)	Erythrocyte genotype	Antigens	Antibodies	Incidence (%)
O	OO	H	Anti-A, anti-B	47
A	AA/AO	A	Anti-B	42
B	BB/BO	B	Anti-A	9
AB	AB	AB	None	3

absent from the red cells. Thus, group A individuals have anti-B; group B individuals have anti-A; group O individuals have both anti-A and anti-B; and group AB individuals do not have any. Although group O individuals are often referred to as 'universal donors', they should always be screened for anti-A and anti-B before their blood is administered to group A and B patients. These natural antibodies, which belong to the immunoglobulin (Ig) M class, are haemolysins and are thought to arise as a result of immunization by gut bacterial antigens closely allied in composition to the A and B antigens. The characteristics of the ABO blood group system are outlined in Table 1.1.

Of the other blood group systems (rhesus, Kelly, Duffy and Kidd), the most clinically relevant is the rhesus (Rh) system. This is inherited by a single complex gene on chromosome 1, which gives various combinations of C or c, D or d, and E or e. An Rh-negative mother (genotype = dd) will be immunized by her fetus if this is Rh positive (genotype = DD), usually as a result of placental bleeding during delivery of the firstborn, with the production of anti-D haemolysins. During subsequent pregnancies, these IgG anti-D antibodies cross the placenta and cause haemolytic disease of the newborn if the fetus is Rh positive. This disease has been virtually eliminated as a result of treatment of the mother with preformed anti-D IgG at the time of birth of her first baby to haemolyse any Rh-positive cells from the baby that reach the maternal circulation.

Leucocyte and platelet antigens

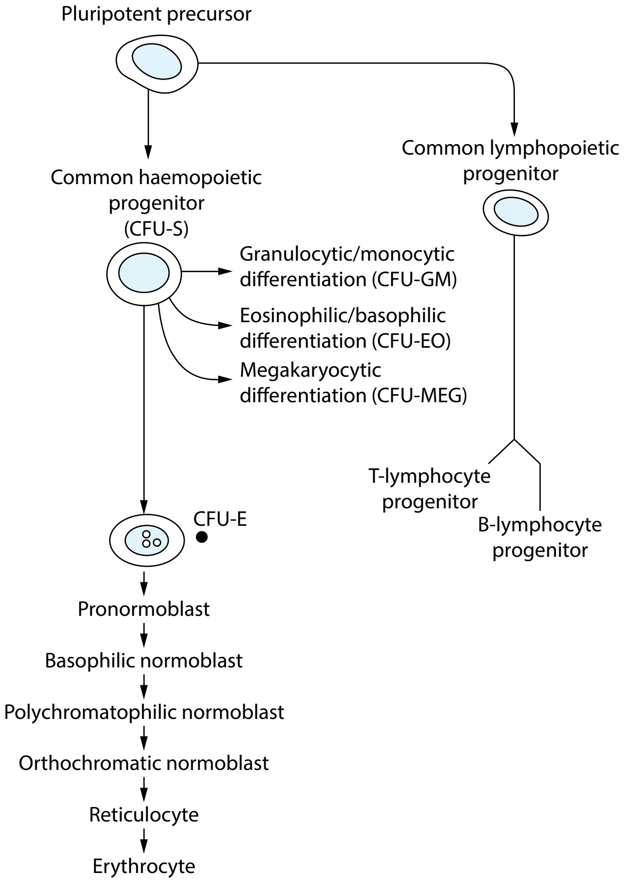
Antigens on the surface of leucocytes and platelets may be cell specific or present on other cells of the body. The latter are known as shared antigens and the most important group in this category is the human leucocyte antigen (HLA) system. It is also referred to as the major histocompatibility complex (MHC) and provides the mechanism by which the immune system recognizes self. These antigens belong to two classes (I and II) and are of great importance in organ transplantation.

Erythropoiesis and function of the erythrocyte

Erythropoiesis

Normal physiological function is dependent on the maintenance of a constant mass of circulating red blood cells (approximately 309×10^9 dL), the primary function of which is the supply of oxygen and removal of CO_2 essential for cellular respiration, continued viability and metabolic activity.

The circulating red cell mass is controlled by balanced replacement of erythrocyte loss due to senescence (normal life span of 120 days) with production (erythropoiesis) in the bone marrow and liver (fetus). Effete erythrocytes are removed by the monocyte–macrophage system, predominantly in the spleen. Marrow hyperplasia and increased activity are encountered in all conditions associated with abnormal red cell destruction, i.e. haemolytic anaemias.



Pluripotent precursor
Common haemopoietic progenitor (CFU-S)
Common lymphopoietic progenitor
Granulocytic/monocytic differentiation (CFU-GM)
Eosinophilic/basophilic differentiation (CFU-EO)
Megakaryocytic differentiation (CFU-MEG)
T-lymphocyte progenitor
B-lymphocyte progenitor
CFU-E
Pronormoblast
Basophilic normoblast
Polychromatophilic normoblast
Orthochromatic normoblast
Reticulocyte
Erythrocyte

Figure 1.15 Schematic representation of normal erythropoiesis.

Erythrocytes originate from a pluripotential cell via the common haemopoietic progenitor [spleen colony-forming unit (CFU-S)]. Under the influence of erythropoietin, some of these CFU-S differentiate into several erythroid colony-forming units (CFU-E), which then differentiate further and mature into red blood corpuscles (Figure 1.15). Erythropoiesis is predominantly regulated by the oxygen tension in the renal blood, which regulates the release of proerythropoietin that is then activated to erythropoietin in the plasma. Low renal oxygen tension leads to increased release of erythropoietic factor by the kidneys and thus enhance erythropoiesis. Recombinant erythropoietin is now available and is used predominantly in the treatment of anaemia associated with chronic renal disease. In addition to erythropoietin, several other growth factors, hormones (growth, thyroid, insulin, androgens), vitamins (B_6, B_{12}), folate, iron and inhibitors (T-lymphocyte factors) are involved in this multistage process. The earliest microscopically recognizable erythrocyte precursor in the bone marrow is the pronormoblast (rubriblast, proerythroblast).

Red cell function

The major fuel supply to the erythrocyte is glucose that is metabolized largely through anaerobic glycolysis (Embden–Meyerhof pathway) and, to a much lesser extent, via the pentose phosphate pathway. Anaerobic glycolysis yields ATP (to meet cellular energy requirements), NADH and 2,3-diphosphoglycerate (2,3-DPG), which influences the affinity of Hb for oxygen. The pentose phosphate pathway produces NADPH. The NADH/NADPH system is necessary to protect against oxidative damage to the Hb.

The main function of the erythrocyte is the transport of oxygen and CO_2. Hb is essential for the carriage of oxygen, as this is only slightly soluble in water. For this reason, at normal atmospheric pressure, only a very small amount of oxygen (approximately 3.0 mL/L) is in solution in the plasma. Thus, the bulk of the oxygen requirement (250 mL of O_2/min at rest) is carried by the erythrocytes. The haemoglobin molecule consists of two α- and two β-chains, with each chain being folded over a haem group. This configuration enables the binding of four molecules of oxygen (one per chain). Thus, oxyhaemoglobin is represented as $Hb(O_2)_4$. At normal atmospheric pressure, the partial pressure of inspired air in the alveoli normally exceeds 100 mmHg (13.3 kPa), whereas the partial pressure in the pulmonary arterial blood reaching the alveolar capillary network is much lower (40 mmHg; 5.3 kPa). This pressure gradient permits rapid diffusion across the alveolocapillary membrane to the plasma for uptake by the Hb in the erythrocytes. This results in 95% saturation of the Hb with oxygen. The PO_2 in the blood (and thus the amount of oxygen in solution in the plasma) can be increased by oxygen therapy and especially by hyperbaric therapy without affecting the amount of oxygen carried by Hb (because this is fully saturated). Hence, breathing pure oxygen instead of air (which contains only 21% oxygen) can raise the arterial PO_2 to 600 mmHg (80 kPa), increasing the amount of oxygen in solution accordingly. Much higher partial pressures of oxygen in the arterial blood are obtained by hyperbaric therapy.

At the blood–tissue interface, oxyhaemoglobin releases oxygen (dissociates) as a result of complex changes in its chemical and structural configuration. Primarily, the extent of dissociation (and conversely the percentage saturation) of Hb is dependent on the PO_2 in the interstitial fluid. This is outlined by the sigmoid oxyhaemoglobin dissociation curve (Figure 1.16). This dissociation curve can be shifted to the left (Figure 1.16), reflecting an increased affinity of Hb for oxygen. This is deleterious as oxygen is less readily released to the tissues. A shift to the left can be brought about by:

- low PCO_2 (hyperventilation)
- high pH (alkalosis)
- hypothermia
- reduced content of 2,3-DPG (stored blood).

By contrast, a shift to the right implies decreased affinity of Hb for oxygen and thus increased delivery of oxygen to the tissues. It is encountered as a physiological compensatory mechanism in pyrexia (from any cause) acidosis and hypercapnia. The relation between shifts in the oxyhaemoglobin and pH changes is known as the Bohr effect.

Simultaneously with the release of oxygen to the tissues, CO_2 diffuses into the erythrocytes. Thus, the essential ongoing first reaction at the blood–tissue interface is:

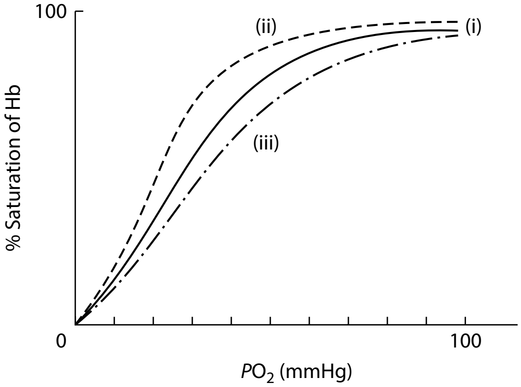


Figure 1.16 Oxyhaemoglobin dissociation curves: (i) normal curve; (ii) dissociation curve shifted to the left reflecting an increased affinity of Hb for oxygen, which is deleterious as oxygen is less readily available to the tissues; (iii) a shift to the right implies a decreased affinity of Hb for oxygen and thus increased delivery of oxygen to the tissues. It is encountered as a physiological compensatory mechanism in pyrexia, acidosis and hypercapnia. The relation between shifts of the oxyhaemoglobin and pH changes is known as the Bohr effect.

$$Hb(O_2)_4^- + H_2O + CO_2 \leftrightarrow Hb^- + H_2CO_3 + 4O_2$$

This reaction is catalysed by the enzyme carbonic anhydrase. Within the physiological pH range, most of the carbonic acid (H_2CO_3) dissociates:

$$H_2CO_3 \leftrightarrow H^+ + HCO_3^-$$

The reduced Hb^- takes up the liberated H^+ to form HHb (isohydric exchange) and the HCO_3^- diffuses out of the cell in exchange for Cl^- (chloride shift). By this process, the pH of venous blood is not significantly altered despite carriage of CO_2. These reactions are reversed at the alveolar capillary membrane in the lungs with the release and escape of CO_2 into the alveolar air and oxygenation of the reduced haemoglobin.

Abnormal haemoglobins

Abnormal affinity for oxygen, increased red cell aggregation or haemolytic episodes can be caused by a variety of disorders of haemoglobin (congenital and acquired). These include hereditary genetic coding disorders characterized by either qualitative (haemoglobinopathies, e.g. HbSS in sickle cell disease) or quantitative [e.g. reduction or absence (thalassaemia) of the globin polypeptide chains] changes. In addition, there are abnormal non-functioning derivatives of haemoglobin. The latter are often acquired and include methaemoglobin (drug induced, e.g. sulphonamides, severe acute pancreatitis), sulphhaemoglobin (drug induced) and carboxyhaemoglobin (CO poisoning, smoking).

Monocyte–macrophage system

Also known as the reticuloendothelial system, this consists of the circulating monocytes and fixed macrophages in lymph nodes, spleen, lungs and the liver, which is the largest component. It is now generally believed that the fixed tissue macrophages are derived from circulating monocytes. The main functions of the monocyte–macrophage system are as follows:

- Phagocytosis and degradation by lysosomal enzymes of particulate matter and bacteria; in this respect, the Küpffer cells and the macrophages in the lung filter bacteria from the bloodstream.
- Removal of senescent red blood cells, especially in the spleen and, to a lesser extent, the liver.
- Antigen presentation: in lymphoid tissue macrophages ingest and break down large antigens into soluble fragments, which are then presented on the surface to β-cells and MHC class II-bearing T-cells. Specialized antigen-presenting macrophages in the lymphoid follicles have dendritic processes that capture immune complexes, retain the antigen from these complexes for long periods and present it to numerous B-lymphocytes, including memory cells. Antigen presentation to T-cells in the paracortical areas of lymph nodes is performed by a different type of macrophage, possibly derived from the dendritic Langerhans cells of the skin
- Storage of iron involving intracellular binding to apoferritin.
- Synthesis of coagulant factors (e.g. fibrinogen), proteinases (e.g. α_2-macroglobulin), cytokines [interleukin (IL) 1], lymphokines (e.g. as colony-stimulating factors that regulate proliferation and differentiation of granulocytes, macrophage precursors and erythropoiesis), erythropoietin, etc.

The monocyte–macrophage system is implicated in various hereditary storage disorders resulting from specific enzyme deficiencies, e.g. various mucopolysaccharidoses and several lipidoses, the most common of which is Gaucher disease.

Function of plasma proteins

The plasma proteins are largely responsible for the oncotic pressure that is crucial to the exchange of fluid across the capillary membrane. In addition, they have other important functions. These include blood clotting, anticoagulation and inhibition of fibrinolysis, transport, buffering of acid metabolites, acute phase response and defence against microbial invasion through the complement–antibody response assisted by the immune cellular response.

Oncotic pressure

The plasma proteins, particularly the albumin fraction, are responsible for maintenance of the circulating blood volume. The effect is mediated by the oncotic pressure that they exert. This reverses the fluid flux from the interstitial space to the intravascular compartment at the venular end of the capillary where the effective oncotic pressure of the plasma proteins exceeds the capillary hydrostatic pressure. This delicately balanced mechanism is disturbed if the plasma protein level is decreased (hypoalbuminaemia) or the hydrostatic pressure in the capillary bed is elevated through congestion (e.g. right heart failure, circulatory overload, varicose veins) or the permeability of the capillary membrane is increased (sepsis, inflammation). All of these events result in expansion of the interstitial fluid compartment with oedema formation.

The normal bidirectional flow of fluid across the capillary membrane also supports the exchange of nutrients and waste products between the capillary blood and the interstitial fluid. The actual exchange is, however, independent of net flow and is governed by the movement of solutes along concentration gradients.

Anticoagulation

A substantial percentage of the globulin fraction of the plasma proteins (approximately 20%) is made up of agents that inhibit the activity of activated clotting factors and fibrinolytic enzymes (Box 1.1). Essentially, these are antiproteinases, although some have other specific physiological roles. As a group they limit and localize thrombosis, fibrinolysis and inflammatory reactions. Hereditary deficiency states may result in recurrent thrombosis, bleeding tendency (α_2-antiplasmin, plasminogen activator inhibitor 1), pulmonary emphysema (α_1-antitrypsin) or hereditary angioneurotic oedema (C1 inactivator).

Transport

The plasma proteins act as an efficient transport system for a variety of endogenous and exogenous substances: hormones, bilirubin, iron (transferrin), copper (caeruloplasmin), vitamins (retinol-binding protein), drugs, etc. In some instances, binding also serves to reduce the innate toxicity of material (e.g. binding of unconjugated bilirubin to albumin). In general, when a substance is bound to the plasma proteins it is inactive. Thus, release from the bound state is necessary for the physiological effect of the hormones on target organs.

Buffer action

Plasma proteins, like all other body proteins, have a high content of weakly acidic and basic groups and thereby contribute to the general buffering mechanism of blood. CO_2 generated by cellular respiration dissolves in the aqueous component of tissue fluid and blood to form carbonic acid (H_2CO_3), which readily dissociates at the normal blood pH range to hydrogen ions (H^+) and bicarbonate (HCO_3^-). Thus, carriage of CO_2 by the venous blood tends to lower pH by increasing the H^+ concentration. However, in the physiological healthy state, the pH of venous blood is only marginally lower than that of arterial blood. This is in part the result of the buffer base supplied by plasma phosphates and plasma proteins. However, oxyhaemoglobin–haemoglobin provides the main buffering of H^+ generated by CO_2 carriage through the process of isohydric exchange.

BOX 1.1 Natural plasma inhibitors

- Antithrombin III (heparin cofactor)
- Heparin cofactor II
- α_2-macroglobulin
- α_1-antitrypsin
- α_2-antiplasmin (α_2-plasmin inhibitor)
- C1 inactivator (C1 esterase inhibitor)
- Extrinsic pathway inhibitor
- Activated protein C inhibitor

Defence against microbial infection: complement system, immunoglobulins and acute phase reactants

Complement system

As with blood coagulation, the complement system consists of a series of enzyme proteins that act in a sequential manner to produce molecular fragments and complexes, which subserve important functions in the host's defence against microbes. Thus, coating of bacteria with fragment C3b facilitates their adherence to phagocytes that have cell-surface receptors for this component. Small peptide complement fragments (C3a and C5a) have intrinsic biological activity and either trigger the release of preformed mediators from mast cells and basophils (histamine, tryptase, chemotactic factors for polymorphs and eosinophils and platelet-activating factor) or activate phospholipase, which releases arachidonic acid from the phospholipids of the cell membrane of the mast cells. The arachidonic acid is then converted to leukotrienes (lipo-oxygenase pathway) or to prostaglandins and thromboxanes (cyclo-oxygenase route). Leukotrienes induce vasodilatation, bronchoconstriction and chemotaxis, whereas prostaglandins and thromboxanes cause platelet aggregation and vasodilatation. Collectively, these agents provide the final common motor pathway for the acute inflammatory response (vasodilatation, exudation of plasma proteins and accumulation of polymorphs). Finally, complement, by the formation of the membrane attack complexes (MACs), consisting of several complement components (C5b, C6–C9) on the surface of the invading organism, increases the permeability of its cell membrane. Thereafter, water and electrolytes enter the cell attracted by osmotic forces in such quantities as to induce cell disruption and lysis.

The complement system is activated by two mechanisms: the alternative and the classic pathways. Some micro-organisms can bind the C3 cleaving (convertase) enzyme directly to their surface polysaccharide molecules and release it from inhibition. The activated enzyme (C3bBb) then generates large amounts of C3b cleavage products from C3 that are deposited on the surface of the organisms. This direct activation occurring in the absence of antibody constitutes the alternative pathway of complement activation. By contrast, the classic pathway is initiated by binding of antibody to the surface antigens of the invading organism. This binds to and activates the C1q component of complement, setting off a multistep cascade reaction involving several complement components and leading to the formation of an activated enzyme (C4b2b) that has C3 convertase activity. Thus, the two pathways converge at the cleavage of the C3 component, which is pivotal to the complement system.

Antibodies

The body has a vast army of B-lymphocytes bearing different antibodies with specific recognition sites for foreign antigenic material. Thus, when an organism gains access, lymphocytes with the appropriate surface antibody 'dock' with the antigen and thereafter proliferate to form a clone of plasma cells programmed to produce large amounts of the required antibody needed to eliminate the invading organism. This process of proliferation of a specific line of B-lymphocytes is known as clonal selection and forms the basis of the acquired immune response. This encounter with a specific pathogen is permanently coded in some of these lymphocytes, which persist as memory cells. When compared with the primary response described above, these cells are capable of mounting a more rapid and vigorous antibody response (higher antibody titres) in the event of a second encounter with the same pathogen (secondary response).

Acute phase reactants

This is a collective term for a group of plasma proteins, the concentration of which rises dramatically in acute inflammation and trauma (Box 1.2). The group includes a wide range of proteins, which normally subserve specific physiological functions: ferritin, fibrinogen, C-reactive protein, caeruloplasmin, α_1-antitrypsin, α_2-macroglobulin, C9, haptoglobin, etc. The most clinically useful in the context of acute illness is C-reactive protein, which is synthesized and secreted by the liver. Endotoxin (during an infection) stimulates the release of IL-1 from the Küpffer cells, which leads to enhanced hepatic synthesis of the protein. In turn, C-reactive protein binds to some bacteria and thereby activates complement. Hence, it performs a useful opsonizing effect, i.e. encourages adherence to phagocytes. In surgical practice, circulating levels of C-reactive protein are often used as an index of severity of the illness, e.g. acute pancreatitis.

Haemostasis

In health, perfusion of tissues and organs is dependent on vascular patency, adequate perfusion pressure, normal blood rheology and interacting physiological mechanisms that prevent intravascular coagulation. At the same time, the body can mount a rapid co-ordinated response aimed at achieving efficient haemostasis in the event of vascular injury. Disorders of the mechanisms responsible for maintaining the fluid nature of blood result in the hypercoaguable state with a tendency to recurrent thrombosis. By contrast, defects in the haemostatic mechanism are manifested by bleeding, which may be spontaneous or occasioned by trivial injury.

Physiological control mechanisms against intravascular coagulation

These are outlined in Box 1.3. An adequate blood flow is crucial to the prevention of intravascular thrombosis as it dilutes and clears activated coagulants away from the site of the injury. In clinical practice, this is well exemplified by venous thrombosis, in which the combination of a hypercoaguable state and venous stasis is required to initiate this pathological event.

BOX 1.2 Disorders inducing a major acute phase response

- Bacterial infections
- Rheumatic disease: rheumatoid arthritis, seronegative spondarthritis
- Vasculitis
- Crohn's disease
- Trauma including burns and surgery
- Malignancy

BOX 1.3 Mechanisms responsible for preventing intravascular coagulation in the healthy state

- Blood flow
- Naturally occurring plasma inhibitors
- Heparin sulphate–antithrombin III mechanism
- Protein C–thrombomodulin–protein S mechanism
- Fibrinolysis
- Endothelial prostacyclin
- Hepatic clearance of activated factors

In addition to the plasma protein inhibitors described previously, two important mechanisms play a key role in the prevention of intravascular coagulation. These are the heparin sulphate–antithrombin III (AT-III) mechanism and the protein C pathway AT-III is a protease inhibitor synthesized and secreted by the liver. Native AT-III neutralizes the activity of thrombin and other clotting factors rather slowly but becomes a rapid and potent inhibitor in the presence of mucopolysaccharides such as heparin sulphate elaborated by the vascular endothelium. The physiological role of the heparin sulphate–AT-III mechanism is therefore to neutralize activated clotting factors on the vascular endothelial surface. Protein C is a vitamin K-dependent serine protease synthesized and secreted by the liver as a zymogen which, together with protein S (also synthesized by the liver) and a vascular endothelial protein (thrombomodulin), provides a major naturally occurring anticoagulant system. When thrombin is generated intravascularly it binds to thrombomodulin on the cell surface of the vascular endothelium. This complex activates protein C, which then forms a complex with protein S on the surface of both vascular endothelium and platelets. This protein C–S complex inactivates factor Va and factor VIIIa and plasminogen activator inhibitor. Thus, in addition to abrogating clotting on these surfaces, the protein C pathway stimulates fibrinolysis. The extrinsic pathway inhibitor (EPI) is a low-molecular-weight plasma protein that stops coagulation initiated by the factor VIIa–tissue factor complex.

Other vascular endothelial defences against thrombosis include the secretion of tissue plasminogen activator (promotes fibrinolysis) and the elaboration of prostacyclin, which is a potent vasodilator and inhibitor of platelet adhesion.

The haemostatic response

The haemostatic response, which prevents exsanguination after vascular injury, has two components:

- primary response: vasoconstriction and formation of a platelet plug
- secondary response (haemostasis): formation of a fibrin seal that ensures continued haemostasis until healing of the vascular injury is complete.

Primary response

The factors that initiate and maintain the vasoconstriction are not known, although platelet factors such as thromboxane A_2 [(TXA_2) a potent vasoconstrictor] and substances released from the endothelium are probably involved. Contrary to former belief, serotonin does not mediate the initial vasoconstrictor response.

The formation of the platelet plug involves three interrelated stages: platelet adhesion, the release reaction and platelet aggregation. Platelet adhesion to the vascular endothelium and adjacent perivascular connective tissue (predominantly collagen) is the initial event and appears to be receptor mediated [von Willebrand factor (vWF)]. Congenital absence of this factor (von Willebrand disease) results in a prolonged bleeding time with a normal clotting time. Following adherence to collagen, the platelets change shape from flat discs to spheres with polypoidal projections and actively secrete a number of factors from their α-granules (release reaction). These include ADP, β-thromboglobulin, platelet factor-4, platelet-derived growth factor and vWF. ADP is largely responsible for the platelet aggregation and this is augmented by TXA_2 derived from arachidonic acid (released from platelet membrane phospholipids) via the cyclo-oxygenase pathway. Actual aggregation of platelets to each other requires the presence of fibrinogen that binds to specific surface receptors on several platelets and links them together. Patients with congenital absence of fibrinogen (afibrinogenaemia) or absence of the specific platelet receptors for fibrinogen (Glanzman's thrombasthenia) have prolonged bleeding times owing to defective platelet aggregation. Several of the clotting factors synthesized by megakaryocytes (fibrinogen, factor V, etc.) are stored in platelets, from which they are liberated during the release reaction, thus contributing to the coagulation cascade. In addition, activated platelets provide a procoagulant factor (PF3), which enhances the activation of prothrombin to thrombin by factor Xa.

Secondary response (blood coagulation)

The essence of blood coagulation is a chain reaction or cascade of proenzyme to enzyme conversions, with each enzyme activating the next proenzyme until thrombin acts on fibrinogen to produce fibrin monomer, which then polymerizes to stable fibrin. The various clotting factors are shown in Table 1.2.

By convention, two pathways of blood coagulation are recognized: extrinsic and intrinsic. Both lead to the activation of

Table 1.2 Coagulation factors

Designation	Synonym
I	Fibrinogen
II	Prothrombin
III	Tissue thromboplastin
IV	Calcium ion
V	Proaccelerin, labile factor
VII	Serum prothrombin conversion accelerator
VIII	Antihaemophilic factor
vWF	von Willebrand factor
IX	Christmas factor
X	Stuart–Prower factor
XI	Plasma thromboplastin antecedent
XII	Hageman factor
XIII	Fibrin stabilizing factor
Prekallikrein	Fletcher factor
HMW kininogen	Contact activation factor

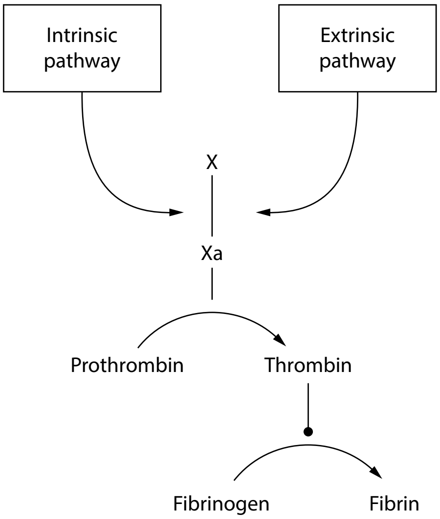

Figure 1.17 The two pathways of blood coagulation: extrinsic and intrinsic. Both lead to the activation of factor X (Xa) and thereafter follow the same cascade reaction.

factor X (Xa), and thereafter follow the same cascade reaction (Figure 1.17). This division is, however, somewhat arbitrary as the two systems converge at other levels (e.g. factor IX). However, the distinction is of practical value as, while the prothrombin time (PT) reflects the activity of both pathways, the partial thromboplastin time measures the activity of the intrinsic system only. The extrinsic system is initiated by exposure of blood to injured tissue via the release of tissue thromboplastin (i.e. tissue factor that is extrinsic to the blood). By contrast, the intrinsic pathway is triggered by contact of Hageman factor with a foreign surface and no extrinsic component is needed for the coagulation process. A simplified system of the blood coagulation cascade is shown in Figure 1.18.

Formation of a stable fibrin clot

Thrombin cleaves four fibrinopeptides from fibrinogen with the formation of fibrin polymer, which polymerizes spontaneously to form fibrin. The stabilization of this to yield the insoluble fibrin requires the action of XIIIa (activated by thrombin) and calcium ions.

Fibrinolysis

The lysis of fibrin by plasmin is an important physiological mechanism that guards against occlusion of blood vessels and is important in tissue repair. Following haemorrhage due to vascular injury, fibrinolysis is temporarily switched off. Premature activation will result in renewed bleeding and this mechanism may be responsible for recurrent bleeding from gastrointestinal ulceration. Abnormal fibrinolysis is associated with severe bleeding disorders and is involved in tumour spread. There are both intrinsic (factor XII, prekallikrein, high-molecular-weight kininogen and prourokinase) and extrinsic (tissue plasminogen activator, urokinase) activators of plasminogen. Inhibition is achieved by the activities of plasminogen activator inhibitor 1 (produced by endothelial cells, hepatocytes and fibroblasts) and α_2-plasmin inhibitor (Figure 1.19).

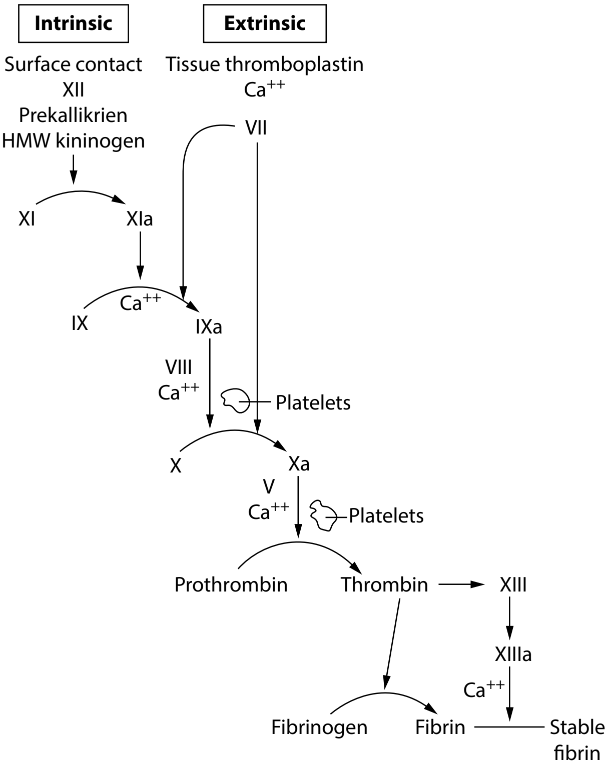

Figure 1.18 Simplified system of the blood coagulation cascade.

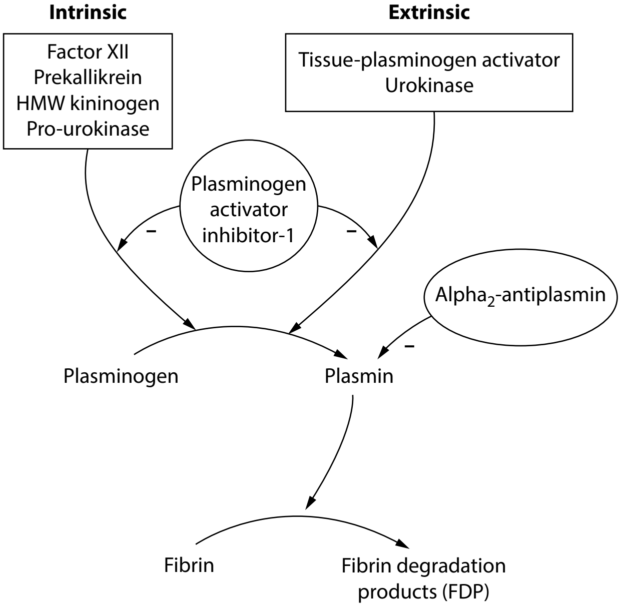

Figure 1.19 The fibrinolytic system.

Therapeutic anticoagulation

In surgical practice, anticoagulation is used:

- in patients with acute intravascular thrombosis (arterial and venous)
- in patients with pulmonary embolism
- as prophylaxis against deep vein thrombosis
- in patients with an implanted intravascular synthetic prosthesis, most commonly heart valves
- patients with atrial fibrillation.

Therapeutically, the anticoagulants used are heparin (administered intravenously), low-molecular-weight heparins (LMWHs) (administered subcutaneously) and warfarin for oral anticoagulation.

Heparin and low-molecular-weight heparins

Heparin consists of a mixture of anionic mucopolysaccharides (glycosaminoglycans): α-L-iduronic acid 2-sulphate; 2-deoxy-2-sulphamino-α-D-glucose 6-sulphate; β-D-glucuronic acid; 2-acetamido-2-deoxy-α-D-glucose; and α-L-iduronic acid. In heparin sodium (used clinically), the acidic protons of the sulphate units are partially replaced by sodium ions. Heparin acts by immediate binding to AT-III. Only about one-third of an administered dose of heparin binds to AT and this fraction is responsible for most of its anticoagulant effect. The dose of heparin is monitored by measurement of the activated partial thromboplastin time (APTT) and its action can be reversed by protamine sulphate (see below). The important attribute of heparin is its immediate anticoagulant effect; because of its potency, it is only administered in hospital practice. Thus, when long-term anticoagulation is needed, patients are started on heparin, but warfarin is commenced at the same time. When this results in the correct prolongation of the PT the therapeutic range is reached (see below), the heparin is discontinued.

Low-molecular-weight heparins

LMWHs possess the following characteristics with respect to heparin:

- reduced antifactor IIa activity relative to antifactor Xa activity
- more favourable benefit–risk ratio
- superior pharmacokinetic properties.

LMWHs were introduced in the 1970s and prepared from standard heparin as derivatives that exhibited a progressively reduced effect on the APTT with decreased molecular size, while still retaining the inhibitory effect on activated factor X (factor Xa).

LMWHs are derived from heparin by chemical or enzymatic depolymerization, yielding fragments approximately one-third the size of heparin. The various LMWHs approved for clinical use are:

- nadroparin calcium (Fraxiparin)
- enoxaparin sodium (Lovenox/Clexane)
- dalteparin (Fragmin)
- ardeparin (Normiflo)
- tinzaparin (Innohep)
- reviparin (Clivarine)
- danaparoid sodium (Orgaran).

LMWHs produce their anticoagulant effect by activating AT-III via a unique pentasaccharide sequence. Laboratory monitoring of LMWH therapy is usually not necessary except in morbid obesity and renal failure, where the dose can be difficult to determine. In these patients, laboratory assay is often needed, i.e. the chromogenic anti-Xa assay. High anti-Xa levels (>0.8 U/mL at steady state) in patients receiving therapeutic doses of LMWH have been associated with bleeding in clinical studies. The optimal time to perform an anti-Xa assay (when indicated) is 4 hours after subcutaneous injection of a weight-adjusted dose of LMWH.

The clinical indications of LMWHs are:

- prevention of venous thrombosis
- unstable angina
- Q-wave acute myocardial infraction
- coronary angioplasty.

Warfarin

Warfarin (coumarin derivative) was originally introduced as a rat poison. It acts as a vitamin K antagonist, which is essential for the synthesis of clotting factors II, VII and IX and anticoagulant proteins C and S. The dose of warfarin needs to be adjusted to the individual patient to achieve the correct prolongation of the PT [international normalized ratio (INR) 2.0–2.5]. This requires several days with frequent monitoring of the PT. The exact dose of warfarin needed is influenced by age, genetic status, medications, diet and certain medical conditions, all of which may alter patient response. Because of these problems in patients requiring long-term oral anticoagulation, new oral anticoagulants have been introduced: (1) dabigatran, which is a direct thrombin inhibitor, (2) rivaroxaban, a direct factor Xa inhibitor, and (3) ximelagatran, also a thrombin inhibitor.

Newer oral anticoagulants

Dabigatran etexilate is a direct thrombin inhibitor. It acts by binding to thrombin, blocking its interaction with substrates, and thereby prevents the thrombin-induced conversion of fibrinogen to fibrin. Several randomized clinical trials with dabigatran etexilate have confirmed that it is equally efficacious as enoxaparin (LMWH) and has a similar safety profile. The National Institute for Health and Clinical Excellence (NICE) in the UK has approved the use of dabigatran as an alternative to LMWH. Three randomized clinical trials have also confirmed that rivaroxaban, which acts by inhibiting factor Xa, is also as efficacious and is as safe as enoxaparin in the prevention of venous thromboembolism in patients undergoing major orthopaedic surgery. Rivaroxaban has also been approved by NICE for the prevention of venous thromboembolism in adults having elective hip or knee replacement surgery. Thus, both dabigatran etexilate and rivaroxaban may well replace warfarin in patients requiring oral anticoagulation, especially as both oral anticoagulants have a rapid onset of action and predictable pharmacokinetics, enabling fixed dosing and avoidance of frequent monitoring of the PT associated with warfarin therapy.

The latest new oral anticoagulant as a potential substitute to warfarin is ximelagatran (Exanta). This acts through its metabolite, melagatran, which inhibits the conversion of fibrinogen to fibrin by thrombin. Two 20 mg tablets of ximelagatran daily provide an anticoagulant effect equivalent to warfarin without any need to monitor the clotting time. Ximelagatran is not metabolized by cytochrome P450 in the liver, and thus its effects are not altered by food or supplements. Furthermore, there is no known interaction of ximelagatran with other pharmaceutical drugs. Although it does carry a risk of bleeding, this is no greater than that of warfarin, i.e. in the 2.0–3.0 INR range. Clinical trials with ximelagatran have been carried out in patients with myocardial infarction, in the prevention of postoperative deep vein thrombosis and in patients with atrial fibrillation – all confirming efficacy and safety.

Protamine sulphate

This is used to neutralize or reverse heparin anticoagulation. Protamine sulphate is a cationic protein derived from fish sperm that binds strongly to heparin in a ratio of approximately 100 U of heparin to 1 mg of protamine. The administration of protamine sulphate carries certain risks of severe adverse reactions, including hypotension and bradycardia, but these can be minimized by slow administration over 1–3 minutes. Allergic reactions can occur, including anaphylaxis (usually after previous exposure to protamine-containing insulin) and in patients with hypersensitivity to fish protein. Alternative treatments to neutralize/reverse heparin in patients with known hypersensitivity to protamine sulphate include hexadimethrine, heparinase (neutralase), extracorporeal heparin removal devices and synthetic protamine substitutes.

Protamine also neutralizes the antithrombin activity of LMWHs, normalizing the APTT and thrombin time. In animal studies, synthetic protamine variants have been highly effective in neutralizing LMWHs (including anti-Xa activity) and are less toxic than protamine.

Surgical immunology

Normally, the immune response is directed against the antigenic characteristics of micro-organisms and, to a much lesser extent, cancer cells. A breakdown in the immune system can take two forms: (1) a lack of appropriate response to a pathogen or (2) a reaction by the immune system against host antigens causing disease or rejection. In order to understand these processes, it is necessary to describe the components of the immune system.

Major histocompatibility complex

The MHC is central to the immunological identity. The MHC consists of a series of antigens expressed on nucleated cells. Thus, red blood cells do not have these antigens but instead have the blood group isoantigens (A, B).

The MHC was first identified on leucocytes, where it is known as the HLA system, the genes for which are located on the short arm of chromosome 6. The MHC gene region encodes for three groups of antigens: class I, class II and class III. The HLA system is made up of class I and II antigens. The function of class III gene product is not clear. There are three class I loci (A, B, C) and three class II loci (DR, DQ, DP) on the chromosome. Thus, this system is highly polymorphic, there being at least 20 alleles in A, 40 in B, eight in C, 16 in DR, three in DQ and six in DP. The inheritance of MHC genes is Mendelian and the expression codominant, so each individual expresses two alleles at each of the loci.

Class I antigens are expressed on all nucleated cells, whereas class II antigens are found on cells involved in the immune response. Both classes are involved in immune recognition, the molecules forming a binding site for processed antigen to be identified by the T-cell receptor. The reason for the diversity of the MHC system is not completely understood, but, like all genetic diversity, it appears to have a survival advantage, e.g. it enables different individuals to mount different responses to invading micro-organisms, i.e. virulent agents are lethal to some but not to other individuals. The MHC is associated with certain disorders, often with an underlying autoimmune basis, e.g. ankylosing spondylitis, which is 20 times more common in individuals possessing HLA B27, and juvenile insulin-dependent diabetes.

In addition to the MHC, there are numerous other tissue antigens collectively referred to as the minor histocompatibility antigens. The loci for these are widely distributed within the genome. They may be the major source of organ allograft rejection in patients matched at the MHC.

Cellular components of the immune system

Phagocytes

Phagocytes are found in the bloodstream (neutrophils and monocytes) and in the tissues as part of the monocyte–macrophage (reticuloendothelial) system as tissue macrophages, Küpffer cells in the liver, microglia in the brain, mesangial cells in the kidneys and dendritic cells in the skin. Phagocytes of the monocyte type are responsible for processing antigens, pathogens and other particles. After alteration of the phagocytosed material by intracellular lysosomes, the phagocytes present the foreign material or antigens to the lymphocytes, which then initiate the immune response. This process is called antigen presentation, and any cell undertaking this function is termed an antigen-presenting cell (APC). The interaction among the antigen, the APC and the lymphocyte leads to the release of chemical messengers called cytokines. In turn, these cytokines enhance the ability of macrophages and other competent cells to recognize and assimilate further antigenic material. Neutrophils do not act as APCs. Instead, they completely degrade the phagocytosed material.

Phagocytosis

The ability of phagocytes to take up pathogenic material is dependent on surface receptors that can recognize activated complement (C3 system) and the Fc fragment of immunoglobulin (see below), both acting as opsonins, i.e. they coat the invading antigen. The density of these receptors on the cell surface determines the level of phagocytosis and the activity of their intracellular lysosomal enzymes.

The processed antigenic fragments become complexed with class II MHC antigens and migrate to the surface of the APC. Here, the combined processed foreign antigen/class II complex becomes exposed for antigen recognition by the immune system. Most antigen recognition requires the combination of foreign antigen with self-MHC for T-cell activation, but there are exceptions. Thus, MHC alloantigens, e.g. tissue antigens of an organ graft, can be recognized more directly by specific T-cells, presumably because these alloantigens resemble the type of modification to self-MHC normally produced by combination with a foreign antigen.

The most active APCs appear to be the tissue macrophages that originate from blood monocytes and continue to recirculate carrying processed antigen from the periphery to the regional lymph nodes, where they initiate the immune response. In addition, the Küpffer cells lining the sinusoids of the liver act as APCs and present processed antigen to the circulating T-cells.

Dendritic cells

Dendritic cells (DCs) are known as the 'pacemakers' of the immune response in view of their key role as the major APCs of foreign peptides and proteins to both T- and B-lymphocytes. DCs are responsible for the induction of T-cell-mediated immunity. T-lymphocytes have surface cell receptors that are able to recognize fragments of antigens (Ags) bound to the MHC (class I and II) on the surface of DCs and other APCs. The MHC class I peptide-binding proteins interact with and stimulate cytotoxic T-lymphocytes, whereas the MHC class II peptide-binding protein stimulates the T-helper cells. Within the APCs, Ags are processed into peptides before being re-expressed on the cell surface linked to MHC proteins. Cytotoxic T-lymphocytes are generated when the re-expressed antigen is bound to MHC class I molecules, which become primed to destroy cells in tissues expressing the Ags.

DCs are derived from the bone marrow and from progenitor cells to form lymphoid DCs (lymphocytic lineage) and the myeloid DCs (myeloid lineage), which include multipotent CD34+ progenitors and peripheral blood mononuclear cells. DC progenitors are released from the bone marrow and circulate through the blood and lymphoid organs awaiting further differentiation and homing signals. The myeloid pathway of differentiation gives rise to DCs that home to peripheral tissues to take up and process exogenous Ags prior to migrating to the secondary lymphoid tissues to present Ags to naive T-cells. The thymic DCs have a different and very specific purpose: their function is to present the self-Ag to developing thymocytes and, hence, subsequently delete autoreactive T-cells.

DCs are present in the peripheral blood (PBDCs), in the interstitial space of all tissues (with the exception of the cornea and central nervous system), in the thymus, lymph nodes and spleen. In the peripheral blood, two subpopulations of PBDCs have been identified, but both contain a specific protein (p55), and are thus detected by monoclonal antibody against p55. The recruitment of DCs in the peripheral tissues is thought to be mediated by the local production of cytokines such as granulocyte–macrophage colony-stimulating factor (GM-CSF) and by systemic signals such as bacterial lipopolysaccharides. DCs migrate to the secondary lymphoid tissues via the afferent lymphatics, but are thought to reach the spleen via the bloodstream. However, the mechanisms of homing to the lymph nodes and spleen are not fully understood, although certain isoforms of the hyaluronic acid receptor (CD44) are thought to be involved. Within the lymph nodes DCs are situated within the T-cell paracortical regions, whereas in the spleen they are located in the marginal zones at the periphery of the periarterial sheaths.

Lymphocytes

Lymphocytes form 20% of the white cell population and are of two kinds: T- and β-cells. The functional classification of lymphocytes depends on the detection of cell-surface markers that are identified using specific monoclonal antibodies. These cell-surface markers are termed clusters of differentiation (CD) and have been defined by international agreement. Some of these markers are specific adhesion molecules, e.g. CD54, which is intercellular adhesion molecule (ICAM) 1.

T-lymphocytes

T-cells differentiate in the thymus (at least in the fetus) and carry a number of important functions:

- regulation of the level of the immune response
- cytotoxic activity against bacteria
- assistance to β-cells in the destruction of virally infected cells
- initiation of cytotoxic activity of other immune effector cells.

All T-cells carry a receptor (Figure 1.20) that recognizes antigens and MHC molecules. This receptor is related to immunoglobulin and is associated with the CD3 molecule that

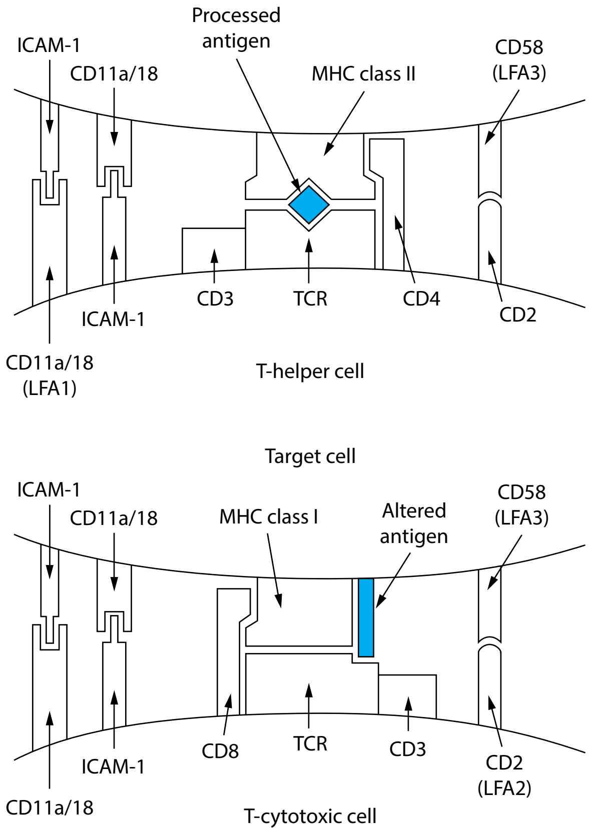

Figure 1.20 Cellular interactions involving the major histocompatibility complex (MHC) and the T-cell receptor (TCR). Processed antigen is presented to the TCR on the T-helper cell by the antigen-presenting cell (APC) together with MHC class II, whereas altered (e.g. viral) cellular antigen is presented to the T-cytotoxic cell with MHC class I. These interactions are also dependent on CD4 and CD8, respectively, and aided by a number of adhesion molecules.

is thus used as a pan-T-cell marker. Both CD3 and the T-cell receptor are members of the immunoglobulin superfamily, as are CD4 and CD6. The T-cell receptor/CD3 complex is essential for the functioning of the immune system. Activated (but not resting) T-cells also carry class II MHC molecules and have receptors for the cytokine IL-2.

There are two main types of T-lymphocyte (helper and suppressor), which are differentiated by their surface markers and function. T-helper cells are characterized by the surface receptor CD4, the ligand of which is part of the MHC class II complex on the APC. Processed antigen is expressed with the MHC class II molecule and is presented to the T-cell receptor/CD3 complex on the T-helper cell, thereby initiating the immune recognition and response. This response involves the T-helper lymphocyte producing several cytokines (particularly IL-2), which are involved in the maturation of cytotoxic T-lymphocytes, B-lymphocytes and various other functions of the immune system.

Cytotoxic T-lymphocytes express the surface receptor CD8, which recognizes class I MHC molecules (expressed in all nucleated cells). When foreign antigen, e.g. from virally infected or tumour cells, is expressed together with MHC class I molecule, this is recognized by the T-cell receptor/CD3 complex on the cytotoxic T-cell. This then releases various proteases that puncture the cell membrane, destroying the abnormal cell.

The T-lymphocytes with suppressor function form an ill-defined group that also expresses the CD8 marker. There is no doubt that suppressor activity exists, but the existence of specific T-suppressor cells remains unconfirmed.

B-lymphocytes

B-lymphocytes develop in the bone marrow and fetal liver. Activated β-cells proliferate and mature under the influence of T-cells. They ultimately differentiate into plasma cells that are characterized by an expanded cytoplasm, a large endoplasmic reticulum and a synthetic system entirely concerned with antibody production. The characteristic surface marker of B-lymphocytes is an immunoglobulin. In addition, β-cells have receptors (C1, C2 and receptor for the Fc fragment of antibody). β-cells produce antibodies (immunoglobulins) in the presence of foreign antigens with the help of antigen-specific T-cells. Immunoglobulin is the β-cell equivalent of the T-cell receptor.

Null cells

Null cells are a distinct group of leucocytes that exhibit neither T-cell nor β-cell characteristics. They carry a mixture of surface markers including CD16 and CD56. In appearance they are large, granular lymphocytes. The presence of receptor for the Fc portion of IgG allows null cells to mediate antibody-dependent cellular cytotoxicity (ADCC). Some cytotoxic T-cells also express the Fc receptor and are thus capable of ADCC (see below).

Natural killer lymphocytes

Natural killer (NK) lymphocytes are able to recognize antigenic determinants on the surface of some tumour and virally infected cells and destroy these without the assistance of antibody, although they are also capable of ADCC. The direct cytotoxic activity is not MHC restricted. NK cells express receptors for γ-interferon and IL-2. They are thought to serve a surveillance role with activity against circulating tumour cells, especially those of lymphoid origin. There is also some evidence that reduced NK activity correlates with tumour dissemination and with postoperative infective complications. Most NK function is undertaken by large granular lymphocytes.

NK cells do not have any cytotoxic activity against solid tumours. However, they can be transformed into lymphokine-activated killer (LAK) cells by incubation with IL-2. LAK cells are cytotoxic against various tumour cell lines. This form of immunotherapy (infusion of ex vivo produced LAK cells from a patient's NK cells) has been demonstrated to show some activity against certain human solid tumours, particularly melanoma and renal carcinoma, but its excessive toxicity has limited its usage and acceptance. Both NK and LAK cells are capable of ADCC.

Cytokines

These are water-soluble, low-molecular-weight peptides that act on or are produced by lymphocytes. They are grouped as follows:

- interleukins: IL-1 to IL-13
- interferons: α-interferon, β-interferon, γ-interferon
- colony-stimulating factors: macrophage colony-stimulating factor (M-CSF), GM-CSF, granulocyte colony stimulating factor (G-CTF).

Cytokines have several functions. In the first instance, some members are involved in the initiation of the inflammatory process. Others promote cell recruitment to the damaged area during the process of repair. Some cytokines are able to act more specifically, e.g. macrophage-stimulating factor enhances the ability of macrophages to ingest micro-organisms. An important function of cytokines is to provide a short-range messenger system of communication between cells of the immune response, hence the name interleukins. Cytokine signalling is extremely complex, and a simplified version is shown in Figure 1.21.

IL-1 is produced by macrophages and, to a lesser extent, by lymphocytes and fibroblasts. It acts as a short-range messenger in combination with antigen to cause T-cells to release IL-2 and probably express the IL-2 receptor (IL-2R). IL-1 also acts as a circulating humoral agent and induces the liver to manufacture acute phase reactive proteins and the hypothalamus to raise the body temperature. It also stimulates β-cells and induces the macrophages to release prostaglandin E_2 and tumour necrosis factor (TNF). IL-1 is responsible for certain symptoms, including arthralgia and myalgia. It also causes weight loss and tissue destruction in certain disorders. The production of IL-1 can be reduced or suppressed by aspirin, indometacin, corticosteroids and antimalarial agents.

IL-2 is produced by T-cells. It acts as a T-cell growth factor causing clonal proliferation in response to an antigen. Most T-cell subsets will proliferate in the presence of IL-2, the extent depending on the density of the IL-2 receptor, the level of expression of which requires restimulation and further exposure to antigen. IL-2 levels are reduced by immunosuppressive agents, e.g. ciclosporin and corticosteroids. The effect of corticosteroids

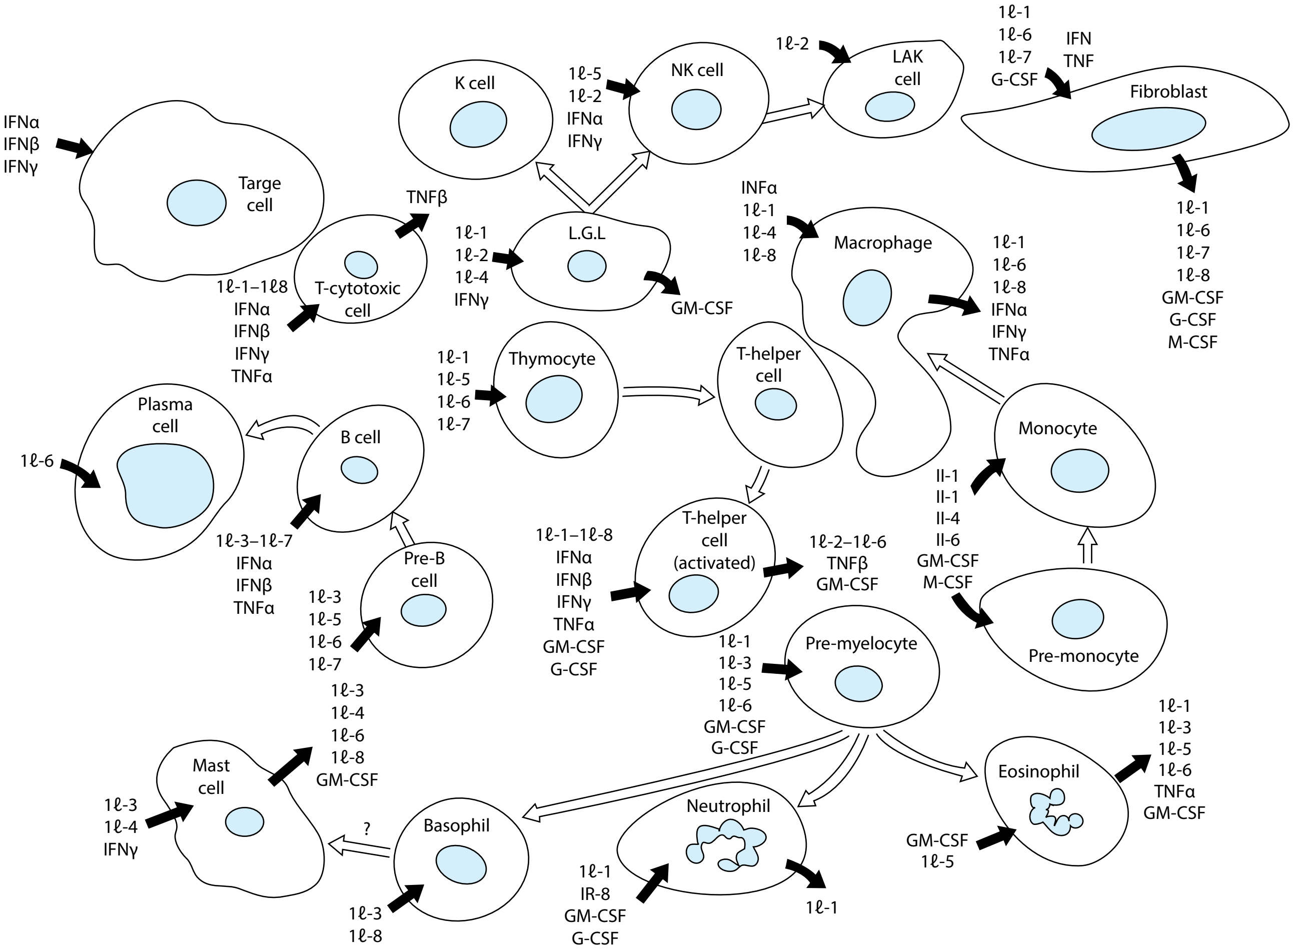

Figure 1.21 Simplified version of cytokine signalling by immunologically active cells. The cytokines produced by and influencing the cells of the immune system are shown. IL, interleukin; IFN, interferon; TNF, tumour necrosis factor; GM-CSF/G-CSF/M-CSF, granulocyte–macrophage, granulocyte and monocyte–macrophage colony-stimulating factors; LGL, large granular lymphocyte; K, killer; NK, natural killer; LAK, lymphokine-activated killer.

is probably secondary to suppression of IL-1 production. IL-2Rs are also found on β-cells, monocytes and null cells.

IL-3 is produced mainly by T-helper cells and mast cells, which produce histamine. It acts as a colony-stimulating factor on all haemopoietic cells. Its presence is obligatory for the development of mast cells.

IL-4 is produced by T-helper cells, for which it acts as an autocrine growth factor. It also stimulates β-cells to proliferate. Activity appears to extend to most haemopoietic cells. IL-4 is of crucial importance in the induction of several immunoglobulins.

IL-5 is produced mainly by T-cells and induces proliferation of both β-cells and eosinophils. It is thus involved in type I allergic reactions. IL-5 acts in synergy with IL-2, in the induction of LAK activity in peripheral blood lymphocytes but is inactive in this respect on its own.

IL-6 is an inflammatory cytokine produced by macrophages, fibroblasts, mast cells and T-cells. It acts on a variety of targets in the immune and haemopoietic systems. Many of the activities thought to be due to IL-1 are actually secondary to the induction of IL-6. It is also a β-cell growth factor, being involved in the production of plasma cells. IL-6 stimulates malignant myeloma cells.

IL-7 is produced by fibroblasts and stromal cells. It stimulates the growth of early lymphoid cells, especially those of the B-lineage.

IL-8 is an inflammatory cytokine produced by stromal cells, endothelium and gastrointestinal mucosal cells. It stimulates neutrophil infiltration.

IL-10 is derived from T-cells and inhibits the production of cytokines from monocytes and macrophages.

Interferons are produced by leucocytes (α-interferon), fibroblasts (β-interferon) and antigen-activated lymphocytes (γ-interferon). The overall role of interferons is to synergize with other cytokines, but α- and β-interferons also enhance class I MHC antigens expression, whereas γ-interferon enhances class II expression. All act as antiviral agents and, together with IL-2, augment NK cell cytotoxicity against certain target tumour cells.

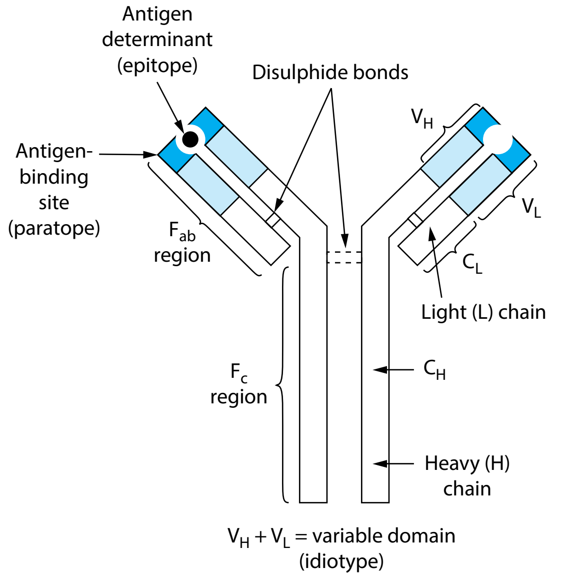
TNF is derived from macrophages and lymphocytes and kills tumour cells in some animal systems but not in humans. TNF exists in two forms, α and b. Cachectin is related to TNF and is possibly the same substance. High levels of TNF are accompanied by wasting of both adipose tissue and muscle and are responsible, together with other cytokines/factors, for wasting syndromes. Thus, prolonged infusion of TNF alone in humans does not result in cachexia. Most of the current interest in TNF relates to its role as one of the mediators of multiple organ failure, although monoclonal antibodies against TNF and endotoxin have proved ineffective against the systemic inflammatory response syndrome (SIRS).

The colony-stimulating factors are manufactured by several cells, including stromal cells, fibroblasts, endothelium and lymphocytes. GM-CSF promotes the growth of granulocyte and monocyte progenitor cells. It has proved useful in aiding the recovery of the bone marrow from cytotoxic chemotherapy and radiotherapy (bone marrow rescue). G-CSF acts in a similar fashion on granulocytes, and M-CSF stimulates cells of the monocyte–macrophage lineage.

Immunoglobulins

Immunoglobulins (antibodies) are classified on a structural basis into types and classes: IgG (four classes), IgA (two classes), IgM, IgD and IgE, and are either membrane bound (surface) or secreted. Each has a non-antigen-binding Fc fragment and an antigen-binding Fab moiety. All immunoglobulins are constructed of two identical light and two identical heavy chains cross-linked by disulphide bonds (Figure 1.22). The N-terminal domains are formed from one heavy and one light chain that serve as the antigen-binding site (paratope) reacting with a specific part of the antigen molecule (epitope). The structure of these domains varies with the different antibodies (variable domain), with the antigenic determinant for each being termed the idiotype. The remaining part of the molecule (Fc fragment and part of the Fab moiety) is constant within classes of immunoglobulin, and this antigenic determinant is referred to as the isotype.

The specificity of an antibody for an antigen is dependent on the variable region, which is coded for by gene segments named V, D and J. Variability is consequent on a process of mutation and genetic rearrangements within these gene segments in the β-cell. By these mechanisms, each individual has an enormous heterogeneity of antibody molecules; in fact, more than could be contained in the genome. Membrane-bound immunoglobulin is found on the surface of the β-cells, where it functions as a cell receptor. This immunoglobulin has the same antigen-binding characteristics as the immunoglobulin that may be produced by cells originating from this lineage.



Antigen determinant (epitope)
Disulphide bonds
Antigen-binding site (paratope)
V_H
V_L
F_{ab} region
C_L
Light (L) chain
F_c region
C_H
Heavy (H) chain
$V_H + V_L$ = variable domain (idiotype)

Figure 1.22 Structure of immunoglobulin of the IgG type. This is formed from two heavy chains and two light chains linked together by disulphide bonds. Both heavy and light chains have constant (C_H and C_L) and variable (V_H and V_L) regions. The C_H/C_L region is termed the isotype and the V_H/V_L region, which contains the binding site (paratope), is termed the idiotype.

Each β-cell can produce only one idiotype. Thus, effective antibody production against a specific antigen results from clonal expansion and maturation of individual β-cells into plasma cells. A particular cell can, however, change the Fc portion, and hence the class of antibody, without changing the characteristics of the antigen-binding site. This is because the genes coding the C and V regions are separate and fragments are only spliced as proteins. This explains why the primary response to an antigen may be mainly IgM, whereas the secondary response is mostly composed of the more avidly binding IgG.

The constant areas of the immunoglobulin molecule are concerned with the interaction between the antibody and the receptor on the cell surface. Many of the effector functions are mediated via the Fc receptors on the cell surface and this permits a variety of functions, e.g. the receptor for the Fc fragment of IgG enables macrophages to phagocytose antigenic particles coated with the antibody, or kill an invading organism (ADCC). Similarly, receptors for IgA located on the deep side of epithelial cells facilitate the transfer of the antibody across the cell to be discharged in the secretions. IgE receptors found on mast cells are involved in the release of inflammatory mediators and lymphokines on contact of these cells with specific antigen, and thus initiate the inflammatory response. Antibodies thus subserve two functions:

1. they bind with antigens via the variable domain
2. they connect with the host's defence effector system through the constant domain.

Immunoglobulin G

This is the most abundant immunoglobulin and it constitutes the major antibody produced during a secondary response. It has the ability to cross the placenta into the fetus and is reinforced by colostral IgG during neonatal life. IgG diffuses readily into the extravascular spaces and thus its predominant role is to neutralize bacterial toxins and bind micro-organisms when it activates complement (classic pathway), thereby inducing chemotaxis and phagocytosis. IgG coating sensitizes the target cells to destruction by killer lymphocytes.

Immunoglobulin A

IgA is found in the secretions of exposed mucosal surfaces, e.g. saliva, nasal mucosa, tears, gastrointestinal tract, bronchial and genitourinary epithelium, as a dimer that is stabilized by a protein synthesized by the epithelial cells (secretory component). The purpose of this mechanism is the prevention of bacterial adherence to the exposed mucosal cells and hence invasion.

Immunoglobulin M

These star-shaped antibodies are also known as macroglobulins because of their high molecular weight. These antibodies induce agglutination and cytolysis. IgM antibodies are the first isotype to appear during the course of an infection and are largely confined to the intravascular compartment. Hence, their primary role is thought to be the containment of bacteraemia.

Immunoglobulin D

IgD is nearly all bound to the surface of some of the circulating lymphocytes. It is probably involved in the control of lymphocyte proliferation and suppression and may be involved in establishing tolerance to certain antigens, although its exact function remains unknown. Some consider it to be an evolutionary relic.

Immunoglobulin E

Only a small subpopulation of plasma cells synthesizes IgE and these are mainly confined to mucosal surfaces. Plasma levels of IgE are normally low but levels rise considerably during parasitic infestations. These antibodies, by coating the parasites, sensitize them to destruction by eosinophils. IgE is also associated with the defence of mucosal surfaces in association with mast cells. Encounter with a foreign antigen induces degranulation of the mast cells with the liberation of vasoactive amines, e.g. histamine, causing increased capillary permeability and exudation of plasma factors into the area. It is the mechanism involved in allergic reactions such as extrinsic asthma and hay fever.

Autoimmune disease

Several mechanisms exist to limit the possibility that the immune mechanism may react and damage the host's tissues. In the first instance, clones of T-cells that express self-recognizing receptors are destroyed in the thymus in early life, a process known as clonal deletion. Second, self-reacting clones are functionally suppressed. This is termed clonal anergy. T-cells are crucial in immune regulation. Thus, it is often possible to detect self-reacting β-cell clones but, in the absence of specifically reacting T-helper cells (deleted in the thymus), they are unable to proliferate. In addition, other suppressor mechanisms specifically involving T-cytotoxic cells appear to limit the host response to self.

Nonetheless, these protective mechanisms may fail. Fortunately, although many individuals appear to suffer a breakdown in tolerance towards their own antigenic make-up, only a few develop autoimmune disease. Individuals who develop autoimmune disease show an alteration in the T-helper/cytotoxic ratio in their peripheral blood because the suppressor mechanism has failed. Sometimes there are alterations in the target organs, e.g. thyroid and pancreas, when cells from these organs express class II MHC antigens that are not found in normal individuals. This abnormal expression can be induced by infection, normal physiological triggering, e.g. lactation, or by the action of interferons and TNF-α. In this situation, class II MHC expression is invariably associated with lymphocytic infiltration, which explains the histological appearance of Hashimoto's thyroiditis (see Chapter 18).

Autoimmune disorders are classified as

- organ specific: primary thyrotoxicosis (Graves disease), Hashimoto's thyroiditis, Addison disease, type 1 diabetes mellitus and pernicious anaemia (megaloblastic anaemia, atrophic gastritis and achlorhydria)
- non-organ specific: rheumatoid arthritis, systemic lupus erythematosus, chronic active hepatitis and primary biliary cirrhosis.

Autoantibodies can be detected in the serum of patients with these disorders, e.g. IgG autoantibody to thyroid-stimulating hormone in Graves disease, IgM autoantibody (rheumatoid factor) to the patient's own IgG in rheumatoid arthritis, and antibodies to double-stranded DNA (antinuclear factor) in systemic lupus erythematosus.

The organ damage is induced by the cytotoxicity of macrophages, NK cells and β-cells primed with the respective autoantibody, as well as cytotoxic T-lymphocytes.

The inflammatory response

The inflammatory response can be acute, subacute or chronic. The clinical histology (especially the cellular response) varies accordingly, with neutrophils predominating in acute inflammations and lymphocytes and macrophages in chronic and subacute inflammations. Some conditions are primarily chronic in nature, while others begin as acute but progress to a chronic stage, especially if treatment is suboptimal. Alternatively, acute episodes of inflammation may subside for a time (remissions) with reactivation of the inflammatory process and renewed symptoms and signs (relapses) during the natural history of the disease. This is exemplified by inflammatory bowel disease.

Although in clinical practice infection by micro-organisms is the most important cause of inflammation, this may be caused by non-infectious putative agents: chemical agents, antigen–antibody complexes, trauma, etc. Indeed, traumatic inflammation is an essential part of the healing/repair process and accounts for the changes of the 'lag phase' of healing described earlier in this module.

Acute inflammatory response

The well-recognized features of acute inflammation are pain, swelling, erythema and heat. All of these manifestations are due to the release of chemical mediators. The response varies with the nature of the putative agent. The inflammatory response related to infection is best considered as a mechanism that allows the rapid accumulation of immunologically competent cells and phagocytes to destroy the invading micro-organisms. In this respect, the host's response depends on a number of factors, including the type of organism and the infecting dose, previous exposure and the site of invasion.

Complement fragments C3a, C5a and bacterial endotoxin activate neutrophils, rendering them adherent to the vascular endothelium. Endotoxin also stimulates macrophages to produce and release IL-1 and TNF, itself a potent neutrophil activator. Both cytokines increase the adhesiveness of endothelium for neutrophils.

Various products of arachidonic acid metabolism, including platelet-activating factor, leukotriene B4, the peptidoleukotrienes C4, D4 and E4, and TXA_2, are also involved in the inflammatory response.

The first stage in the acute inflammatory response consists of the migration of neutrophils through the vascular endothelium to the inflammatory source. This involves adherence to the endothelium. The activated neutrophils leave the central column of blood cells of the flowing blood and tumble on the activated endothelial lining before they stick (a phenomenon known as rolling). The binding itself is mediated by two adhesion molecules, L-selectin (leucocyte adhesion molecule 1) and E-selectin (endothelium leucocyte adhesion molecule 1). This is followed by the binding of other molecules known as b_2-integrins on the neutrophils with ICAM-1 and ICAM-2 on the vascular endothelium.

The fully activated extravasated neutrophils produce elastase and free radicals or species, e.g. superoxide ions and hydrogen peroxide, designed to destroy the invader but which can also damage the host's own tissues. This mechanism, with the production of highly destructive reactive oxygen species, can be disadvantageous to the host, as in the ischaemia–reperfusion injury and in certain specific infections such as tuberculosis and leprosy. It may also be involved in SIRS.

Immunocompromised patients

Patients with immune deficiency are unable to mount an appropriate defence against invading organisms and are thus liable to serious infections; moreover, they may show minimal signs in the presence of severe disease. The risk is determined by the severity of the immune deficiency and, in the clinical context, this is more important than the underlying cause. Low-risk patients are more susceptible to infections by organisms that are known to be pathogenic to immunologically competent individuals. Patients with moderate immune deficiency are additionally susceptible to infections by organisms that are normally considered to be harmless commensals. Malnourished patients, patients on steroid therapy and organ transplant recipients belong in this moderate-risk group. In patients within the high-risk group (severely immunocompromised), the risk of fatal infections with both pathogenic and commensal organisms is so high that they may require isolation and the use of prophylactic antibiotics.

Minor degrees of immune deficiency are very common in surgical practice and are frequently overlooked. Some of the factors often encountered in surgical practice include:

- age: neonates, infants and advanced age
- metabolic factors: chronic renal and liver disease
- drugs: antibiotics, non-steroidal anti-inflammatory drugs, steroids, gastric antisecretory drugs, tobacco
- specific disorders: diabetes mellitus, advanced malignancy, collagen disorders, rheumatoid arthritis, cystic fibrosis
- malnutrition
- surgical procedures: intravenous cannulas, bladder catheterization, endotracheal intubation, nasogastric intubation, abdominal drains.

Aside from cystic fibrosis, congenital disorders causing immune deficiency are rare and include congenital neutropenia, deficiencies in antibody production and cell-mediated immunity.

Serious immunosuppression

The causes include drug-induced bone marrow failure from cytotoxic chemotherapy, total body irradiation and graft-versus-host disease and AIDS. A severe degree of immunosuppression results from total body irradiation (1000 Gy), normally used to treat residual leukaemia. This therapy destroys most immunocompetent lymphocytes and there is a decrease in the granulocytes and monocytes, leading to impaired reticuloendothelial activity and antibody formation. Furthermore, radiation also causes chromosomal damage so that the immunoglobulin structure may be altered and less effective. Severe infections *per se* can cause a fall in the neutrophil count in addition to a defect in neutrophil function, detected as toxic granulation in the circulating neutrophils.

The risk of infection is proportional to the level and duration of the neutropenia and is compounded by the anaemia and thrombocytopenia that accompany bone marrow failure. Organisms that commonly cause infections in these patients include pyogenic and endogenous enteric bacteria. Patients are also at risk from exogenous enteric pathogens, e.g. *Pseudomonas, Klebsiella* spp., *Serratia, Actinobacter* and endogenous *Candida* spp. and airborne *Aspergillus*.

The management of these patients is primarily directed to the prevention of infection until the severely immunocompromised state recovers or is reversed by bone marrow rescue or transplantation. Measures used to achieve this objective include strict personal hygiene, use of prophylactic antibiotics including gut decontamination, protective isolation in rooms with a laminar flow system and controls over food and visitors.

Mucosal barriers

The skin clearly has a major role in protection as a physical barrier against invading micro-organisms, but it is also immunologically active, as exemplified by its resident large numbers of antigen-presenting dendritic cells. The protective skin barrier is breached by extensive trauma, including burns, in normal individuals. Immunocompromised individuals are prone to significant infections even after mild skin injuries. Pressure sores (decubitus ulcers) are important sources of infection, common organisms being *Staphylococcus aureus* and *Staphylococcus epidermidis*. In compromised patients, colonization with *Pseudomonas* and *Candida* is common in moist skin areas, and enteric organisms are prevalent on the perianal skin.

The gastrointestinal tract also acts as a barrier and harbours immunologically competent cells. The mucosa of the normal gastrointestinal tract is protected by both mucin and secreted IgA, which prevent the adherence of pathogens. Some pathogens are capable of destroying the mucin protection and, in the event of mucin deficiency, certain normal enteric organisms are capable of attacking the intestinal mucosa. In a similar fashion, gastric acid acts as a strong barrier to infection, but in the event of gastric haemorrhage, gastric neoplasm and the use of gastric antisecretory drugs, e.g. H_2-receptor blockers and proton pump inhibitors, this acid barrier is lost or its efficacy reduced. Normally, commensal organisms with the gastrointestinal tract (the gut microflora) adhere to the mucosa. Invading micro-organisms have to compete for binding sites and available nutrients. This phenomenon is termed colonization resistance. If a patient is prescribed a broad-spectrum antibiotic, especially if this is poorly absorbed, the commensal gut microflora reduces by a factor of 10^3–10^5. This allows an organism that is resistant to the antibiotic used to become established and cause a clinical infection, e.g. *Clostridium difficile* pseudomembranous colitis. Even minor trauma to the mucosal surface, e.g. following endoscopy, can prevent adherence of commensal organisms.

Aside from immune mechanisms, the integrity of the gastrointestinal barrier is dependent on physical continuity of the mucosal lining, adequate blood supply and luminal supply of calories and specific amino acids such as glutamine. There is also evidence that the permeability is increased in severe cholestatic jaundice. The pathological significance of lost or impaired barrier function is the translocation of pathogenic Gram-negative bacteria and/or endotoxins into the portal blood stream. If the Küpffer cell barrier function is overwhelmed, systemic bacteraemia and endotoxinaemia ensue. Thus, significant translocation of bacteria and endotoxin may be encountered:

- after major trauma including major surgery
- in severe sepsis
- in patients on prolonged parenteral feeding
- in patients with intestinal ischaemia
- in patients with severe cholestatic jaundice and liver failure.

A similar pathological mechanism has been implicated in SIRS, which results in multiorgan failure. The widespread damage to the endothelium is now thought to be the result of activation/trafficking of systemic neutrophils. Previously, endotoxin/TNF was held to be primarily responsible, but other substances including cell wall aminophospholipids may be involved in the widespread activation and endothelial damage. In an attempt to reduce this usually fatal condition, selective decontamination of the digestive tract (SDD) has been advocated for critically ill patients within intensive care units. This involves the application of antibiotic and antifungal pastes to the oral cavity and pharynx and oral administration of non-absorbable antibiotics. At least one trial has shown benefit in patients on ventilatory support, although the practice of SDD is still not in widespread usage.

Colonization resistance is also important in the respiratory tract, but only in the upper respiratory passages. In normal individuals, inhaled micro-organisms are rapidly cleared by alveolar macrophages, although this function is impaired in patients with even mild changes in immune function. When an endotracheal tube has been in place for a few days, there is severe mucosal damage, allowing colonization with enterobacteria. Flow of urine is the major factor preventing infection in the urinary tract.

Trauma

Trauma, including surgery, is associated with a multifactorial non-specific immune depression that involves the cell-mediated rather than the humoral response. This is demonstrated by reduced, delayed-type sensitivity on skin testing to recall antigens, e.g. *Candida* and tuberculin. Changes in lymphocyte function that have been documented after trauma and surgery include a decrease in the CD4/CD8 ratio, decreased IL-2 production from T-lymphocytes (CD4+ T-helper cells), reduced NK activity and reduced generation of LAK cells from peripheral lymphocytes. Monocytes are also affected, with the most notable change being reduced class II MHC expression. Indeed, persistent depression of class II MHC expression is associated with a poor prognosis after major trauma. Perioperative blood transfusion adds to the immune depression after surgery and has been shown to be associated with an increased incidence of postoperative infection. Recombinant cytokines and other immunological agents may have a place in patients undergoing major surgery for cancer and in patients sustaining major trauma. Thus, low-dose IL-2 prevents the fall in NK activity and LAK cell generation after surgery. However the clinical efficacy of these agents in these situations remains to be confirmed by prospective studies.

Nutrition

Severe malnutrition has profound effects on the immune system but these are largely confined to the cell-mediated response. All of the commonly measured tests of cell-mediated immunity are depressed. Thus, there is a generalized lymphopenia with marked depletion of the CD4+ T-helper cells, impaired IL-2 production, reduced lymphocyte proliferative response to mitogens, reduced NK activity and generalized atrophy of the lymphoid organs. As with severe trauma, the delayed-type sensitivity to recall antigens is severely impaired and in extreme cases the patient fails to react (anergy). There are no significant changes in the humoral immunity, and the β-cell and immunoglobulin production is not impaired.

Surgical pathology

Surgical pathology involves the macroscopic and microscopic examination by an expert pathologist of surgical specimens removed by surgical operations in the treatment of patients with (1) diagnosed or (2) undiagnosed disease. In the latter instance, the histological examination by the pathologist provides the definitive diagnosis. In cancer, whre the diagnosis is established preoperatively, the purpose of the pathological examination is to:

- establish that the entire tumour has been removed locally by histology of the tumour margins (tumour-free or involved distal, proximal and circumferential margins)
- provide confirmation of the diagnosis and grading of the cancer
- provide a quality control of the locoregional lymphadenectomy performed (adequate or inadequate lymph node harvest)
- determine involvement or otherwise of the regional lymph nodes.

All these affect the subsequent management of the patient and influence the ultimate prognosis. In addition, on the basis of the detailed histology, the surgeon is able to determine that the resection undergone by the patient is:

- potentially curative
- potentially non-curative
- definitively non-curative, which includes debulking procedures.

It follows (without saying) that all surgical specimens and biopsies must be subjected to surgical pathological examination, and it is the duty of the surgeon to ensure that the specimen reaches the pathology laboratory fixed or fresh (depending on the individual need) in a pristine state and that the specimen is clearly labelled in accordance with patient's details.

Tumour margins

The tumour margins relate to the edges of the surgical specimen containing the tumour and determine whether the resection has been locally removed completely, i.e. that the resection has been through normal tissue beyond the limits of the tumour. The extent of the tumour margin will vary with the biological aggressiveness of the tumour and thus will vary from 3–5 mm in well-differentiated tumours to 10–15 mm or more for dedifferentiated (anaplastic) lesions. Although emphasis is placed on proximal and distal tumour margins, it must be remembered that a surgical specimen has a three-dimensional configuration, and a more complete assessment is obtained by including the circumferential tumour margin. This assumes great importance in total mesorectal resection for rectal cancer.

The tumour margins can be examined by the surgical pathologist in different ways: (1) perpendicular section taken at a right angle to the edge of the specimen and or (2) by parallel sectioning.

The perpendicular section enables the important distinction between a lesion that truly extends to the margin and a lesion that comes close but does not involve the margin.

In contrast, a shave section made parallel to the edge of the specimen obtains a relatively large surface area of the margin and is used in determining margins in tumours arising in hollow viscera. However, it does not effectively demonstrate the relationship between the edge of the tumour and the resection margin, i.e. it is unable to identify that the tumour extends to but does not actually involve the margin. Thus, parallel sections are used when macroscopically the margin is large and obviously free of tumour or when dealing with small luminal organs.

Node sampling

The primary purpose of node sampling is to determine the histological lymph node status of the solid cancer. An equally important but often overlooked role is for the pathologist to provide an indication of the oncological appropriateness of a curative operation. Thus, for example, the specimen from a D2 resection for gastric cancer (dissection includes the second tier of lymph nodes draining the tumour) should contain at least 40–50 regional nodes provided the surgical pathologist has harvested the nodes by the appropriate technique as there are many pitfalls, e.g. the lymph nodes may be small and embedded in fat. Many pathologists prefer to search in the fresh specimen, relying on palpation that is not possible if the tissues have been hardened by fixation. Some pathologists prefer to immerse specimens in certain clearing agents to remove excess fat. The nodes collected during the harvest are labelled in appropriate anatomical groups whenever possible. Every lymph node obtained is submitted for microscopic examination after staining with haematoxylin and eosin (H&E). Lymph nodes larger than 5 mm are serially sectioned at 2–3 mm intervals.

Sentinel node biopsies

Aside from routine histological examination of serial sections, special immunohistochemical stains and reverse transcriptase polymerase chain reaction are used to detect small clumps of tumour cells.

Tumour grade

The grade of a tumour is used by the pathologist to estimate the biological aggressiveness in terms of potential for growth, invasion and metastasis of a malignant tumour in a given patient. It is a reflection of the extent of differentiation (how closely the tumour cells approximate to the normal) or dedifferentiation (anaplasia) of the cells constituting the tumour based on the microscopic appearances, i.e. degree of atypia, ploidy, mitotic index, etc., using grades (G1, most differentiated; G4, least differentiated). For some tumours, the tumour grade is based on counting the number of mitoses per 10–50 high-power fields (mitotic index). Grade 1 is a well-differentiated tumour (low-grade malignancy) and grade 2 is moderately differentiated (intermediate grade). The worst prognosis is seen with grade 3 (poorly differentiated, high grade) and especially with grade 4 (totally undifferentiated/anaplastic tumour, high grade). In some tumours, the tumour grade cannot be assessed, in which case the designation GX is given. Individual cancers have their own recognized grading system, e.g. Bloom–Richardson grading for breast cancer, Gleason grading for prostate cancer, etc.

Types of resections

The detailed pathological examination will also modify (usually downgrade) an operation. Thus, a surgeon may consider that he has performed *a potentially curative D2 resection* with no macroscopically visible residual tumour (R0 resection). If the pathological examination confirms clear tumour margins and no histological node involvement (provided the node harvest was of the order expected for the resection), the resection is classed as *definitively curative*. In contrast, even if a few nodes are involved on histological examination, the operation is downgraded to *potentially non-curative*. Positive tumour margins relegate the resection to *definitively non-curative*.

Pathological techniques

Perhaps the most important requirement is the establishment of good communication between the surgeon and the pathologist in terms of the provision of relevant clinical information, correctly obtained biopsy specimens and the need or otherwise for their fixation prior to dispatch to the pathology department. In some situations special laboratory techniques are required in the handling of specimens. These necessitate prior consultation with the pathologist to ensure that the laboratory is set up for the correct handling of the specimen when it arrives. The pathologist can only report on the material received. This may not always be representative of the disease process. In this respect, the surgeon must have the necessary experience and knowledge of surgical pathology to be able to obtain the appropriate biopsy of the lesion in any given situation.

Tissue harvest: biopsy techniques

Tissue diagnosis by the examination of biopsy material, histology, is the final arbiter in establishing the nature of the disease process. The alternative, which is applicable to certain situations and may indeed complement histology, is cytology. This attempts to characterize the cell yield obtained as normal, hyperplastic or neoplastic. The accuracy of both techniques depends on three factors: the skill in obtaining the right representative material, adequate processing and staining of the specimen, and the interpretative skill of the histopathologist or cytologist.

Biopsy

By definition, this involves the removal of a piece of tissue for the examination of the histological architecture and cellular details. It can be open (obtained during surgery), endoscopic or closed (percutaneous). The last two are always partial, whereas open biopsy can be incisional or excisional (total).

Percutaneous closed biopsy

This involves the targeted removal of a needle core of tissue from the suspected site. When this is deeply situated it can be performed 'blind', as in percutaneous liver biopsy, or under visual control (guided biopsy) by radiographic techniques (fluoroscopy, CT), ultrasound or laparoscopy. The type of biopsy needle varies with the nature of the tissue involved, e.g. Abrahams needle for pleural biopsy or Menghini needle for liver biopsy, although the most commonly used implement for soft-tissue biopsy (including liver) nowadays is the Tru-cut needle. Automatic, spring-loaded modifications of this needle, e.g. Biopty device (Figure 1.23), are used for guided needle-core biopsy. With the advent of Tru-cut needle systems, the use of high-speed drill biopsy has become largely confined to bone.

Open biopsy

Open biopsy can be incisional or excisional. Incisional biopsy entails the removal of a wedge of the lesion with adjacent normal margin, whereas in excisional biopsy the entire lesion is excised with a surrounding rim of normal tissue. In practice, all small lesions should be excised *in toto*. Incisional biopsy is used for large lesions prior to treatment.

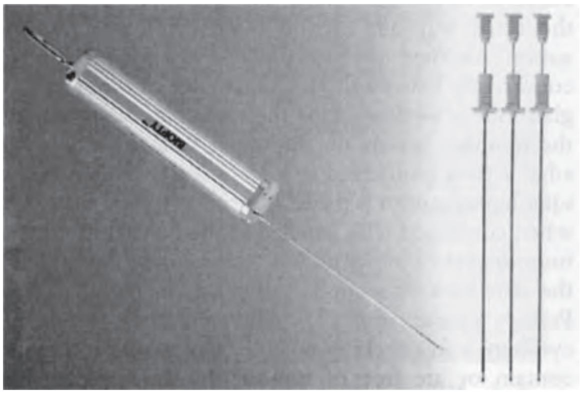


Figure 1.23 Biopty device: a mechanized form of Tru-cut needle-core biopsy.

Endoscopic biopsy

This is now the most commonly performed tissue-sampling procedure. The technique is used in association with both rigid and flexible endoscopy with a variety of biopsy forceps, which have cutting cup-shaped jaws. As the specimens obtained are small, interpretation may be difficult and multiple biopsies are desirable. Endoscopic biopsy is often accompanied by brush cytology, especially for upper gastrointestinal tract lesions, and the combined use of the two techniques enhances the overall diagnostic yield. For inaccessible regions such as the small intestine, special techniques are used. This involves the swallowing of a suction biopsy capsule on a lead (e.g. Crosby capsule). When the desired location, as determined by radiographs, is reached, suction is applied and the cutting knife, situated at the outlet of the capsule, is activated thereby enclosing the desired portion of tissue, after which the capsule is retrieved (Figure 1.24).

Rules governing tissue biopsy

The objective is the harvest of a tissue sample with its tissue architecture preserved and that is representative of the underlying pathological process. This may, on occasion, prove problematic and there are a number of practical difficulties with the various techniques that may limit the usefulness of the histological interpretation. In general, however, certain guidelines may be followed:

- The larger the lesion, the greater the number of biopsies needed for adequate evaluation: multiple biopsies overcome the problem of heterogeneity.
- Biopsies should not be taken from the central crater of ulcerated lesions because this region usually consists largely of necrotic tissue. A wedge peripheral slice that includes the adjacent normal margin is likely to be more informative.
- Whenever safe, the biopsy should include the whole thickness of the lesion so that the pathologist can establish the relationship with the surrounding tissue. This is especially important in providing information on the depth of the lesion: used in the staging of some tumours, e.g. malignant melanoma.
- Large, deeply situated masses are often surrounded by a pronounced peripheral tissue reaction that can form a thick layer simulating

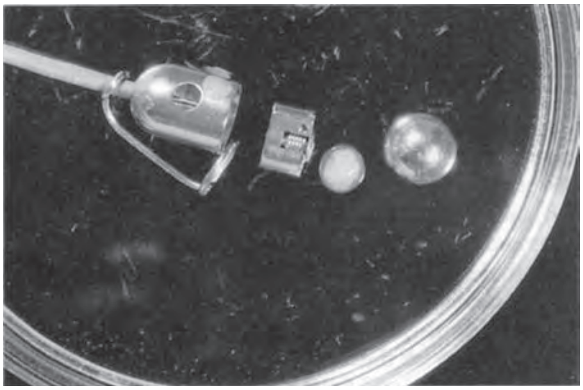

Figure 1.24 Opened Crosby capsule with a jejunal mucosal biopsy specimen in a Petri dish.

a 'capsule'. It is important for the surgeon to ensure that the biopsy wedge transgresses the capsule to include a representative portion of the lesion itself.

- When electrocautery is used to obtain the wedge biopsy, the surgeon should use a cutting current and the biopsy should be larger to ensure that there is sufficient tissue within the wedge that is suitable for histological interpretation.
- The tissue should be handled gently with minimal grasping of the wedge to avoid crushing damage and distortion of the histological features.
- Vascular lesions should be biopsied with extreme care and biopsy should not be attempted unless the surgeon is able to deal with any resulting haemorrhage. These lesions should be excised *in toto* if considered necessary on clinical or pathological grounds.
- Special considerations apply with regard to the biopsy of lymph nodes. This procedure should be considered only after a detailed examination of the patient and the non-invasive appropriate tests have been carried out. The following must precede all lymph node biopsies: search for a primary tumour, exclusion of infectious disease, documentation of the generalized or localized nature of the lymphadenopathy and, in the case of cervical lymphadenopathy, a full ear, nose and throat examination. Whenever possible, lymph nodes should be biopsied intact with the removal of a single node or a group of nodes. When this is not possible because of fixation and matting, a good wedge that includes the capsule and surrounding stroma of the mass is obtained. All lymph node biopsies should be sent fresh to the pathology department, as they often require special immunohistochemical staining and electron microscopy.
- Orientation is essential when the surgeon requires information on resection margins and staging. This has to be performed by the surgeon at the time of excision using easily identifiable markers (e.g. sutures of different materials or lengths), as it may be impossible for the pathologist to orientate the specimen after it has been excised.
- Special considerations apply to liver tumours.

Cytology

In terms of the techniques used, cytology may be exfoliative, brush, imprint or aspiration. The last is obtained by aspiration of fluid or solid masses using a fine-gauge needle and, for this reason, it is commonly referred to as fine needle aspiration cytology or FNA. It is used most commonly by surgeons for the diagnosis of fluid collections (ascites, pleural effusion, etc.), breast lumps and other subcutaneous lesions, thyroid swellings and prostatic enlargement, although it is applicable to a wide variety of conditions and is used routinely by chest physicians for the diagnosis of pulmonary lesions. For breast lesions, a special aspiration gun is often used (Figure 1.25). This enables the surgeon to fix the lump with the left hand while the lesion is aspirated in several directions by the right hand. Deep-seated lesions within the abdomen (e.g. hilar tumours and renal lesions) can also be subjected to FNA under CT or ultrasound control.

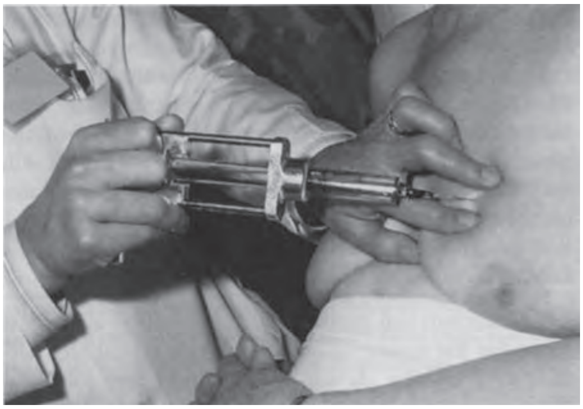

Figure 1.25 Aspiration gun used for fine needle aspiration cytology. It allows the surgeon to fix the lump with the left hand while aspirating the lump in several directions with the right hand.

Brush cytology is employed in endoscopic work. A special brush, introduced through the operating channel of the endoscope, is used and brushings are obtained from the entire surface of the lesion. Some of the superficial cells of the lesions are caught among the bristles and are then transferred to a glass slide. In China, 'blind' brush cytology is used for screening for oesophageal cancer. The patient swallows a small abrasive balloon tied to a piece of string. Once in the stomach, this is pulled up and slide smears are prepared.

Although valuable, imprint cytology is infrequently used by surgeons. One technique entails the application of a sterile glass microscope slide to the cut surface of the tissue, e.g. lymph node. The surface cells become adherent to the glass slide, which is then processed in the usual way and subjected to cytological examination. Another method, scrape cytology, produces a consistently better cell yield. The edge of one end of a glass slide is used to scrape the surface of the tissue and the resulting 'scoop' on the upper surface of the glass edge is then transferred to a second glass slide before a squash preparation is made. Imprint cytology, especially when combined with labelled monoclonal antibody to tumour surface antigens, is a very sensitive method for the detection of secondary deposits in lymph nodes. Perhaps a more surgically useful application of imprint cytology is in checking whether the resection margins contain or are free of tumour. In this respect, it is superior to frozen section, but necessitates the availability of immediate reporting by a skilled cytologist.

Irrespective of the technique used, cytology smears are made on glass slides (both fresh and fixed in carbowax) for staining prior to examination by the cytologist. The stains most commonly used are the Giemsa and the Papanicolaou, but it is important to stress that many of the special stains used in histopathology can be used for the evaluation of cytological material, e.g. stains for glycogen, melanin and mucin. Indeed, it is now possible to determine the oestrogen receptor status of a breast cancer by immunoperoxidase staining of the fine needle aspirate using special antibodies.

Cytological diagnosis is based on the cellular characteristics (nuclear size, chromatin architecture, nucleoli, etc.) and the degree of cohesion of the cells (reduced in cancer aspirates) (Figure 1.26). There are several disadvantages to the existing practice whereby the surgeon obtains the fine needle aspirate of a solid lump and then sends the smears to the cytological department for examination. The most important of these is the high incidence of unsatisfactory samples (smears containing stroma only). This necessitates a repeat of the procedure on a separate occasion. There are several ways in which this problem can be overcome. In some countries such as Sweden, the cytologist takes the fine needle aspirate. In the UK, the preferred option is immediate reporting by the cytologist. This entails the provision of a small laboratory near the clinic. The surgeon hands the fine needle aspirate to the technician, who prepares the smears and stains one with a special haematology stain, 'Diff Quik'. This enables the cytologist to give a definite answer within 5 minutes. Moreover, if the specimen obtained is unsatisfactory, the procedure is repeated immediately.

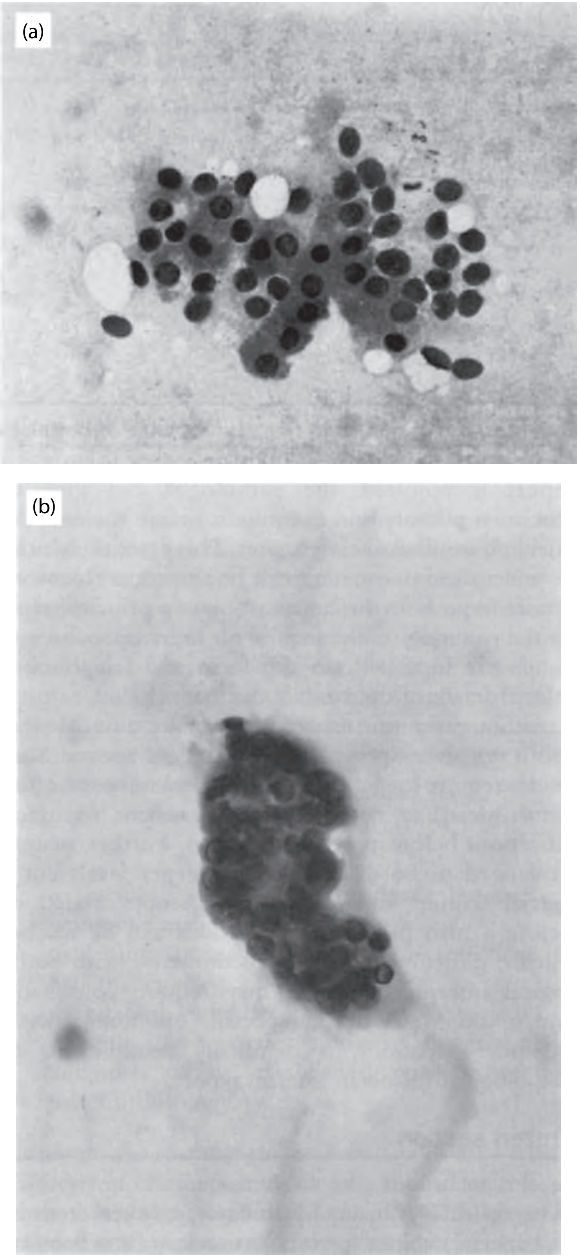

Figure 1.26 (a) Benign cytological aspirate from a fibroadenoma. (b) Malignant aspirate from an invasive breast cancer.

Basic handling of pathological specimens

Fixation

The first consideration relates to fixation of the tissue. Although most specimens should be fixed as soon as possible after removal, there are certain situations in which maximum information is better obtained by the examination of unfixed (fresh) tissue. The usual fixative is 10% buffered formalin and this is suitable for most specimens. However, certain tissues are better fixed in alternative solutions, e.g. Bouin's solution for testicular biopsies and peripheral nerves, chromate solutions for chromaffinomas and glutaraldehyde for tissues to be submitted for electron microscopy. The most important practical consideration relating to the fixation of tissue is the use of a suitably sized container that can accommodate at least 10 times the volume of fixative relative to the specimen. Furthermore, the specimen must be totally immersed in the fixative and the pot accurately labelled.

Certain tissue specimens are best sent fresh to the pathology department for a variety of reasons, e.g. preparation of dabs or smears, culture, enzyme histochemistry and electron microscopy. There must be minimum delay between obtaining the tissue and its arrival at the laboratory and the staff there must be given prior warning and subsequently informed when the specimen is on its way.

Request form

Every specimen must be labelled correctly and accompanied by a completed and signed request form. The information on the request form must correspond to that on the label of the specimen jar. The form must contain details of the following: patient identification, unit and consultant in charge, nature of specimen, date, previous histopathology report numbers (if any), clinical features, operative findings and presumptive diagnosis. If the specimen is considered to be infectious, this should be clearly stated on the form. In addition, most hospitals use hazard stickers for this purpose. In this event, the specimen is usually left in the fixative for a longer period before being examined and cut up in a class I safety cabinet. Culture swabs may be taken from the fresh specimen by the surgeon before fixation and sent to the microbiology department.

Cut-up

All specimens are measured and their macroscopic features described. Solid organs are weighed. Biopsy material is put through for processing intact. The rest are cut up and representative pieces of the tissue processed. Specimens of organs are best left uncut (solid) or unopened (hollow) and simply immersed in the fixative solution, providing they arrive at the pathology department on the same day. The pathologist can then cut or open the specimen, clean it if necessary and thereafter, in the case of hollow organs, pin it out on a cork board. The material is then immersed in fresh fixative for representative blocks to be taken on the following day. This ensures good preservation of the interior of the specimen or mucosal lining, avoids distortion and permits better histological evaluation. One exasperated pathologist, upset by the persistent habit of surgeons in opening the specimens, was known to reiterate that 'surgeons should get out of the habit of opening their bowels in theatre'.

The removal of pieces of fresh tissue for any purpose, e.g. estimation of oestrogen receptors or research, is best undertaken by the pathologist, who can ensure that the correct pieces are given while retaining sufficient material to enable a firm histological diagnosis. Gross specimens, if considered to be of special interest, are photographed before blocks are taken for processing and histological analysis.

Tissue processing, cutting and staining

Processing and embedding

The aim of tissue processing is to embed the fixed tissue in a supporting medium that will permit the subsequent cutting of histological sections without deformation or damage of the tissue. In practice, paraffin wax is the most satisfactory routine embedding medium. The actual steps involved after fixation include:

- dehydration to remove the fixative and the tissue water by alcohol and acetone
- clearing of the tissue by substances that are miscible with the dehydrating agents and the embedding medium, i.e. xylene or toluene
- embedding in hot wax.

Nowadays, the dehydration and clearing of the fixed tissue are conducted by the automatic tissue processor.

Cutting and staining

Sections are cut on a microtome and are then mounted on glass slides before staining. The routine stain used is H&E, and this provides enough details of cellular and tissue architecture to enable the vast majority of routine histopathological diagnoses to be made. However, there are situations in which special stains, including histochemical staining (Figures 1.27 and 1.28), are needed to identify specific tissue components or cellular inclusions.

Reporting

Laboratories do vary, but usually a report should be available to the clinician within 2–3 days. If an urgent report is required, the pathologist can give the specimen priority and examine it before the rest, thus enabling issue of an early report. This practice, which is in widespread usage, must not be abused, as this would render impossible the organization of a priority service by the pathologist. The request for an 'urgent paraffin' report must be clearly indicated on the form and telephone or 'bleep' details of the contact doctor included.

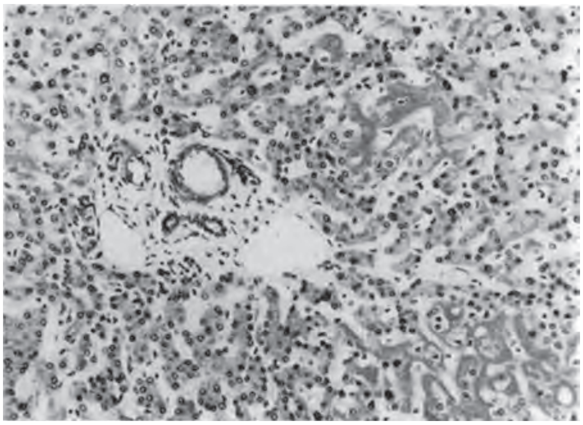

Figure 1.27 Liver stained by Congo red to demonstrate deposition of amyloid.

Although routine reports are issued within 24–48 hours, this is not always possible for a variety of reasons. Some tissues require longer to fix (infectious) or process (fatty tissue, breast) or require special treatment, e.g. decalcification (bone), before processing. Further material may need to be examined and deeper levels cut or special staining or electron microscopy carried out before a firm pathological diagnosis can be reached. Finally, difficulties may be encountered with pathological interpretation that may require consultation and, in some cases, outside specialist opinion. However, in these situations, it is usually possible for the pathologist to issue an interim report.

Frozen section

In this technique, the fresh tissue is frozen (-25°C) using solid CO_2 or liquid nitrogen and then sectioned in a special cabinet (cryostat) containing a microtome. The cut frozen sections are stained, usually with H&E, for immediate reporting to the surgeon. It is an exacting technique that requires the services of an experienced histopathologist, as the interpretation is more difficult than that experienced with fixed paraffin sections. Furthermore, there is some pressure on the pathologist to provide the information needed in a short time interval. In all cases, it is essential that the pathologist be briefed with the details of the clinical features and the nature of the biopsy taken. If all of these conditions are fulfilled, the accuracy of frozen section reporting is high, with low false-positive (0.2%) and false-negative (0.6%) results.

Frozen section is used for three purposes during surgery:

1. To establish the nature of suspect lesions: is it benign or malignant?
2. To ensure disease-free margins in resections for malignancy.
3. To establish whether the biopsy obtained in a difficult case contains sufficient material for a diagnosis to be established with subsequent paraffin histology.

Although the pathologist is able to give a definite diagnosis in the majority of cases, there are instances when this is not possible

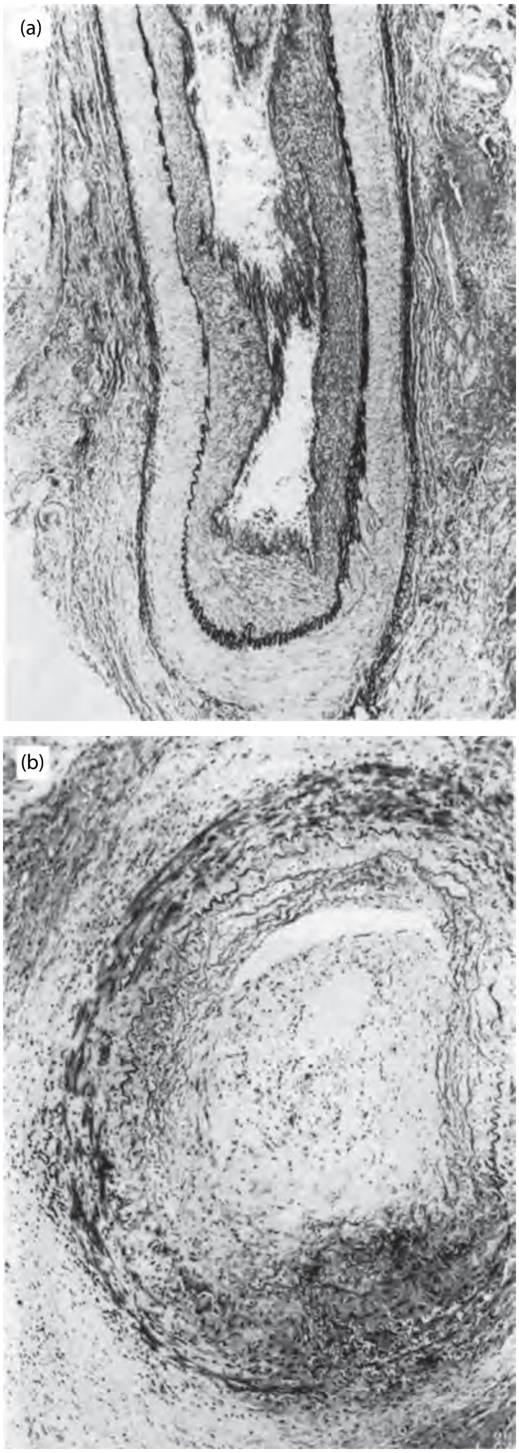

Figure 1.28 Elastica red/yellow stain: (a) normal artery; (b) disruption of elastic tissue in giant cell arteritis.

and the diagnosis has to be deferred until permanent sections are examined. In this situation, the surgeon, after ensuring that the pathologist has received adequate tissue, may opt to terminate the procedure and postpone definite surgical treatment until the result of the paraffin histology is available.

All frozen sections in patients undergoing elective surgery should be booked with the pathology department prior to the operation. There is no doubt that the frozen section service is abused by surgeons and a large number (50% in one reported audit) are unnecessary. *The most important guideline to the surgeon in deciding the need or otherwise for a frozen section is whether the findings of this process will influence the nature of the procedure carried out at that time.*

Handling of special specimens

Breast screening

Breast screening programmes are based on mammography performed in screening units or mobile vans. If an abnormality is detected on the initial screen, the woman is called for more detailed mammography and clinical examination. Some of these individuals are found to have palpable breast lumps. Others have impalpable lesions, which appear on the mammographic films as 'areas of disordered architecture', 'microcalcification' or 'localized densities', or a combination of these. These lesions require preoperative localization by special techniques (most commonly by the Mammolock needle inserted by the radiologist) immediately prior to excision biopsy performed under general anaesthesia (see Chapter 17).

The specimen with the localizing needle is radiographed in the pathology department using a Faxitron machine. These specimen films are compared with the preoperative mammographic films to determine whether the lesion has been removed. If the abnormality is not identified, the surgeon is informed and more tissue is removed, and the process repeated until radiographic confirmation of excision of the lesion is obtained. In practice, most lesions are identified on the first biopsy (Figure 1.29).

The circumference of the specimen is then marked with dye. Following inspection and palpation, the specimen is cut in serial coronal slices to a predetermined thickness (5.0 mm) on a special board. The tissue slices are then placed in sequence on a radiographic film, which is then exposed to determine the exact location and extent of the lesion (Figure 1.30). Blocks of tissue are taken from the slices containing the radiographic abnormalities and are labelled to match the slices from which they are taken. Particular attention is paid to the resection margins. The blocks are then fixed in formalin and processed for routine paraffin histology.

Approximately 50% of the subclinical lesions identified by screening are benign (sclerosing adenosis, duct ectasia, etc.) and the rest malignant. Non-invasive cancer (ductal carcinoma *in situ*, lobular carcinoma *in situ*) is more commonly found than invasive cancer in these screening biopsies. Compared with the naturally presenting disease, a greater incidence of tubular and cribriform invasive cancer is found by breast screening.

Lymph nodes

Ideally, these should be received fresh and are handled by the pathologist in a safety cabinet. The node is bisected and dabs (imprint cytological smears) are made on glass slides. These are stained with Giemsa and Lieshman stains. Thereafter, the procedure is as follows:

- Representative cross-sections of the nodes are fixed in formalin for paraffin embedding and routine H & E staining.
- Another piece is fixed in formalin but is embedded in resin to enable cutting of semithin sections (1–2 μm), which give better morphological details of lymphoid cells (Figure 1.31).

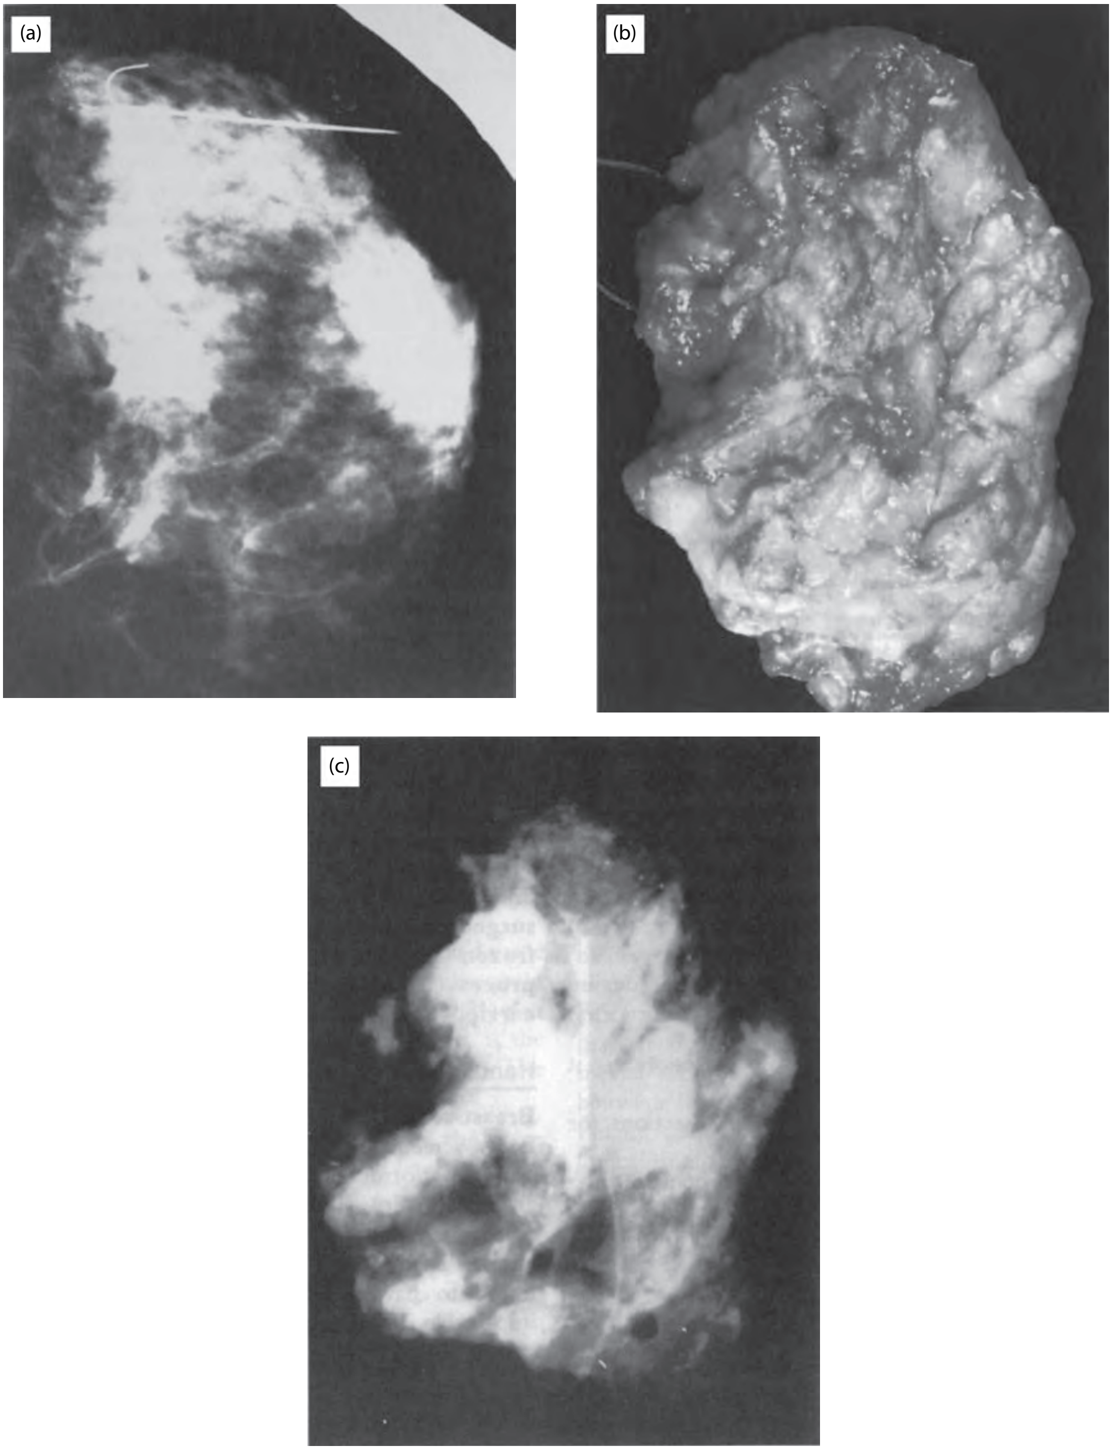

Figure 1.29 (a) Localizing mammogram with a Mammalock needle; (b) excisional biopsy of the lesion; (c) radiograph of the same specimen.

- Small cubes (2.0 mm^3) are fixed in glutaraldehyde for electron microscopy.
- A piece is snap frozen (−70°C) for enzyme and immunohistochemistry. The latter is important for the identification of T- and β-cells using specific monoclonal antibodies.
- A small piece is kept in the refrigerator at 4°C for microbiological examination should this be desirable: the infective nature of the lesion may not have been appreciated at the time of the biopsy. In this situation, culture of the retained fresh lymph node may furnish valuable confirmatory evidence for the establishment of a definite diagnosis.

Small intestinal biopsy

The specimen is removed from the capsule and dabs made onto glass slides, which are then stained with Giemsa or toluidine blue in the search for *Giardia lamblia*. The specimen is then placed in a Petri dish containing isotonic saline and examined under the dissecting microscope to assess the villous architecture. The orientation of these small specimens before embedding is important for accurate histological interpretation. If enzyme histochemistry is desired a portion is kept deep frozen.

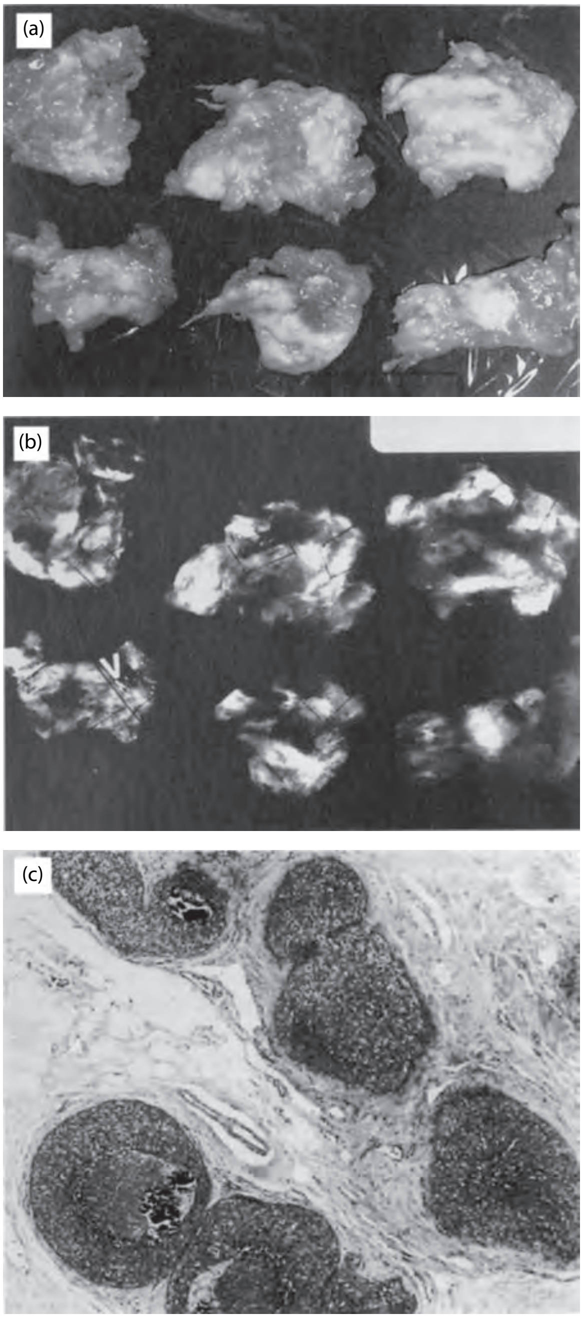

Figure 1.30 (a) Slices of the specimen; (b) radiograph of the specimen with microcalcification (arrow) in one of the slices; (c) histology of the lesion from this slice (ductal carcinoma *in situ*).

Skin biopsies

Most skin biopsies are fixed in formalin as the purpose of the biopsy is usually to exclude malignancy or confirm the exact diagnosis of benign lesions. However, when certain skin disorders are suspected, e.g. chronic autoimmune vesiculobullous disorders, all forms of lupus erythematosus, leucocytoclastic vasculitis, etc., the skin biopsies are sent fresh. These are processed in a special manner. The skin ellipse is divided longitudinally and one half is frozen for direct immunofluorescent examination to detect IgA, IgG, IgM and C3. The other half is fixed in formalin for routine paraffin blocks and H&E staining.

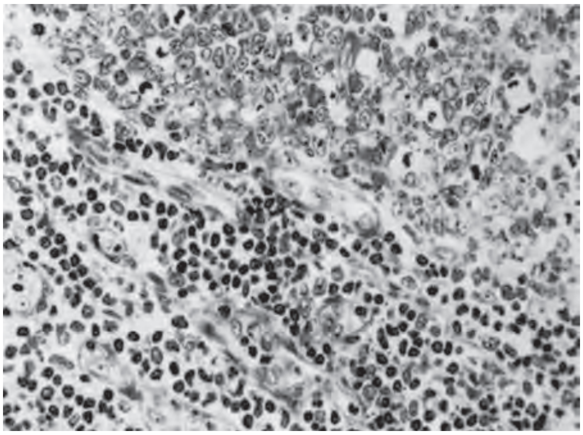

Figure 1.31 Semithin section showing greater cellular detail of the lymph node.

Muscle biopsies

The specimen should be received fresh so that special procedures can be carried out and the correct orientation obtained. The specimen is divided into three portions. Small blocks are fixed in glutaraldehyde for electron microscopy. A representative cross-section is snap frozen for diagnostic enzyme histochemical studies. These include staining with Gomori trichrome, periodic acid–Schiff with and without diastase, ATPase at various pH values, NADH diaphorase, non-specific esterase and SR19. A myophosphorylase is performed if glycogen deficiency is suspected. The remainder is left to relax on a piece of cardboard for 10 minutes before being cut in longitudinal and transverse blocks for fixation in formalin, paraffin embedding and routine H&E staining.

Enzyme histochemistry

As enzyme activity is partially or totally lost when tissue is fixed and processed in paraffin blocks, enzyme histochemistry is usually performed on fresh-frozen material. These techniques are not employed routinely but are indicated in certain specific circumstances, the most important of which are:

- myopathies: in which a specimen of skeletal muscle is stained for the following enzymes involved in normal muscle metabolism and contraction: ATPase (which differentiates type I from type II fibres; Figure 1.32), phosphorylase, cytochrome oxidase, phosphofructokinase and aldolase
- malabsorption: for the diagnosis of alactasia, a jejunal biopsy is examined for lactase and sucrase deficiency, whereas in suspected gluten enteropathy the jejunal biopsy may be stained for acid and alkaline phosphatase
- diagnosis of Hirschsprung disease: rectal biopsy is stained by the acetylcholinesterase method for the identification of nerves and ganglia
- detection of acid phosphatase in metastatic prostatic cancer
- detection of alkaline phosphatase in vascular endothelial tumours.

Immunohistochemistry

This is a technique by which specific antibodies are utilized to detect cellular or tissue constituents. Direct techniques involve the application of the specific antibody to the tissue.

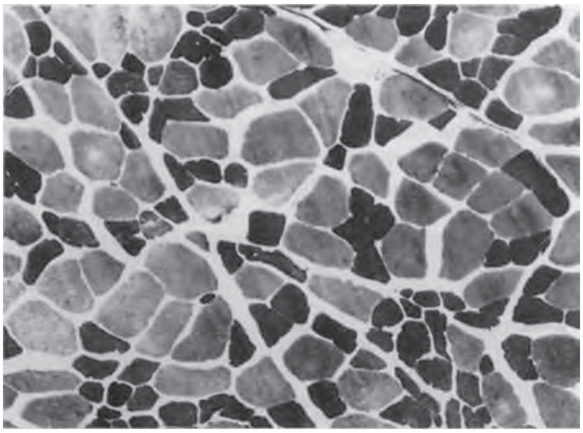

Figure 1.32 Muscle biopsy stained with ATPase showing type I and type II fibres.

As the antibody is labelled (by conjugation with a marker), the presence and site of the antigen–antibody reaction can be determined (Figure 1.33). These direct methods are, however, insensitive. They have been largely superseded by indirect (sandwich) immunohistochemical techniques that are much cleaner and more sensitive. The indirect method employs two antibodies. The primary antibody (for the detection of the desired antigen) is unlabelled and is applied to the tissue. The second tracer antibody raised in a different animal species against the primary antibody is labelled. When applied to the section it will bind to the primary antibody and the resulting complex (tracer antibody + primary antibody + antigen) is detected by the marker on the tracer antibody. The most sensitive indirect method is the avidin–biotin complex technique, in which use is made of the fact that avidin (derived from egg white) binds with high affinity four molecules of biotin (a water-soluble vitamin). The labelled biotin is conjugated to the tracer antibody (biotinylated). The first stage consists of the application of the mouse primary monoclonal antibody to the tissue for binding to the target antigen. In the second stage, the labelled biotinylated anti-mouse tracer antibody is added. This binds to the primary antibody. Finally, the addition of avidin-labelled biotin complex results in the formation of the avidin–biotin complex binding the entire conglomerate by strong molecular bridging (Figure 1.33b). This technique has been modified with the substitution of avidin with streptavidin (protein component of *Streptomyces avidinii*), which is less prone to non-specific attachment to tissue lectins.

The most common markers or labels used as conjugates with the tracer antibodies are enzymes (horseradish peroxidase, calf intestinal phosphatase, glucose oxidase), since these can be readily identified by specific colour reactions with chromogenic substrates. Other markers include colloidal metals (gold, silver, silver-enhanced gold, ferritin), radioisotopes and fluorescent labels. Radiolabels are used for quantitative immunocytochemistry and autoradiography.

The most important significant advance to contribute to the widespread routine use of immunohistochemistry was the development of the hybridoma technique for the production of monoclonal antibodies. It consists of the fusion of a normal plasma cell or transformed B-lymphocyte with a neoplastic myeloma cell. The resulting hybridoma cells are immortal and, during in vitro cell culture, can produce large quantities of a variety of antibodies when exposed to antigen. By careful subculture the clone producing the desired antibody that is specific to the antigen in question and which does not react with any other molecules is isolated. The resulting pure antibody is referred to as monoclonal (derived from one clone of cells) to distinguish it from polyclonal antibody, i.e. by several clones of plasma cells, as happens when a host animal is immunized with a purified specific antigen.

In general, the fixation of tissue does not destroy the antigens of interest to diagnostic histopathology and thus immunohistochemistry can be used on fixed tissues. There are, however, some exceptions. The important ones include lymphoid cell-surface antigens, cell membrane or nuclear receptors, hormones and neuropeptides. These are best detected on freeze-dried specimens or frozen sections.

In practice, immunohistochemistry is important in the following situations:

- Typing of lymphoid tumours with the use of antibodies that recognize specific surface antigens on leucocytes. These are referred to by the CD system and are used to classify lymphomas into β-cell origin (CD45R), T-cell origin (CD3), Hodgkin's (CD30, CD15) and histiocytic lymphomas (CD68).
- Identification of specific tumours: (1) germ cell tumours by placental alkaline phosphatase (seminomas, dysgerminoma), α-fetoprotein (non-seminomatous germ cell tumours, embryonal carcinoma), human chorionic gonadotrophin (HCG) (malignant teratoma trophoblastic), human placental lactogen (HCG-positive germ cell tumours); (2) carcinoid tumours by Singh (argentaffin) and Grimelius (argyrophil) (Figure 1.34); (3) prostatic tumours by prostate specific antigen (Figure 1.35), prostatic acid phosphatase; (4) melanoma by S100, HMB45 and vimentin; (5) thyroid tumours by thyroglobulin for thyroid epithelial lesions and calcitonin for medullary carcinoma; (6) vascular tumours by endothelial markers – factor VIII (CD34); and (7) early lymph node metastatic deposits (Figure 1.36).
- Soft-tissue tumours: in these tumours, immunohistochemistry is used to identify specific intermediate filaments such as vimentin, actin and desmin. The last is found in skeletal and smooth muscle cells (normal and neoplastic). Actin identifies myoepithelial cell origin.
- Anaplastic tumours: some tumours are so anaplastic that ordinary histological examination cannot even identify the tissue of origin of the tumour: epithelial, soft tissue or lymphoma. This problem can be resolved by immunohistochemical staining with a panel of monoclonal antibodies. The first step in the solution to this problem is the differentiation of the tissue of origin: epithelial, lymphoid or mesenchymal. Epithelial origin is identified by a panel of antibodies to cytokeratins, epithelial membrane antigen and carcinoembryonic antigen, lymphomatous origin by leucocyte common antigen, mesenchymal origin by vimentin and desmin (Table 1.3).

Table 1.3 Immunohistochemical characterization of anaplastic tumours

Antibody against	Nature of tumour
Cytokeratins	Epithelial
Epithelial membrane antigen	Epithelial
Leucocyte common antigen	Lymphoid
Vimentin	Mesenchymal, lymphoid
Desmin	Muscle
Actin	Myoepithelial
Neuron-specific enolase	Neuroendocrine, neuronal
S100	Melanocyte, nerve sheath
Factor VIII	Endothelial
CD34 (QB end)	Endothelial

Immunofluorescent techniques

Fluorochromes (fluorescein isothiocyanate isomer I, tetramethyl rhodamine isothiocyanate isomer R) are used as labels for the tracer antibody. A fluorochrome absorbs radiation in the ultraviolet or visible light range. As it is bound irreversibly to the antibody, the site of the antigen–antibody complex is visible by fluorescence even at the subcellular level, e.g. mitochondria, microsomes and muscle fibres. This technique is often used in flow cytometry (see below).

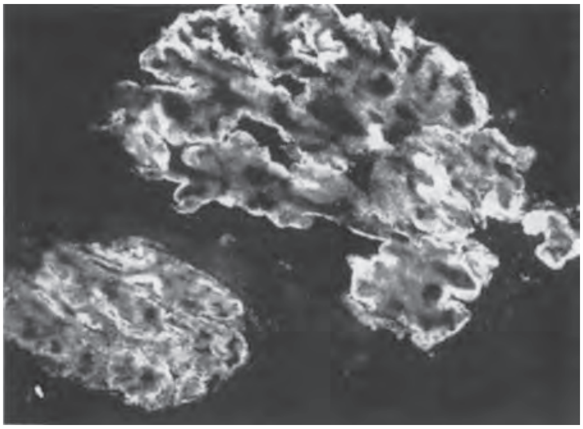

Figure 1.37 Renal biopsy: fluorescent staining of a frozen section specimen showing positive immunoglobulin G in membranoproliferative glomerulonephritis type I.

The main routine indications for immunofluorescent staining are skin and renal biopsies. In the former, they serve to outline the patterns of immunoglobulin distribution in systemic lupus erythematosus, bullous disorders and the vasculitides. In renal biopsies immunofluorescent techniques are used to localize immunoglobulins, complement and fibrin within the glomerular basement membrane, mesangium and vessel walls. Various renal disorders exhibit different specific distribution of these substances (Figure 1.37).

Electron microscopy

Electron microscopy uses an electron beam produced by an electron gun. There are two types of instrument: transmission and scanning electron microscopes, although modern versions of the former have a scanning capability. Special fixatives (e.g. osmium tetroxide, glutaraldehyde), embedding media (e.g. epoxy resin) and stains (e.g. lead citrate, uranyl acetate) are used for electron microscopy.

Transmission electron microscopy

The principle is similar to that of light microscopy. However, instead of visible light a high-velocity homogeneous beam of electrons is focused on the specimen that is thin enough to transmit at least 50% of the incident electrons. The transmitted beam then enters the imaging system composed of a series of lenses, which together produce the final, highly magnified image of the specimen (Figure 1.38). Modern instruments can achieve a resolution of 0.14 nm.

Scanning electron microscopy

When an electron beam hits a specimen, some electrons are transmitted or back scattered, whereas others interact with the atoms of the specimen to produce secondary electrons (low energy), X-rays and visible light (cathode luminescence). The secondary electrons are used to form three-dimensional images of the surface architecture of the specimen when the instrument is in the emissive mode (Figure 1.39). In the X-ray mode, scanning electron microscopy (SEM) can be used to provide a chemical analysis of the specimen.

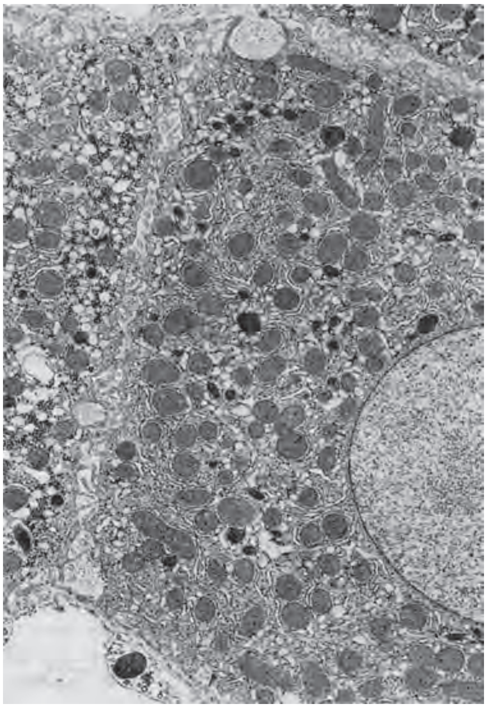

Figure 1.38 Transmission electron microscopy: liver hepatocyte.

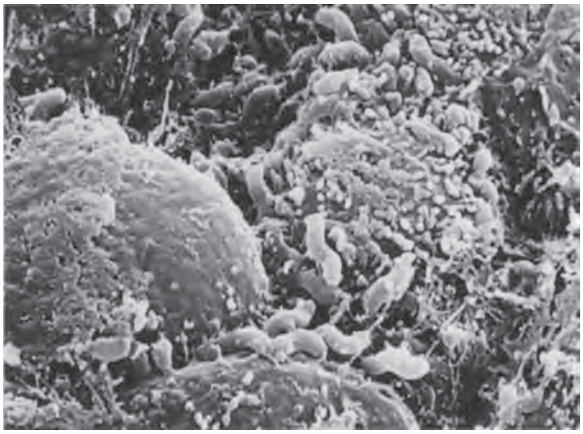

Figure 1.39 Scanning electron microscopy: *Helicobacter pylori* in gastric mucosa.

Diagnostic use of electron microscopy

In routine practice, electron microscopy is used for the following procedures:

- Interpretation of renal biopsy material: for the identification of immune complex deposits in basement membranes and mesangium (Figure 1.40).
- Tumour diagnosis: electron microscopy is used to differentiate an anaplastic carcinoma from a lymphoma, in the identification of neurosecretory granules in APUD (amine precursor uptake decarboxylase) tumours (e.g. carcinoids, medullary carcinoma of thyroid), and identification of melanosomes in suspected melanomas and in the differentiation of spindle cell tumours and lymphomas. Even with histochemistry, spindle cell tumours can be difficult to interpret. In these tumours, electron microscopy can help to differentiate epithelial (spindle cell carcinoma) from smooth muscle or fibroblastic tumours. Although electron microscopy can be used to identify the cell origin of lymphomas, this is better achieved nowadays with immunohistochemistry.
- Diagnosis of inborn errors of metabolism.
- Diagnosis of viral and other infections.
- Skin disorders: electron microscopy is useful in the diagnosis of viral disorders, skin infiltration by T-cell lymphomas, classification of epidermolysis bullosa and histiocytosis X, etc.
- Identification of amyloid.

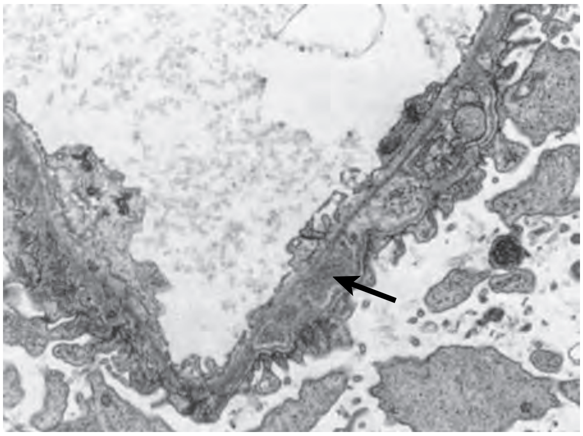

Figure 1.40 Renal biopsy: deposits in the basement membrane (arrow) in membranous glomerulonephritis.

Quantitative techniques

Histometry and stereology

The techniques of histometry provide quantitative measurements of histological preparations such as volume proportions, surface area, particle/tissue component numbers and particle dimensions. The techniques involve the use of purpose-designed glass covers, which incorporate parallel lines (straight or sinusoidal) or spatially related dots (e.g. outlining equilateral triangles) on the mounted specimens. The number of particles, cells, etc., under study that are crossed by the lines or superimposed by the dots is counted (point counting). Histometric techniques have a number of applications:

- measurement of certain histological changes: cellularity, staining intensity and grading of tumours
- examination of three-dimensional features from the two-dimensional planes using geometrical procedures (stereology), e.g. number of cells per volume, surface area per volume
- valid comparisons of histological studies from different centres because the results can be standardized.

Flow cytometry

This technology is in established usage for the following:

- rapid measurement of the biological properties of cells or subcellular organelles
- physical separation of desired subpopulations of cells based on these measured properties
- objective measurements of cellular features, including tumour cell DNA analysis (e.g. ploidy)
- cell cycle analysis.

Flow cytometry is applicable to blood, bone marrow, malignant effusions, lymphoid tissues and cell suspensions from solid tumours, although the last are more difficult to prepare and require extensive mechanical or enzymic disaggregation. The flow cytometric work published during the 1990s has led to a better understanding of the behaviour and classification of many tumours. The main application of flow cytometry has been in the study of solid tumours and cellular immune response to tumours and organ allografts. Flow cytometric examination of tumours can support the diagnosis when morphological examination is equivocal and has provided useful data in the study of borderline lesions. In addition, the ploidy status of a tumour can provide useful prognostic information, which is independent of stage and grade. It has been used to monitor responses to chemotherapy and to evaluate tumour recurrence after successful treatment.

The principle of flow cytometry entails the passage of a single column of cells in suspension through a transparent chamber. The cell column is irradiated by a beam of laser light that is scattered at various angles depending on the characteristics of the cells and their inclusions. The scattered light is detected and converted to electronic signals, which are digitized and stored by an online computer that is able to generate the required information in histogram form, e.g. cell size, viability and cell granules. Specific stains are used according to the intended investigation. For tumour ploidy and proliferative activity a DNA fluorochrome (propidium iodide) is used to stain nuclear suspensions obtained from the tumour. The flow cytometric profile of normal cells consists of a predominant peak in the diploid (2N) region and a much smaller peak in the tetraploid (4N) region. The former corresponds to cells in the G0–G1 phase (resting) and the latter to the G2–M phase (post-DNA synthesis/mitosis) of the cell cycle. Tumour cells exhibit additional (abnormal) aneuploid peaks with nuclei containing abnormal amounts of DNA relative to the diploid state. The degree of aneuploidy is defined by the DNA index, which is the ratio of the DNA content of the G0–G1 aneuploid peak to the DNA content of the G0–G1 diploid peak. For most tumours, this is greater than 1.0 (hyperdiploid) and, much less commonly, lower than 1.0 (hypodiploid).

Flow cytometry is also used to provide data on the cell cycle kinetics of tumours. With the aid of specific computer programs and specialized techniques (bromodeoxyuridine uptake, Ki-67 monoclonal antibody), the relative proportions of cells in the G0–G1, S1 and G2–M phases can be calculated. In general, DNA aneuploidy and elevated proportions of cells in the S phase (synthesizing DNA) indicate aggressive tumours with a poor prognosis.

Autoradiography

In autoradiography a radioactive label (β-emitting isotope) such as tritium (^{3}H) or ^{125}I is introduced into the tissue either by injecting an animal or following *in vitro* incubation of tissue or cells. The labelled tissue is then opposed to a special water-soaked film (Kodak AR 10 stripping film) or dipped in special photographic emulsions (Eastman-Kodak, Ilford, UK). The autoradiographic process results from the activation of the emulsion by the β-radiation from the radioisotope as it decays. The resulting image reproduces in great detail the distribution of the radioactive label within the section.

Autoradiography is rarely used for routine purposes but is an extremely useful tool in biological research, including studies involving *in situ* hybridization for the detection of DNA and RNA sequences with radiolabelled probes.

Hybridization techniques

In the production of cellular polypeptides, the genetic instructions contained in the double-stranded DNA genome are copied on to the single-stranded messenger RNA (mRNA) by a process known as transcription, with the DNA acting as the template. The message encoded in the mRNA is then used in the process of translation to form the specific polypeptides. The detection of abnormal DNA or mRNA can be achieved in the laboratory in two ways. The first consists of immobilization by heating of preparations of the DNA or RNA on inert supporting membranes (nitrocellulose or nylon), followed by the addition of specific labelled (radioactive or chromogenic) nucleic acid probes (produced by recombinant biotechnology),which then hybridize with the specific sequences. In the case of DNA, denaturation by alkali is essential to convert the molecule into a single strand prior to the application of the specific probe. Examples of filter hybridization (or blotting techniques) are dot–blot hybridization for measuring specific amounts of DNA or RNA extracted from tissues, Southern blotting for the detection of DNA fragments produced by digestion using special enzymes called restriction endonucleases, northern blotting for the determination of the molecular size of specific mRNAs and western blotting for the detection and sizing of specific polypeptides.

The second technique involves the demonstration of the abnormal DNA and RNA in the tissues (formalin fixed or fresh) and is known as *in situ* hybridization. The process is essentially similar to that involved in the blotting techniques. The cellular DNA is first denatured by heat or alkali, specific labelled nucleic acid probes are applied in the presence of formamide and 1.2 M NaCl, and the specimen is then incubated for several hours. Non-specific staining is minimized by using the smallest amount of labelled probe possible and an excess of unlabelled non-competing DNA or RNA to block non-specific binding sites.

Although *in situ* hybridization is likely to play an increasing role in histopathology in the future, at present its use is restricted to research institutions and major centres. Currently, it is employed in the detection of viral colonization (e.g. cytomegalovirus, human papillomavirus, Epstein–Barr virus), examination of genomic material in hereditary disorders and clonal derivation of lymphomas.

CHAPTER 2

Surgical craft approaches and technologies

SIR ALFRED CUSCHIERI

Introduction

Surgeons require (1) knowledge of the disease processes that they manage; (2) cognitive skills that underline clinical judgement and decision-making; and (3) the necessary level of psychomotor skills to ensure technical operative competence – the ability to perform operations consistently well hence ensuring safety of the patient; therefore, surgery is one of the *craft specialties.* All of these components of surgical practice are important, but the level of technical competence distinguishes the master surgeon from the average. In psychomotor research, ability is defined as 'the adaptive capacity, trait, attribute or aptitude that an individual brings to a given task', whereas skill is the result of a specific combination of abilities reinforced by practice and training. Ability is thus innate and determines the ultimate level of skill that an individual will attain with practice and experience. Performance relates to the overall efficiency with which a complex activity such as a surgical operation is executed. Competence is reached when an individual can perform a task safely, to an acceptable standard and within an acceptable time frame, i.e. the individual can perform the operation safely and with good patient outcome, but is still acquiring experience in executing the procedure and has to use what the ergonomic psychologist calls 'control active mode' throughout. Proficiency indicates that competence is consistent and has reached the 'expert level' as a result of experience and reinforcement by a sustained caseload. This is the level that every surgical trainee must achieve as an independent consultant. In achieving proficiency, the surgical trainee progresses though a proficiency-gain curve that is as specific to an operation as it is to the individual trainee. Proficiency gain requires supervised training by a tutor assisting the trainee and reinforcement, i.e. perform the same operation (caseload effect) until the proficiency plateau (Figure 2.1) is reached, when surgeons attain the semiautonomic operating mode, i.e. they can do the operation without having to think of the various steps of the procedure. Unfortunately, the *proficiency-gain curve* is often erroneously called the *learning curve*, but the two are not equivalent. Learning refers to acquisition of knowledge of the indications for the operation, the component tasks and steps of the procedure, the instruments and technologies

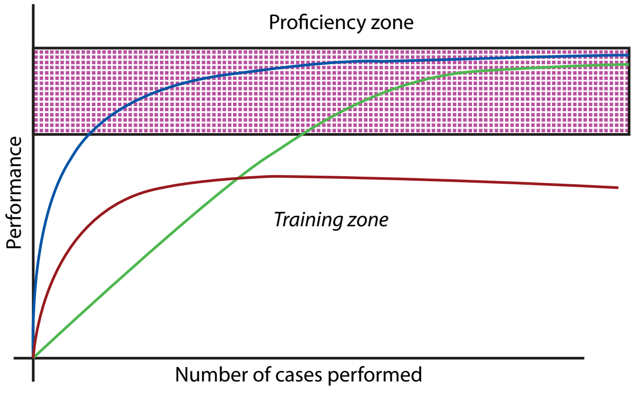

Figure 2.1 Proficiency-gain curve. The proficiency zone refers to the proficiency plateau that the surgical profession and society expects from fully trained surgeons certified and credentialed or licensed to operate on patients. For most trainees (the green line), the proficiency plateau is reached after doing the operation under supervision *x* number of times (reinforcement/case load effect), with *x* varying with the individual trainee (some need more than average, others less) and the operation (minor, medium, advanced, specialist). The blue line refers to individuals who are innately very gifted with the necessary psychomotor skills, such that they reach the proficiency plateau much quicker, requiring less cases. The red line denotes individuals who, despite having the required cognitive skills, lack the necessary level of innate psychomotor ability to be able to reach the proficiency plateau. It is the job of the programme director to identify these trainees at an early stage and advise on redirection of their medical careers.

required to do the operation, etc., but gives no indication that the individual can actually do the operation.

Until recently, operative training was based exclusively on the apprenticeship system. This entails graded exposure to operative work depending on progress as assessed by the consultant. The trainee graduated from second to first assistant, to performing minor operations under supervision by more senior surgeons, followed by exposure to major surgery initially as first assistant, then as principal surgeon under supervision until competence to perform certain operations unsupervised is reached. Competence is, of course, specialty and procedure related. Increasingly, the apprenticeship system is being supplemented by training of component operative generic skills, e.g. suturing and anastomosis, in purpose-designed skills laboratories or units. This has assumed greater importance since the period of surgical training was reduced.

Categories of operation

Operations can be classified by various criteria:

- total operative insult to the patient
- risk of infection by the procedure
- urgency of treatment
- lack of progress of acute disease
- remedial
- ablative or functional
- prophylactic
- validated.

Total operative insult

An operation, however expeditiously performed, inflicts injury to the patient and can really be defined as a controlled traumatic insult on a patient with a therapeutic intent. The total operative trauma has two components: (1) the trauma of the exposure needed to reach the operative site and (2) the trauma of the procedure itself (procedural trauma). There is no correlation between the access trauma and the procedure trauma. Indeed, with some operations, the access trauma accounts for the major part of the total operative insult, e.g. vagotomy or cardiomyotomy. The ratio of access trauma to procedure trauma of specific operations determines the benefit obtained by using the laparoscopic approach instead of open access by laparotomy. Benefit is likely to be significant if this ratio is high.

The extent of the total operative insult is used to classify operations into minor, medium and major, and it determines the rate of recovery of the patient from the intervention. The surgical trauma is responsible for the catabolic response and, together with general anaesthesia, for the non-specific immunosuppression. Although there is a relation between magnitude of the operation and the perioperative risks, it is important to stress that other factors are involved, chief among which is the preoperative state of the patient and overall quality of perioperative care.

Major operations require intensive or high-dependency care for this and other reasons, including cardiovascular and respiratory care and support. Patients undergoing medium operations require intensive or high-dependency postoperative care only if their preoperative condition is compromised by comorbid disease. Recovery from moderate operations includes a period of high-dependency care, followed by a stay in a surgical ward, discharge and convalescence before return to full activity or work. Convalescence is referred to in North America as the period of short-term disability (PSD). There is a wide variation in the PSD following major operations, as many factors operate in the individual case: personality type, social class, motivation, general health and performance status before the operation, type of healthcare provision (private or national), employment, etc.

Minor operations pose no immediate risk but nonetheless can be attended by complications. As the overall risk is minor, most of these patients are treated in day-case or ambulatory care surgical units.

Risk of infection

The majority of infections complicating surgical procedures are endogenous from the patient's own resident microflora. With good modern theatre practice, the risk of airborne infection is low and can be ignored except in prosthetic implant surgery and in the immune-compromised patient. The use of microenvironment modules and biological isolators is an established practice in joint replacement surgery and in patients at risk from opportunistic infections.

It is customary to classify surgical procedures into three categories depending on their infectivity risk:

1. *Clean operations*: do not involve bowel and are conducted in the absence of sepsis.
2. *Potentially infected (clean contaminated) operations*: include all elective operations on hollow viscera, which usually (low small bowel, colon), or on occasions, harbour pathogenic organisms, e.g. the biliary tract and upper gastrointestinal (GI) tract.
3. *Infected*: operations carried out for or in the presence of sepsis.

Ideally, clean operations should carry a negligible infection rate and any infection occurring in this category of operation indicates failure of the system and could jeopardize the long-term outcome, e.g. recurrence of hernia repair. The postoperative infection rate in the clean contaminated group is due largely to endogenous infection and can be substantially minimized by good aseptic technique, appropriate antibiotic prophylaxis and careful surgery designed to avoid spillage of the intraluminal contents with contamination of the peritoneal cavity and wound. The surgical principles governing the management of infected cases include treatment of the underlying pathology, efficient peritoneal toilet that entails complete evacuation of pus and culture of infected material. In addition, there is clear evidence for the value of two procedures in the management of severe intra-abdominal sepsis:

- peritoneal lavage with isotonic saline solution to which antibiotics may be added (tetracycline, cephalosporins)
- delayed closure of the abdominal wall: this usually refers to delayed closure of the skin and subcutaneous tissue layers on the premise that wound infection is likely; the musculoaponeurotic layer is closed with 1/0 monofilament absorbable material such as polydioxanone (PDS), and the wound is then packed with gauze soaked in proflavine

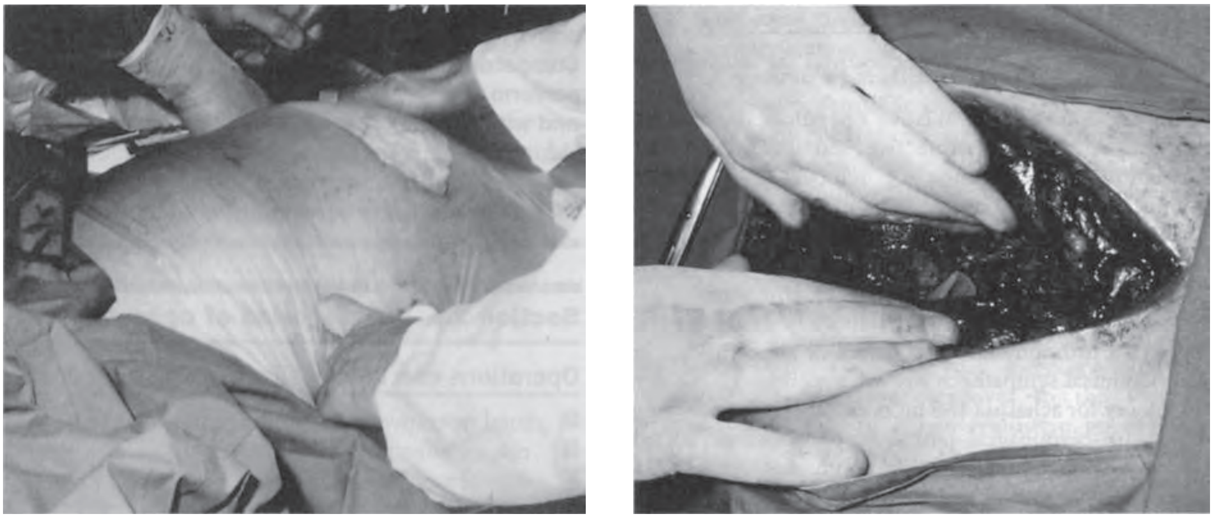

Figure 2.2 (a) Non-closure of the abdominal wall in severe sepsis (anterior coeliotomy, marsupialization). The patient had pancreatic necrosis with peripancreatic abscess formation. After resection of the pancreatic sequestrum, evacuation of the abscess and saline lavage, the space between the transverse colon and the stomach extending between the pancreatic bed and the parieties is packed with proflavine emulsion gauze. Evisceration is prevented by the application of an Opsite dressing. (b) Renewal of the pack and toilet of the cavity is performed every 24–48 hours under intravenous sedation in the operating theatre until sepsis is eliminated and healing is well under way.

The skin is closed 4–7 days later once granulation tissue has formed. If gross sepsis is encountered and recurrent intra-abdominal sepsis or abscess formation is considered likely, the entire laparotomy wound is left unsutured and the infected region of the peritoneal cavity and the wound are packed. Evisceration is prevented either by application of an Opsite dressing (Figure 2.2a) or by a prosthetic mesh (Prolene or polyester) fitted with a zip (or the two halves are sutured). The edge of each half is sutured to the edges of the skin wound. Irrespective of the method used, the peritoneal cavity is opened under sedation and the packing renewed at intervals of 1–2 days (Figure 2.2b), when the wound and the affected region are inspected and any necessary toilet and debridement carried out. In these severely septic patients, the antibiotic regimen must be based on the results of the bacteriological culture and sensitivity tests, and advice from the hospital microbiologist sought. Usually, the infection is a mixed one with both Gram-negative aerobes and anaerobes. Extra precautions are instituted in the operating theatre during and immediately after completion of infected cases to prevent the spread of infection. The theatre is thoroughly cleaned and the floor mopped with antiseptic solution before its further use.

Clean operations should precede potentially infected procedures in elective surgical lists. Infected cases are performed last, or preferably in a separate theatre reserved for these cases.

Urgency of treatment

Patients may require surgical treatment for the following reasons:

- They have chronic symptoms attributable to a diagnosed surgical disorder but have no acute manifestations or immediate life-threatening complications. In this instance, the operation is conducted on an elective basis. This category (elective operations) carries the lowest risk as there is time for detailed assessment and the patient is fully prepared physically, mentally and prophylactically for the planned operation. The underlying condition may, of course, be serious, e.g. cancer. In this situation, careful treatment planning on a multidisciplinary basis is essential in the individual case. In some instances chemotherapy or radiation therapy or both (chemoirradiation) is undertaken before the operation itself.
- Patients develop a life-threatening condition from trauma or because of an acute complication of an underlying benign or malignant disorder. These patients require emergency operation after adequate resuscitation (if needed). For all non-cardiac operations, the single most important risk factor is an emergency intervention. Thus, all emergency operations carry a definite risk of death but this varies with the nature, extent and severity of the underlying pathology, the cardiorespiratory reserve and age of the patient. Some surgical disorders are treated most commonly as an emergency because the involved organ does not usually present with chronic symptoms, e.g. acute appendicitis or acute Meckel's diverticulitis.

Emergency laparoscopy is nowadays increasingly used primarily to establish the diagnosis of acute right lower abdominal pain, but also to deal with conditions such as acute appendicitis and perforated ulcer. Overall, the benefit from interventional emergency laparoscopy for common general surgical emergencies (appendectomy, perforations, diverticulitis) can be substantial. Thus, in patients with a perforated duodenal ulcer, if the laparoscopy confirms that the perforation is well sealed, all that is needed is peritoneal lavage of the right paracolic gutter and pelvis and, perhaps, the insertion of a drain. Otherwise, the perforation is closed by suture or omental flap (depending on size) followed by lavage. It has to be stressed that the recovery of a patient from localized peritonitis caused, for example, by appendicitis/perforations is determined by the severity of the peritoneal infection and is not materially influenced by whether the appendix is removed through a grid-iron incision or by the laparoscopic approach. The argument that laparoscopic appendectomy is not justified because it does not reduce the hospital stay is illogical, especially as it significantly reduces the wound infection rate. Once the diagnosis of acute appendicitis is established by laparoscopy, the choice between open and laparoscopic appendectomy depends on the surgeon's preference and expertise. There have been 12 randomized trials comparing open with laparoscopic appendectomy. All have shown equivalent safety. The benefits for the laparoscopic approach registered by the majority of these studies are improved diagnosis of other causes of peritonitis (appendix inflamed secondarily as a result of disease elsewhere, e.g. perforated diverticulitis), reduced surgical site (wound) infection and earlier return to school and games in children. Laparoscopic interventions for acute small bowel obstruction are still only practised in a few centres, and there is no consensus on its benefits and risks. However, there is considerable reported experience on the benefits of laparoscopic treatment of the acute complication of colonic diverticular disease. Colonic obstruction by carcinoma is nowadays managed by stenting prior to laparoscopic or open resection.

Lack of clinical improvement in acute disease

Some patients have signs and symptoms that suggest an impending major complication. These patients are usually in hospital on conservative management or medical therapy with frequent observations and assessment of physical signs. Lack of progress with conservative management is an indication for *urgent (planned or scheduled)* intervention. In many instances, this decision is taken in consultation with the gastroenterologist and anaesthetist. A typical example is the acute exacerbation of ulcerative colitis with megacolon that does not settle with high steroid therapy.

Remedial

This term is reserved for operations on patients designed to correct:

- an iatrogenic complication
- persistent adverse symptoms that occur as a consequence of an operation that was otherwise successful in curing the patient of the disease
- deformity and restoration of the patient's body image.

By and large, these are specialized operations conducted by expert surgeons and the interest of the patients is best served by referral to tertiary referral centres. The repair of bile duct strictures following iatrogenic injury to the common bile duct during cholecystectomy is a case in point. The general surgeon should not attempt correction and is well advised to refer the patient to a hepatobiliary centre. There is good evidence that the best results in patients with postcholecystectomy bile duct strictures are obtained when the first corrective operation is conducted by a hepatobiliary surgeon experienced in dealing with this pathology (see Chapter 25).

Remedial surgery for persistent disabling symptoms is usually encountered in patients after surgery on the upper GI tract, e.g. vagotomy, gastric resections and antireflux surgery. These patients are very difficult to treat because they often have a multiplicity of symptoms, although, on careful history-taking, one is always able to determine the dominant symptom. Remedial surgery is aimed primarily at correcting this. In general, remedial surgery for adverse GI symptoms results in amelioration rather than cure, although the gain from surgery may be substantial, e.g. a patient with small stomach syndrome or severe dumping can eat, or a patient with severe intractable diarrhoea can lead a reasonable social life. The management of these patients entails careful selection, choice of the appropriate operation and expert dietetic management. Again, management in a tertiary referral centre gives the best results (see Chapter 23).

Surgery to deal with deformity is usually conducted after ablative operations for cancer, e.g. breast reconstruction after mastectomy, although primary reconstruction at the time of mastectomy is undertaken more frequently nowadays. Scar revision, usually following surgery on the face, neck and exposed extremities, is undertaken by plastic and reconstructive surgeons.

Ablative or functional

Operations can also be classified as ablative or functional. In the course of an ablative operation, the surgeon removes a block of tissue (surgical specimen). Such operations can be minor, e.g. removal of a subcutaneous swelling; moderate, e.g. cholecystectomy and partial thyroidectomy; or major, e.g. curative resections for cancer. It is axiomatic that all resected specimens must be submitted for histological examination. In cancer surgery, resections are classified as:

- *potentially curative*: assessment by surgeon at the end of the operation
- *definitely curative*: assessment after detailed histological examination: T, N and tumour-free margins
- *potentially non-curative*: after histological examination, any of serosal involvement, positive regional nodes, positive tumour margins (includes circumferential)
- *debulking*: reduction of tumour volume before either intraperitoneal chemotherapy or adjuvant chemotherapy
- *palliative*: (1) cancer is resected but there is residual disease; (2) bypass procedure for non-resectable cancer.

Obviously, for all potentially curative resections for cancer the surgeon must achieve a block resection with related regional lymph nodes up at least to level II and there must be no macroscopic evidence of residual disease (R0 resection).

In contrast to resections, functional operations are designed to correct a pathophysiological defect or abnormality, e.g. cervicodorsal sympathectomy for hyperhidrosis, cardiomyotomy for achalasia and fundoplication for pathological gastro-oesophageal reflux. As previously indicated, functional operations are best conducted through the minimal access approach as the access trauma (laparotomy or thoracotomy) constitutes the major component of the operative traumatic insult to the patient.

Prophylactic

These operations are only undertaken in patients at risk to prevent the development of serious disease, usually cancer, and thus increase life expectancy in the individual patient. Examples include prophylactic proctocolectomy in patients with familial polyposis coli and in patients with longstanding total ulcerative colitis on a surveillance programme. It is likely, with advances in molecular genetics and the identification of genes responsible for hereditary cancer, that more prophylactic operations including mastectomy will be undertaken in the future. To a large extent, bariatric surgery (surgery for morbid obesity) has a prophylactic intent as the weight loss not only improves the quality of life of the patient (immediate effect) but will reduce the risk of heart disease and disabling osteoarthritis/spondylosis, and increase the life expectancy and quality of life of these patients. As it also corrects maturity-onset diabetes, it is now referred to as bariatric and metabolic surgery (see Chapter 28).

Validated versus non-validated

Validated operations are those in established practice, the efficacy and outcome of which are known from past long-term usage or reported clinical studies/series. Non-validated operations are new procedures that have not been evaluated in terms of their efficacy and safety. The fact that an operation is carried out by the minimal access approach does not necessarily mean that it is a non-validated operation. Thus, for example, laparoscopic cholecystectomy, even when it was introduced, was a validated operation as the nature of the operation was unchanged from traditional open cholecystectomy. By contrast, laparoscopic hernia repair, when first introduced, was not a validated operation because both the anatomical approach and the nature of the repair differed from the traditional anterior inguinal canal approach. Subsequent clinical trials have established the merits and superiority of the posterior laparoscopic approach, which has largely replaced open repair of groin hernia.

It takes some time (years) to validate a new operation or interventional procedure. Heneage Ogilvie said of gastric operations that 'every gastric operation is good until it is found out'. In the ideal situation, new operations or interventions should initially be conducted in a few selected centres with strict external audit of the results. This preliminary assessment determines efficacy and safety, the documentation of which is essential before dissemination to other centres (after adequate training of staff).

There is a proficiency-gain curve for a new operation or intervention or surgical approach during which the surgeon's ability to perform the operation improves to the level of proficiency needed to obtain consistent good results with minimum morbidity. The problem is to ensure that surgeons go through this proficiency-gain curve without inflicting morbidity on the patients. This can only be achieved by supervised training, by which is meant assistance by an approved expert tutor until proficiency is reached. This approach ensures operative training with minimum morbidity and mortality.

Surgical exposure

The adequate exposure of the anatomical site of the operation is crucial to the efficient and safe execution of the procedure. Until recently, maximal exposure with a large enough incision was considered axiomatic. The advent of minimal access surgery (MAS) would, at first glance, appear to have changed this surgical principle, but in fact it has not.

The surgical exposure needed depends on the operation and the build of the patient. In practice, the options are:

- open surgical exposure
- laparoscopic exposure with positive pressure pneumoperitoneum
- laparoscopic exposure without gas insufflation – gasless (isobaric) laparoscopy
- hand-assisted laparoscopic surgery (HALS)
- thoracoscopic approach
- hand-assisted thoracic approach
- single port/incision laparoscopic surgery
- endoluminal surgery
- natural orifice surgery
- natural orifice transluminal endoscopic surgery (NOTES).

Open surgical exposure

Abdomen

Laparotomy or exposure of the peritoneal cavity is derived from the Greek *laparos,* meaning flank.

General considerations

Certain general considerations should be taken into account. In the first instance, the length of the incision depends on the thickness of the subcutaneous fat, which becomes a problem in the morbidly obese. These patients require large incisions and the subcutaneous fat should be split by distraction of the wound edges rather than cut, as this causes less bleeding from the large subcutaneous veins embedded in the fat (difficult to control by electrocoagulation). Second, females have a more commodious intraperitoneal space (including pelvis) than males who, especially when young and muscular, have tightly packed organs. The thicker musculoaponeurotic layer in males adds to the exposure problems and necessitates more strenuous retraction. In general, males have a deeper upper abdomen and, for this reason, access to the subdiaphragmatic space is more difficult. This becomes a problem in males with chronic obstructive airways disease and a barrel chest.

In addition to obesity, the type of build of the patient (asthenic, hypersthenic) is also important in the correct choice of incision. Thus, in patients with hypersthenic build and a long narrow subcostal angle, an upper transverse/oblique incision gives a very limited approach to the supracolic compartment. These patients are better served by a midline approach.

Incisions

Abdominal incisions may be longitudinal (midline, paramedian), transverse, oblique or a combination. Transverse incisions heal more successfully and are less painful than longitudinal but, to provide equal access, they need to be longer. The paramedian longitudinal approach is a poor choice incision. It used to be popular because of its trap-door design: the rectus muscle is interposed between the incisions on the anterior and posterior rectus sheath when the wound is closed. However, this had a bad result as the medial mobilization of the rectus muscle from the anterior and posterior rectus sheath inevitably devitalized sections of this muscle close to the tendinous intersections and, for this reason, resulted in partial atrophy of the muscle. If a longitudinal approach is preferred, the midline incision through the linea alba is a better proposition. The midline incision is advised when the diagnosis is not clear (exploratory laparotomy).

Both oblique and transverse abdominal incisions are muscle cutting to a greater or lesser extent but do not usually cause denervation problems, contrary to the longitudinal muscle-cutting rectus incision. The exception is the right subcostal (oblique) incision used commonly for open cholecystectomy, In which damage/division of the right subcostal nerve is almost inevitable and may cause subsequent neuralgic-type pain. The grid-iron incision (transverse or oblique) centred over McBurney's point (junction of the outer with the middle third of a line joining the anterior–superior iliac spine and umbilicus) is a muscle-splitting incision used routinely for open appendectomy. It may cause damage to the ileoinguinal nerve and thus weaken the musculoaponeurotic components of the inguinal canal, thereby predisposing to subsequent formation of an inguinal hernia on the ipsilateral side.

The bilateral subcostal incision used for wide exposure of the supracolic compartment of the abdomen is an example of a combination incision. Often, a third midline component is added between the two subcostal incisions and this combination (which may split the lower sternum) is referred to as the Mercedes incision. Other types of combination incision include the trap-door variety, in which one component is at right angles to the other. In the USA, a large curved transverse incision in the upper abdomen, which crosses the entire epigastric region, is often referred to as the 'sabre slash'.

Mini-laparotomy

The size in centimetres of a mini-laparotomy has never been defined and, to a large extent, the term is relative, i.e. the incision is smaller than the standard approach. On average, however, mini-laparotomy incisions are 7.0 cm in length. In practice, mini-laparotomy is used either as the only access for an operation, e.g. mini-cholecystectomy, or as part of laparoscopic-assisted surgery (see below).

Wound protection

In principle, wound protection is a sensible practice designed to prevent contamination by bacteria and thus wound infection and, in cancer patients, to reduce the incidence of implantation of exfoliated viable tumour cells and the subsequent development of tumour implantation deposits.

As almost all wound infections are endogenous in origin, protection of the operative wound from gross contamination is practised by some, either as plastic drapes or with antiseptic-soaked swabs (e.g. chlorhexidine). The disadvantage of plastic drapes is that their removal cannot be achieved without some contamination of the wound. To date, there has not been any firm evidence that the use of wound protectors significantly reduces the incidence of postoperative wound infection, which depends on (1) bacterial count of the wound edges at the end of the operation and (2) surgical technique (surgeon factor).

The exact incidence of tumour deposits in the wound following open surgery for cancer is not known. Current estimates are based on a large retrospective report on patients undergoing resections for colorectal cancer. This showed an incidence of 0.6% at 12 months, rising to 1% over the subsequent few years. Tumour deposits are related to the implantation of viable exfoliated tumour cells (spontaneous or induced by surgical manipulations). Lavage cytology studies have shown that GI tumours (stomach, colon) that have reached the serosa and pancreatic and ovarian cancer shed viable cancer cells spontaneously in 30–40% (in the absence of obvious peritoneal deposits). With the advent of MAS, concern arose from early reports of an increased incidence of tumour deposits in the access port wounds (port site deposits). In fact, the median reported incidence of port site deposits after laparoscopic surgery for potentially curative cancer is 1.2%, i.e. similar to open surgery; and again it appears to be surgeon related. Correct surgical technique based on oncological principles, selection of cases and wound protection during delivery of the specimen are crucial in the prevention of wound deposits.

Closure of abdominal incisions

Abdominal incisions are nowadays closed in a single layer (mass closure) in preference to layered closure, which had been popular in the past. Mass closure is quicker and gives consistently good results. Strong monofilament (1/0 gauge), as opposed to braided suture material, is preferred for closure of abdominal wounds for two reasons: (1) improved tissue slide and (2) less bacterial adherence. The monofilament material may be non-absorbable, e.g. Prolene, or biodegradable, e.g. PDS. Contrary to popular belief, nylon is biodegradable, as is silk. The use of large tension sutures to relieve tension on the suture line is favoured by some, especially when closure of the abdomen is difficult or prolonged postoperative ileus is predicted. If and when used, tension sutures should be tied loosely as otherwise they devascularize the wound.

Chest

The chest can be opened by (1) posterolateral thoracotomy, (2) prone thoracotomy – favoured in children, (3) anterolateral thoracotomy or (4) median sternotomy.

Posterolateral thoracotomy

This is the classic open access approach to the right or left chest cavity. The patient is placed on his or her side with the table split underneath the lower chest to widen the intercostal spaces. Appropriate supports for the arm, back and neck of the patient are essential. The incision is oblique and follows the line of the sixth rib. It should skirt a distance of 2.0 cm below the inferior angle of the scapula to avoid scapular adhesion after the operation. Posterolateral thoracotomy gives an excellent access but is accompanied by a high incidence of post-thoracotomy deafferentation pain. The right thoracic approach is favoured by most surgeons for subtotal oesophagectomy.

Correct positioning of the patient in a stable secure position is the responsibility of the surgeon. A double-lumen endotracheal tube (Carlen's or equivalent) is used to block and collapse the lung on the operating side (single-lung anaesthesia). In prolonged operations, this collapse is held partially responsible for some of the postoperative chest complications. Periodic reinflation for a few minutes intermittently during the course of the operation is practised by some to improve the cardiovascular condition of the patient during surgery and to reduce the risk of postoperative pulmonary collapse. Some patients are found at operation to be intolerant of single-lung anaesthesia, despite adequate lung volume estimates (spirometry) before the operation. In these cases, the surgeon has to operate with an inflated lung, using gentle compression to obtain the relevant access.

Anterolateral thoracotomy

The patient is in the supine position and the chest wall is open anteriorly on one or other side, usually along the fifth or sixth rib. A mini-anterolateral thoracotomy is used in video-assisted thoracoscopic surgery, e.g. lobar resection, pneumonectomy and Belsey mark IV procedure for reflux and hiatus hernia.

Median sternotomy

This provides access to the heart, great vessels and the trachea (central mediastinum) and to both sides of the chest. The skin incision is midline and the sternum is split by means of an electrical oscillating saw. Median sternotomy is the approach used for open cardiac surgery in combination with cardiopulmonary bypass (CPB), systemic hypothermia and cardioplegic arrest. The CPB systems use either a bubble or membrane oxygenator with roller or centrifugal pumps that provide a non-pulsatile flow. A heat exchanger is incorporated in the system for cooling and rewarming the patient. All CPB systems cause activation of the fibrinolytic and complement systems, and damage the blood cellular components. Nonetheless, CPB systems are quite safe for a period of up to 4–6 hours of use. Hypothermia (25–30°C) is used in most cases to decrease the patient's metabolic rate and tissue oxygen demands. Further selective cooling of the heart is achieved by topical cold solution within the pericardial sac and/or by infusion of cold (4°C) cardioplegia crystalloid solution into the coronary circulation.

Laparoscopic exposure

Positive-pressure pneumoperitoneum (capnoperitoneum)

In laparoscopic MAS, the standard exposure is through the creation of a positive-pressure pneumoperitoneum by an inert gas, traditionally CO_2; hence, the appropriate name should be positive-pressure capnoperitoneum. Other gases may be used, such as nitrous oxide, and this is preferred when laparoscopy is carried out for diagnostic purposes under local anaesthesia, as it appears to induce less pain.

The surgical exposure of the operative field by a positive-pressure capnoperitoneum (10–12 mmHg) is undoubtedly better than that achieved by open surgery, particularly for relatively inaccessible areas such as the subdiaphragmatic space and pelvis. Therefore, the surgical principle of maximal exposure of the relevant anatomy is not compromised. Indeed, the anatomy with the standard laparoscopes is magnified approximately two times. However, positive-pressure capnoperitoneal laparoscopic approach has some drawbacks:

- the charged couple device (CCD) camera used provides a tunnel view without any peripheral vision of the rest of the abdominal cavity
- the CO_2, which is kept at a set pressure (10–12 mmHg) by the automatic insufflator, creates convection currents that may be responsible for the spread of exfoliated tumour cells or bacteria
- the CO_2 dries and cools the patient's intra-abdominal contents unless heated and humidified by the insufflator
- the raised intra-abdominal pressure has adverse respiratory, cardiovascular, hormonal and metabolic effects.

There is evidence that a positive pressure capnoperitoneum above 12.0 mmHg reduces venous return and portal vein and splanchnic blood flow. Additionally, unless the gas is heated and humidified, the core body temperature of the patient drops significantly during long laparoscopic operations in addition to drying of the intestinal small bowel loops. Although with good anaesthesia the adverse haemodynamic changes can be tolerated by fit patients, the same cannot be said for patients with cardiorespiratory compromise. There is a clear correlation between the incidence and severity of adverse cardiovascular and respiratory complications and the level of positive pressure used for insufflation of the peritoneal cavity. Thus, the operative principle is to use the minimum pressure that gives adequate exposure. In children, this should rarely exceed 6.0 mmHg.

Gasless (isobaric) laparoscopy

Gasless laparoscopy is based on the use of technology, which elevates the anterior abdominal wall and thus creates the necessary work space. Its purpose is to abolish the adverse cardiovascular effects of the positive-pressure capnoperitoneum. The initial techniques consisted of either insertion of slings through the anterior abdominal wall around the midline and surrounding the falciform, or metal 'hooks' of varying shapes. Both are fixed to a chain that is then attached to an overlying gantry once sufficient lift is achieved (Figure 2.3). The anterior wall sling is simple and very useful. It permits conduct of a standard laparoscopic procedure (e.g. cholecystectomy, antireflux surgery) with the intra-abdominal pressure set at 4.0 mmHg. There is now good evidence from randomized studies that abdominal wall-lift devices (completely gasless or low-pressure pneumoperitoneum) substantially reduce adverse cardiovascular, hormonal and metabolic changes, accelerate recovery from anaesthesia without the problems of CO_2 narcosis and are accompanied by less postoperative pain.

However, the first generation of abdominal wall-lift devices had two major disadvantages: (1) tenting effect with reduced exposure and (2) trauma to the parietal peritoneum of the anterior abdominal wall. The space created by these lift devices is a conical space with the apex at the point of elevation by the retracting device, compared with the ovoid work space created by positive-pressure pneumoperitoneum. It is thus difficult to undertake complex operations with the gasless approach and the risk of iatrogenic injury during the dissection may be increased.

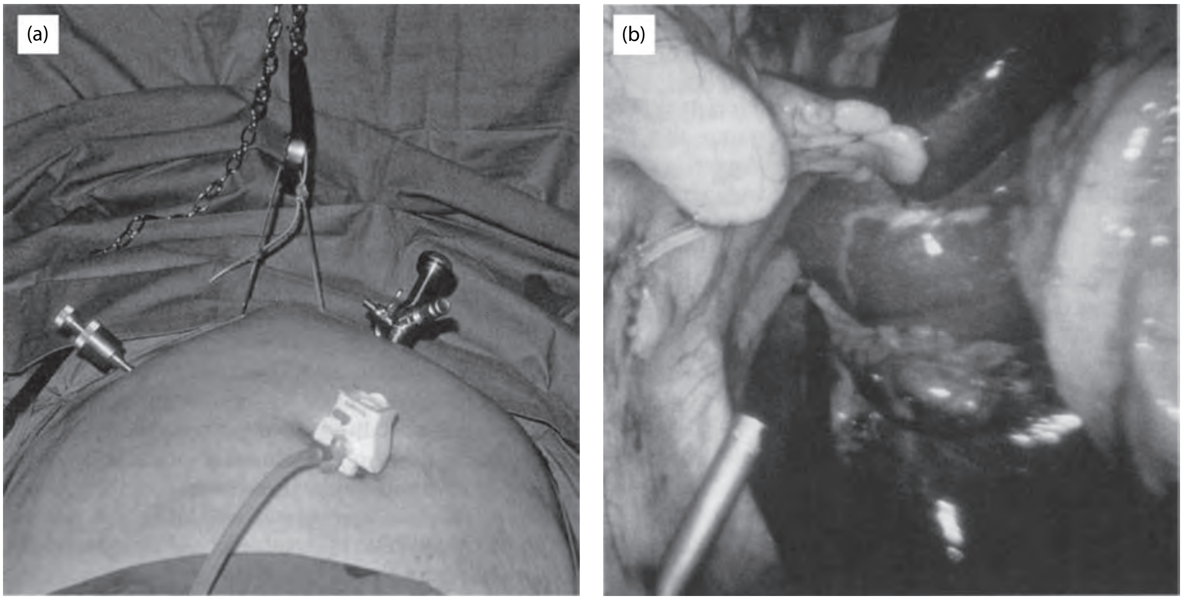

Figure 2.3 Right: surgeon operating from da Vinci console; left: robotic arms covered with sterile plastic drapes with end-effectors (instruments) introduced through parts inside the insufflated peritoneal cavity.

The second problem concerns the sustained compression/ischaemic trauma by the retractor on the parietal peritoneum of the anterior abdominal wall, especially during long procedures. This will encourage adhesion formation and, possibly, tumour implantation in operations for cancer.

The second generation of abdominal wall-lift devices have reduced but not abolished these problems by (1) providing extraperitoneal elevation and (2) minimizing the tenting effect. One example is the LaparoTensor (Figure 2.4), which is based on the insertion of two curvilinear needles in the subcutaneous plane of the anterior abdominal wall over the operative field. When inserted, the needles enclose a large circle open at one end. The butts of the needles projecting at one end beyond the skin are clamped together and to the lifting device. The shape of the needles has been designed by mathematical modelling of the abdominal wall to provide a better work space (the apex of the cone is widened), although this is still not as commodious as that provided by positive-pressure pneumoperitoneum. The gasless laparoscopic technique is seldom used in general surgery but the technique is favoured by gynaecologists for certain minor procedures such as laparoscopic myomectomy.

Extraperitoneal and retroperitoneal exposure

In this situation, there is no natural cavity, but one is created by finger and balloon distension of the loose areolar tissue surrounding an organ or anatomical region. Once the space is created, CO_2 insufflation through the optical port maintains the exposure. This approach is used for endoscopic adrenal surgery (as an alternative to the laparoscopic approach), lumbar sympathectomy, transabdominal preperitoneal groin hernia repair, pelvic node dissection for tumour staging of urological and pelvic tumours, etc. There is some evidence that the risk of CO_2 embolism is higher during retroperitoneal endoscopic than laparoscopic (intraperitoneal) surgery.

Combined exposure: laparoscopically assisted

There is no precise definition of laparoscopically assisted surgical operations. The endoscopic purist would regard an operation as laparoscopically assisted when the entire dissection is completed laparoscopically, and a mini-laparotomy is used at the end of the operation to deliver the specimen and perform the reconstruction of the gut, e.g. laparoscopic partial gastrectomy, laparoscopic right hemicolectomy and laparoscopic left colectomy or anterior resection. The ratio of the endoscopic to the external component of the operation can be varied and, in some instances, the combined approach is used to reduce the size of the abdominal incision for an open intervention. A pertinent example of this situation is anterior resection when, for whatever reason, the laparoscopic approach is contraindicated. In this situation, preliminary mobilization of the splenic flexure and adjacent transverse colon will permit an 'open' anterior resection through a transverse suprapubic (Pfannenstiel) or a lower midline incision. This combination provides 'the best of both options'.

There is no evidence that laparoscopically assisted operations are safer than the totally laparoscopic intervention in terms of the risk of iatrogenic injuries. The adoption of the combined approach, however, reduces the operating time and results in a better functional reconstruction of the GI tract. This is particularly the case after partial gastrectomy.

Hand-assisted laparoscopic surgery

There is a fine but important difference between laparoscopic-assisted and HALS. In laparoscopic-assisted surgery or GI operations, the procedure (dissection and excision) is carried out by the total laparoscopic approach. Then an appropriately sited abdominal incision (5–7 cm depending on specimen) is performed and, following insertion of a wound protector, the stomach or bowel containing the diseased segment/neoplasm

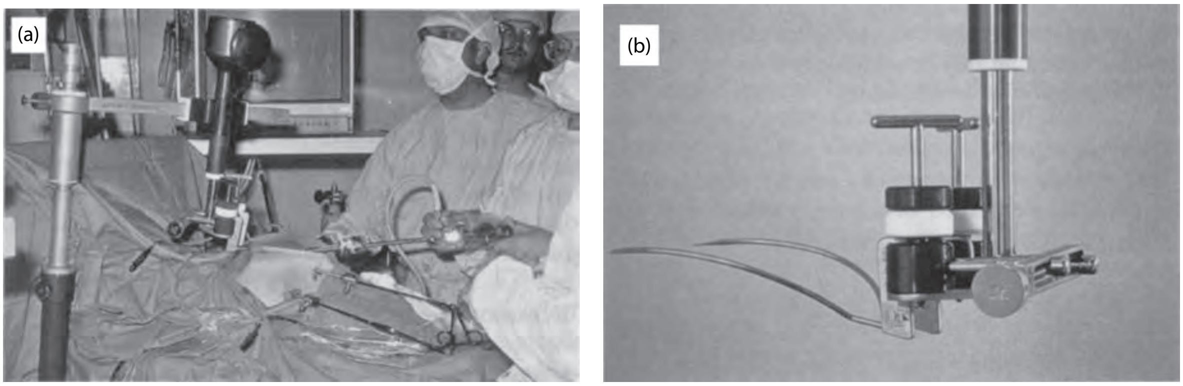

Figure 2.4 (a) LaparoTensor in use; (b) the subcutaneous needles provide a more uniform lift than intraperitoneal lift devices.

is extracted. After external resection of the lesion, continuity of the GI tract is restored by external anastomosis (suture or stapled) of the two ends. In HALS, a similar incision is placed at the start of the operation for the insertion of a hand port (various devices available) that allows the insertion of the non-dominant hand of the surgeon, or indeed, in some cases, the hand of the assistant, without loss of the positive capnoperitoneum. There is little doubt that the HALS approach facilitates the conduct of major and difficult operations for several reasons:

- restoration of the of the tactile feedback
- efficient and atraumatic hand retraction and exposure
- immediate control of haemorrhage.

There is good published evidence that the HALS approach does not reduce the benefits of MAS as, in comparative studies, the recovery is equivalent to that of the total laparoscopic approach. The HALS approach does reduce execution times for advanced operations, e.g. total R2 gastrectomy, subtotal oesophagectomy, pancreaticoduodenectomy and right hepatectomy. The HALS approach is essential for splenectomy for massive splenomegaly (see Chapter 26).

Thoracoscopic and video-assisted thoracic approach

The advantages of avoiding a large thoracotomy include accelerated recovery, especially in patients with compromised cardiorespiratory reserve, and less pain. The instruments and equipment used are similar to those used in laparoscopic surgery. There are several techniques for safe endoscopic access to the pleural cavity and the procedures can be carried out with (1) single-lung anaesthesia (endobronchial occlusion by a double-lumen tube) or (2) with bilateral pulmonary ventilation, when intrapleural CO_2 at a pressure of 6–8 mmHg is used to compress the lung. This level of positive intrathoracic pressure is well tolerated by most but not all patients.

Thoracoscopic approach

The complete thoracoscopic approach is now the standard treatment in many centres for pulmonary wedge biopsies, mediastinal node biopsy, for treating patients with spontaneous pneumothorax, for sympathetic denervation, mobilization of the intrathoracic oesophagus, for pulmonary segmentectomies and assessment/management of chest injuries. The approach can be anterior, posterolateral or posterior depending on the procedure and preference of the surgeon. The prone posterior jack-knife approach (Figure 2.5) is particularly useful for sympathetic denervation (cervicodorsal ganglionectomy and splanchnicectomy), for mediastinal node biopsy and for mobilization of the intrathoracic oesophagus. The telescope port is placed 2.5 cm below and in line with the inferior angle of the scapula with the elbows of the patient suspended along the edges of the operating table.

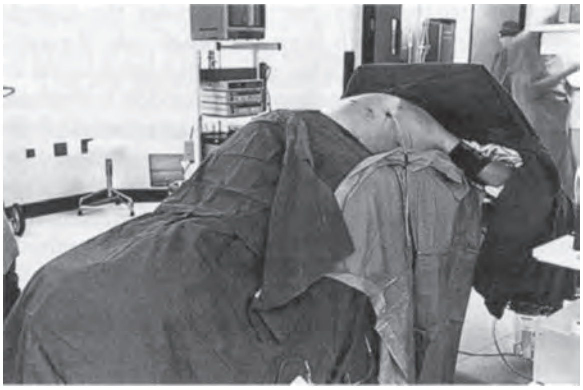

Figure 2.5 Prone posterior thoracoscopic approach. This allows access to both pleural cavities without changing the position of the patient. In addition, simple procedures can be carried out without single-lung anaesthesia.

Video-assisted thoracoscopic approach

In this instance, a 5.0 cm mini-thoracotomy (equivalent to mini-laparotomy) is made at the start of the procedure. Its exact location depends on the nature of the operation being performed. Video-assisted thoracoscopic approach is used for major interventions such as Belsey mark IV fundoplication, pulmonary lobectomies, pneumonectomy and coronary artery bypass surgery.

Endoluminal surgery

This refers to operations performed through operating flexible endoscopes or platforms and is well established in routine practice for submucosal resection of early gastric cancer using various techniques developed in Japan. Often saline or other fluid is injected submucosally to lift the mucosa containing the lesion, before it is resected.

Endoluminal surgery differs from NOTES as the integrity of the wall of the hollow organ (usually stomach, oesophagus and colon) is not intentionally breached and inadvertent perforation is a complication that needs immediate treatment; which at times can be performed endoscopically but often requires a laparoscopic or open operation. More recently dedicated systems have been introduced for the performance of endoluminal full-thickness fundoplication and the early reported results on their efficacy at achieving lasting control of gastro-oesophageal reflux have been promising but the reported experience and follow-up is too limited to enable a valid assessment on their ability to replace laparoscopic fundoplication. More recently, endoscopic myotomy 'POEM' has been shown to give equivalent results to laparoscopic cardiomyotomy for achalasia.

Natural orifice transluminal endoscopic surgery

NOTES is a novel technique utilizing the body's natural orifices to gain access to the peritoneal cavity for abdominal surgery. The goal is to perform intraperitoneal operations through a natural orifice using novel technology platforms based on modified operating flexible endoscopes. The perceived advantages include: (1) avoidance of abdominal incisions and thus painful wounds since no somatic nerves are involved and (2) the interventions can be carried out under sedation rather than general anaesthesia. The concept has generated new operating technologies by the flexible endoscopic industry, which is still evolving. The Natural Orifice Surgery Consortium for Assessment and Research was set up in the USA in 2005 as a joint initiative supported by the American Society for Gastrointestinal Endoscopy and the Society of American Gastrointestinal and Endoscopic Surgeons to oversee and guide through the development and introduction of NOTES into clinical practice. In Europe, a similar consortium was set up soon after by the European Association of Endoscopic Surgeons in association with industry for the same purpose. NOTES is undoubtedly a novel concept in human surgical intervention aimed at improved cosmesis (no visible scars) and reduction of postoperative pain; but, at the same time, it challenged some of the fundamental deeply entrenched dogmas in surgery and gastroenterology, including the important violation of asepsis as the operating system traverses a potentially infected environment before entering the peritoneal cavity, despite preparation of the hollow organ (stomach, colon, oesophagus, urinary bladder, etc.). It thus generated a series of experimental studies aimed at exclusion of the risk of contamination and infection of the peritoneal cavity and of techniques and technologies that ensure safe full thickness closure of the perforation of the hollow organ. Insofar as the stomach is concerned, these studies have confirmed that, with adequate preparation (gastric lavage with povidone–iodine solution and with intravenous antibiotic cover), the risks of infection into the peritoneal cavity are low and acceptable. Equally, the efficacy and safety of various technologies and techniques for safe closure of the gastric perforation have been confirmed. Even so, NOTES, despite the latest technology platforms, is difficult and requires two operators: one manipulating the platform and the other performing the procedure. Thus, despite the initial expectations, the uptake of NOTES by surgeons worldwide has been minimal and limited to a small number of transgastric NOTES operations, e.g. appendectomy, cholecystectomy, tubal ligation, replacement of percutaneous endoscopic gastrostomy, laparoscopic cancer staging and volume reduction of the gastric pouch after gastric bypass surgery for morbid obesity, and, although some of these interventions were performed with the pure NOTES approach, others have required insertion of abdominal laparoscopic ports (hybrid NOTES). The current view is that, unless robotic-based technologies are developed specifically for NOTES, this surgical approach is unlikely to become established in routine surgical practice.

Natural orifice surgery

This is related to NOTES but is less problematic as it poses fewer technical problems and infective risks. It is best exemplified by transvaginal interventions following the insertion of operating ports into the pouch of Douglas through the vaginal ports. To date, several hundred cases of vaginal cholecystectomy have been reported in humans with good results, but case selection is important. An interesting new development of natural orifice surgery is transanal endoluminal colonic surgery being developed in Europe by Dr Antonio Lacy. The procedure starts with insertion of the TEM (transanal endoscopic microsurgery; Wolfe) or TEO (transanal endoscopic operation; Storz) operating proctoscope. The rectal wall is divided with electrosurgery just above the dentate line through the operating proctoscope. The distal end is then closed by a continuous suture leaving the rectum and anal canal as a conduit to the pelvic peritoneal cavity. Both sigmoid and extended left hemicolectomy have to date been performed but the reported experience is limited. The specimen is extracted per annum and is followed by a stapled anastomosis guided by a single laparoscopic port for the camera.

Single port/single incision laparoscopic surgery

The trend towards reduction of traumatic insult to patients has continued in the quest for reduction of the invasiveness of surgical interventions. In this development single-port laparoscopic surgery (SPLS; also known by a variety of other names, e.g. SILS for single incision laparoscopic surgery, reduced port surgery) has experienced the greatest uptake by surgeons, far exceeding NOTES. The concept of single-port endoscopic surgery is not new as it was used initially by Dr Raimund Wittmoser for single-port thoracoscopic surgery on the sympathetic and vagal nerves in the 1970s. One-wound laparoscopic cholecystectomy was first reported in 1997. Resurgence in the interest and uptake of SPLS occurred with the advent of NOTES in 2005 with substantial advances in port technology, novel retraction systems and related instrumentation.

There is no doubt that SPLS imposes more ergonomic restraint than traditional multiport MAS: (1) insufficient triangulation, which limits the manipulation angle (ideal = 60° triangle) between two working instruments held in the dominant and non-dominant hands; (2) internal and external collisions between the instruments and optic is more problematic when standard straight laparoscopic instruments and a 0° (forward viewing) telescope are used; (3) problems with retraction and exposure; (4) enforced approximation of the surgeon's hands by the single port or incision; all of which add to the difficulty in the execution of the operation.

Thus, the traditional methods used in conventional multiport laparoscopic surgery have to be adapted for SPLS. Often, additional ports (reduced port surgery) are used to insert instruments specifically for exposure and retraction.

Technologies for single-port laparoscopic surgery

Considerable effort in research and development has been made and techniques devised in the effort to restore, at least to some degree, the triangulation and a reasonable operating angle. The majority of single-port devices for SPLS are disposable but two are reusable: the EndoCone and the X-port (Storz, Tuttingen, Germany). The EndoCone has a detachable bulk head (cap) that contains six latex valve inlets admitting use of 5 mm instruments and two central inlets that allow the insertion of large instruments including a stapler (Figure 2.6). The surgeon is able to use three instruments and an optic at any one time during the course of the operation. This EndoCone has been successfully used for laparoscopic right and left hemicolectomy splenectomy, and nephrectomy and sleeve gastrectomy.

The commonly used disposable single-port devices are the SILS port (Covidien), the TriPort (Olympus), the GelPOINT (Applied Medical) and the AirSeal (SurgiQuest). The SILS port is a blue flexible soft-foam port. It is designed to be inserted through a single 15–25 mm periumbilical incision. The device has three access channels that can accommodate three 5 mm cannulas or two 5 mm cannulas and one 12 mm cannula. The main drawback of the SILS port is that it is associated with difficult insertion, lack of abdominal wall adjustability, and insufficient maintenance of capnoperitoneum during the operation. The TriPort Access System has three instrument channels that can accommodate two 5 mm instruments and one 12 mm instrument and the device can be inserted through a single incision of 12–25 mm. It has one distal ring and one proximal ring. The GelPOINT system consist of the Alexis wound protector/retractor, GelSeal cap and 5 mm self-retaining trocars. The critical disadvantage of the GelPOINT is that it only has 5 mm self-retaining trocars, which limit the usage of larger instruments such as a stapler.

Instrumentation and optics for single-port laparoscopic surgery

The curved coaxial instruments modified with proximally deviating handles (Figure 2.6a) are able to restore useful triangulation and overcome the problem of enforced approximation of the surgeon's hands. Another useful development relates to instruments of variable length, which enable placement and manipulation at different levels and planes and increase the external working space close to the port, thereby avoiding external collision. A more advanced development for SPLS concerns articulated instruments that can allow work

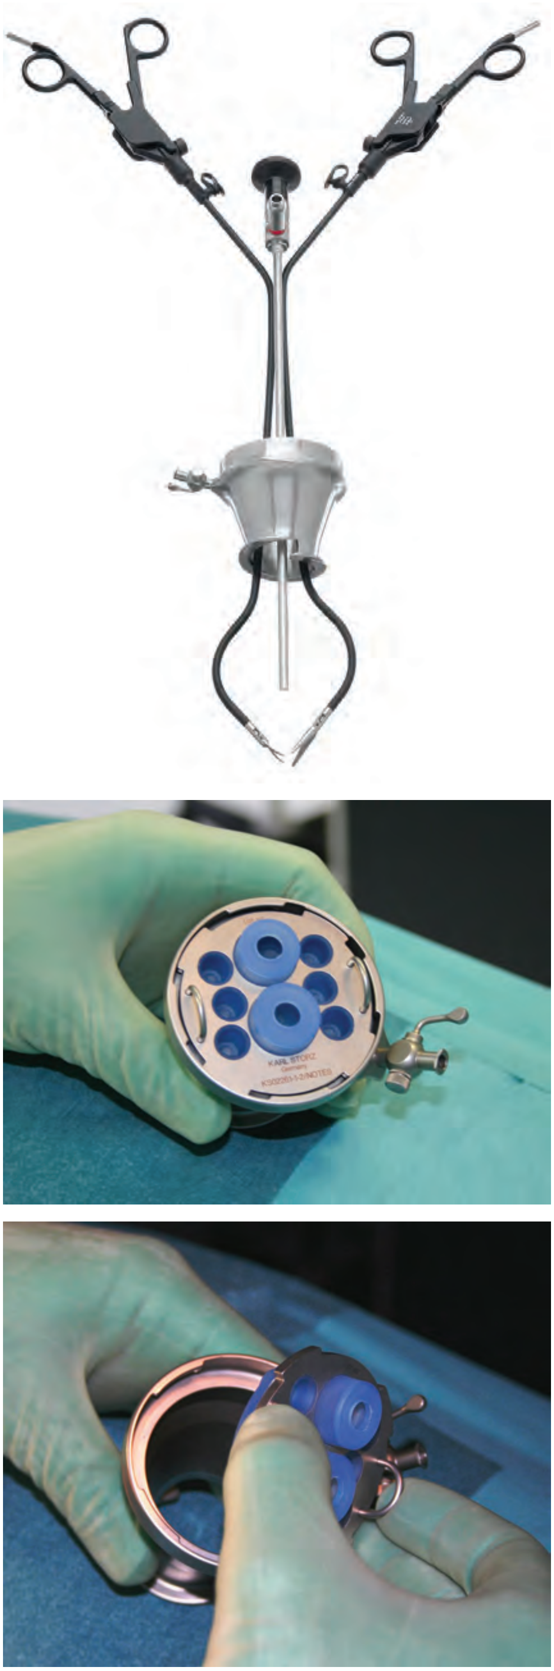

Figure 2.6 (a) Dundee EndoCone, which is self-retaining after insertion using a screwing action with proximally deviating handles (to separate the surgeon's hands) and distal curved instruments (to restore useful triangulation). (b) EndoCone fitted with a cap containing the ports. (c) The cap is detachable for extraction of small specimens through the cone, thus acting as a wound protector.

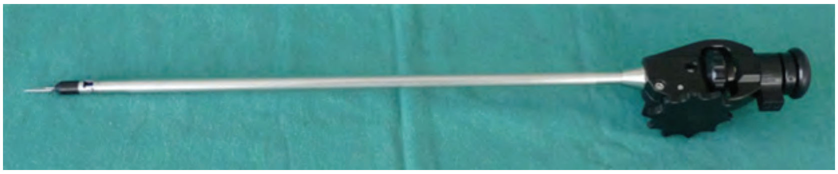

Figure 2.7 Dares hand-held manipulator with seven degrees of freedom. The instrument has a flexing and rotating functional tip.

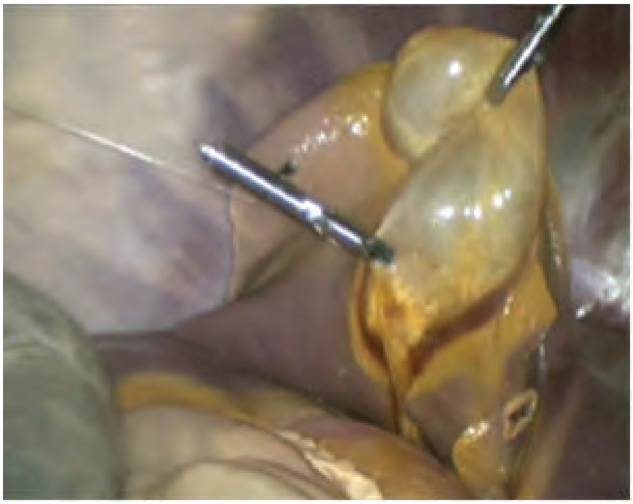

Figure 2.8 Dundee anchored and retraction tether system (DARTS). This uses small, tethered self-grasping anchors (instead of sutures) introduced through a modified Veress needle-type introducer. Image shows exposure of the gall bladder.

in the operative field despite a straight proximal segment. Aside from reducing external collision of instruments, they help to restore triangulation at the tips of the instruments. More advanced systems include the hand-held manipulations with six degrees of freedom (DOFs). These manipulators enable controlled adjustable bending of the distal segment of the instrument and rotation of the jaws of the instrument, thereby considerably facilitating intracorporeal suturing during SPLS operations (Figure 2.7).

New optics for SPLS include the Olympus EndoEye (Olympus), which has a distal chip and yields more working space close to the access port. Also, some surgeons prefer to use flexible-tip endoscopes to reduce the 'moving together' effect between the scope and instruments.

Retraction systems for single-port laparoscopic surgery

Suspension sutures are often used for retraction and exposure of Calot's triangle for SPLS cholecystectomy. Dedicated systems such as Endo-retractor have been used clinically. A new device, known as DARTS, is currently under evaluation in preclinical studies (Figure 2.8). The DARTS retraction system uses small atraumatic self-grasping tethered 1.5 mm clamps introduced through a modified Veress-type placement system that function in the same way as suspension sutures but avoid the difficulty of suture placement.

In human cadaveric tests, the ability of DARTS to provide successful retraction and surgical exposure of the cystohepatic angle through a single incision without use of extra ports has been demonstrated.

Dissection and fascial planes

'There is no such thing as a surgical postoperative complication – all are enacted on the operating table.' This quotation is attributed to a master surgeon from Liverpool. It is correct insofar as technical complications are concerned, but ignores the systemic factors that may complicate surgical intervention. Nonetheless, it stresses, by exaggeration, the importance of technical execution (task quality) to the clinical outcome. Whatever the complexity of the pathological anatomy and density of adhesions, the operation progressed at a steady pace and the tissue planes seemed to open up as he dissected. When watched, he appeared to be slow but, in fact, the operations were completed fairly quickly. When once asked to explain his technique, his reply was 'this is how I have always done it'. On reflection, the operative technique of this and other master surgeons had the following characteristics:

- immediate grasp in three dimensions of the abnormal anatomy of the case (spatial perception)
- appreciation of tissue planes
- economy of movements with purposeful manipulations
- operative choreography
- upper limb co-ordination and manual dexterity
- gentle but purposeful touch
- strict adherence to the sequential steps of an operation.

This surgeon had reached the stage when he rarely committed any execution errors. He had developed these skills over many years to an extent that his brain was conditioned to execute 'macro-operative programs'. He operated on autopilot and, for this reason, could not specify the components of his surgical operative skill. These are the skills that every surgical trainee should strive by constant effort to improve and to hone his or her operative manipulations. Some of these skills are worth considering in some detail.

Touch

The essence of good dissection is the application of the right amount of stretch on the tissue with the assisting hand before division/suture, etc. of the tissue with the active hand. The correct amount of stretch on the tissue (without trauma) is entirely dependent on the tactile force feedback that the surgeon has developed from the innate level with which he or she was born. It is the level of appreciation by the surgeon of this sensory feedback to the hand that distinguishes the surgeon with the gentle touch from the rough one. Research into psychomotor skills has shown that left-handed individuals are by nature more gentle than right-handed individuals, although the latter are more precise and commit fewer errors (swings and roundabouts). A gentle touch must be accompanied by accuracy and decisive manipulations by the active hand. Tentative active manipulations, e.g. scratching with the scissors or inadequate needle passage, should be avoided.

Identification of tissue planes

Normal tissue planes are made up of condensations of areolar tissue and are relatively avascular, permitting separation with ease and without significant blood loss if the surgeon proceeds in the correct plane. Otherwise, bleeding, difficulty and resistance to separation are encountered. These are indications that the dissection has deviated to the incorrect plane. These normal fascial planes are altered by previous surgery and inflammation: the fibrotic component is increased and this is most dense close to the visceral side, becoming less so as the parieties and retroperitoneum are reached. The transition between the dense fibrous layers and the outer areolar tissue forms a distinctive 'white line'. This indicates the correct plane of dissection.

Economy of movement

All movements made by the surgeon in performing tasks must be deliberate and purposeful, and achieve the desired objective. Unproductive movements not only waste time but also increase the risk of error. Another aspect of this skill requires that one step of an operation be completed before proceeding to the next. Thus, flitting from one step to another is counterproductive to the progress of an operation.

Choreography

Each operation is made up of a number of steps which, in turn, are composed of a series of sequential tasks. Choreography implies a coordinated performance of the various component tasks of a step such that the execution of one task facilitates the performance of the subsequent one. In this fashion, the step is executed smoothly and efficiently. Errors are of two kinds: intrastep (execution) or interstep (procedural). An intrastep or execution error means that the task is executed poorly, e.g. a needle swivels during passage through the tissue, or scissors cut the wrong layer. By contrast, a procedural or interstep error indicates missing a step or the wrong order of steps, e.g. failure to clamp or coagulate an arteriole before dividing it. In essence, choreography signifies that a surgeon has an orderly checklist of the steps of an operation in mind and, in executing the procedure, he or she follows this rigidly.

Types of dissection

Surgical dissection can be either blunt, i.e. the tissue planes are teased apart, or sharp, when a cutting device is used.

Blunt dissection

When used judiciously, blunt dissection is effective and safe. It requires the presence of loose areolar tissue that allows easy separation as a shear force is applied by hand or using a gauze swab or a pledget (peanut) held in a forceps (or long, secure grasper in endoscopic surgery). It relies for its safety on tactile feedback to the surgeon's hand and, unless this is refined, excessive shear force can be inadvertently applied so that tissues are torn and vessels avulsed. Blunt dissection is very useful in anatomically crowded areas or when the correct anatomy cannot be identified, especially if important structures, the integrity of which must be preserved, are known to be present within the block of tissue.

Sharp dissection

Sharp dissection, which involves division of tissue and separation of tissue planes, is carried out by mechanical (scissors, scalpel) or energized [high-frequency (HF) electrosurgery, ultrasonic devices, etc.] equipment. Irrespective of the equipment used, sharp dissection is a two-handed procedure that involves the application of the correct amount of tension by the assisting hand (often with atraumatic dissecting forceps, but sometimes directly with the hand over a gauze swab), while the division/separation is effected by the active hand. Clean separation and cleavage is as much dependent on the 'cutting instrument' as on the amount of stretch applied to the tissue.

HF electrosurgery is the most commonly used form of energized sharp dissection but, during the 1990s, vibrating (ultrasonic) equipment, water-jet and laser devices were introduced both in open and in endoscopic surgery. The physical principles governing the safe use of these forms of energized dissection are discussed in Surgical technology.

Adhesions

Adhesions result from previous inflammation or operative interventions within serous cavities. The reported incidence of adhesions after open general abdominal operations ranges from 67% to 93%, although there is great variation in the formation of adhesions between individuals. Adhesions are also much less common after laparoscopic surgery. The adverse consequences of adhesions are:

- intestinal obstruction
- difficult reoperative surgery
- increased risk of bowel damage during abdominal surgery
- chronic pain
- infertility in females
- increased healthcare costs.

The division of adhesions is an integral part of abdominal surgery. Adhesiolysis may be necessary to obtain exposure or because the adhesions are responsible for the primary pathology, i.e. mechanical small bowel obstruction.

Adhesiolysis

Aside from causing symptoms and intestinal obstruction, adhesions influence the surgical access used and the level of technical difficulty of an operation, whether this is open or endoscopic. Undoubtedly, adhesions increase the morbidity from iatrogenic injury in laparoscopic surgery, especially during the creation of the pneumoperitoneum, when adherent bowel can be impaled by the Veress needle or, worse, by the optical trocar cannula. There are now safe techniques for the creation of pneumoperitoneum in patients with adhesions from previous surgery. In open surgery, the technique for safe adhesiolysis relies on:

- establishing the anatomy of the adhesions
- putting the adhesions on the stretch (usually with the flat of the assisting hand over a swab), to identify the white line; this marks the insertion of the adhesion, which is completely avascular and can thus be divided by scissors without bleeding
- separating adhesions over a wide front; otherwise, the surgeon 'digs himself into a deep hole', with poor exposure and risk of damage to bowel loops.

Adhesions must not be separated by energized dissection and should not be clamped and divided between ligatures. This obscures the tissue planes and promotes further adhesions.

Tissue approximation

Accurate tissue approximation is essential for operative repair of defects and execution of safe anastomosis. Aside from gentle handling of tissues and careful dissection, the approximation must be achieved without tension and without compromise of the integrity of the blood supply essential to the healing process. The approximation itself can be performed by:

- sutures
- staples or clips or tacks
- glues.

Approximation by suturing

Approximation of edges involved in the anastomoses of hollow viscera, closure of wounds and repair of defects by interrupted or continuous suturing is an acquired craft based on established surgical principles. The key principles involved are:

- Preservation of the blood supply.
- Approximation of the edges without tension; this applies equally to repair of hernias and to intestinal anastomoses that should 'sit' rather than 'stand'.
- Meticulous technique with attention to detail and execution in the same way every time.
- Correct suture spacing and suture bites. It should be remembered that wounds heal despite sutures, which tend to devascularize the wound edges. Thus, especially in GI anastomosis, the balance between creating a seal and devascularization is fine. In this respect, crowding the anastomotic line with too many sutures predisposes to failure of the anastomosis. As a general rule, the space between the individual sutures should approximate to the size of the individual suture bites.
- Selection of the correct suture materials.

Continuous and interrupted suturing

Although in some instances either continuous or interrupted suturing can be used with equally good results, this is not always the case and certain specific anastomoses require the use of one and not the other of these two techniques. Continuous suturing is quicker than interrupted suturing and results in a more leak-proof and haemostatic join. Hence, it is the technique deployed in vascular anastomoses. The 'purse-string' effect inherent to continuous suturing is minimized by correct suture spacing (the greater the distance between suture bites, the more pronounced the purse-string effect) and by the use of separate sutures for the posterior and anterior suture walls of the anastomosis. Even so, such an anastomosis cannot enlarge and this is an important consideration in children, in whom an anastomosis has to allow for growth. Continuous suturing is inadvisable in the anastomosis of small tubular structures and is difficult in deep cavity work.

Interrupted suturing is slower but allows more accurate suture placement. It is the technique used routinely in microsurgical work. Although less waterproof than the continuous technique, interrupted suturing is preferred by most surgeons for oesophageal, small bowel and colonic/rectal anastomoses. The sutures are placed on the back wall of the anastomosis before they are tied and the procedure is then repeated for the anterior wall. This technique ensures correct suture placement and precise coaptation of the edges. Interrupted suturing is less likely to devascularize GI anastomoses. This is an important consideration in high-risk areas such as oesophageal and colonic anastomoses. Both interrupted suturing and stapling (see below) are accompanied by a higher incidence of postoperative suture line bleeding from anastomoses involving the stomach, particularly gastrojejunostomy.

Ligatures and suture materials

Ligatures, as opposed to sutures, are lengths of biocompatible thread used to tie structures such as blood vessels. The vast majority of sutures used in surgery nowadays are atraumatic, i.e. the needle is attached to the material by either swaging or crimping. In swaging, the rear of the needle is flattened and then folded over as a tunnel to hold the suture. Crimping, which is used for larger needles, entails drilling a canal at the rear of the needle (by laser) to accommodate the thread, which is then crimped in place. Crimping provides a more secure join between thread and needle. Swaging is used for fine atraumatic and detachable sutures (controlled release or pop-off), in which the attachment is intentionally set to a minimum strength, so that after passage through the tissue the needle can be easily pulled off. Controlled release atraumatic sutures are invaluable for interrupted suturing in deep cavity work. They should not be used for continuous suturing.

The attachment of the thread to the needle by either technique creates a problem because the diameter of the needle at the junction is always larger than the suture. In practice, this ratio averages 2:1 for large and 3:1 for small sutures. The adverse effect of this step is that the suture lies loosely in the tissue, as the tunnel made by the needle is at least twice the size of the suture. Atraumatic sutures made from expanded polytetrafluoroethylene (Gortex) provide an exception to this, since the compressible sponge-like nature of this material results in a ratio of 1:0.8, i.e. the suture fits snugly in the tissues, improving the seal.

All materials used, whether natural or synthetic, meet certain mechanical, biological and handling requirements.

The important mechanical characteristics are tensile strength, yield point, elasticity and breaking strength retention (BSR). A high tensile (breaking) strength is always a good attribute because it permits the use of a finer suture. In terms of the bulk of the suture material in contact with the tissue, a 2/0 suture has a circumference that is double that of the 3/0 equivalent; hence, the inflammatory response is higher and the risk of infection greater. The tensile strength is also important in relation to knotting, since the strength of a perfect knot is, at most, only 50% of the tensile strength of untied ligature or suture material from which it is made. The BSR is an important mechanical characteristic. It is a reflection of the rate and extent of biodegradability of the suture following immersion in fluids (*in vitro* BSR) or implantation in animal tissues (*in vivo* BSR). When a suture is subjected to progressive distraction in a tensiometer, a certain point is reached when the material starts to deform and stretch permanently before it breaks if the distraction force is continued beyond this yield point. Young's modulus of elasticity (which is measured from the start of the distraction force to the yield point) is an expression of the resistance to elongation of the suture before it breaks. The higher the modulus, the less elastic the suture. A measure of elasticity is a good attribute as it enables the material to undergo elastic deformation when tied, thereby increasing knot security. By contrast, excessive elasticity is a nuisance as the material lengthens and distorts (crinkles) during knotting. The ideal combination is a suture with a high tensile strength, good BSR and a low to medium modulus of elasticity. The biological characteristics depend on the composition, structure and surface charge of the material. They include biodegradability, reactivity (extent of inflammatory reaction), tissue incorporation (tissue growth into the interstitial microstructure of the material), effects of infection and site-specific adverse effects, e.g. deposition of calcium on non-absorbable material in the urinary tract and calcium bilirubinate in the biliary tract.

The surgical/handling characteristics relate to the ease of handling, slide through the tissue, knot run-down and knot security. The friction coefficient of a suture determines the ease of slide through the tissue, the knot run-down and the resistance to knot slip. Monofilament sutures slide more easily through tissues (and are thus less traumatic) than their braided equivalents. In the case of synthetic sutures, this disadvantage of braided sutures is largely, but not completely, overcome by coating the braid with a lubricant copolymer such as polybutylene. A low-friction suture exhibits excellent tissue slide and good knot run-down at the expense of an increased tendency to spilling. Thus, knots fashioned from these sutures require several throws (minimum of five) as opposed to the traditional three. The visibility of a suture is an important yet overlooked property. Only a limited range of dyes is approved for dyeing sutures and ligatures (violet, black, shades of blue–green). The visibility of a suture helps considerably in the execution of correct suturing and is an important characteristic in laparoscopic work, in which blue–green is the most appropriate. Transparent (undyed) biodegradable monofilament sutures are difficult to use, especially in the smaller gauges, but are preferred by plastic surgeons for subcuticular closure as the dyed sutures may lead to tattooing when the dye leaches out as the material degrades.

Table 2.1 Size of suture/ligature material: empirical gauge versus metric systems

Empirical gauge	Metric size (mm)
10/0	0.02
9/0	0.03
8/0	0.05
7/0	0.07
6/0	0.1
5/0	0.15
4/0	0.20
3/0	0.25
2/0	0.35
0	0.4
1	0.45
2	0.55

Traditionally, the size (diameter) of sutures and ligatures is expressed by the empirical gauge system. The equivalent metric size (diameter in tenths of a millimetre) is shown in Table 2.1. The gauge range used in general surgery is from 1 to 5/0 (0.45–0.15 mm).

Natural materials

These include catgut (plain, chromic, alcohol packaged, dry), silk, linen, cotton and collagen. In most countries catgut (which despite its name is made from bovine collagen) is banned because of the potential risk of bovine spongiform encephalopathy. From a physical standpoint, all natural suture materials can be considered as twines of fibrous polymers. As a group, they have excellent handling characteristics and knotting properties. However, they excite a prominent inflammatory response within the tissues and, moreover, are easily colonized by bacteria, which invade the interstices of the twine and are then less susceptible to antibiotics.

All of the natural materials (including silk) are biodegraded by proteolytic digestion. The degradation is rapid with catgut and slow with silk and cotton. Another property of the natural materials is that they absorb water (tissue fluid) and thus swell following implantation. This swelling increases the knot security and is probably the reason why black silk is still popular with some surgeons. The BSR of plain catgut (derived from bovine intestine) is poor, and this material loses 50% of its tensile strength within a few days of implantation. Chromic catgut has twice the BSR of plain catgut and is thus preferable, although it is nowadays banned in most countries.

Synthetic non-absorbable materials

These *hydrocarbon polymers* are all derived from coal and oil. They are hydrophobic and therefore do not swell following implantation. Although generally regarded as non-biodegradable, some, such as polyamide (nylon), degrade in the tissues slowly with time. The group characteristics include flexibility, high tensile strength, resistance to creep and relative inertness. The main disadvantage of these hydrocarbon polymers in the monofilament form is their poor knot-retaining quality, with a tendency to knot spilling. The development of multifilamentous copolymers (by braiding of multifilaments or by looping from a single filament) has solved this problem.

Polypropylene (olefin) is marketed as Prolene (Ethicon) and Surgipro (USSC). It is a monofilament material with a low friction coefficient (slides well through the tissues), excites a minimal tissue reaction and handles better than nylon. It is, however, elastic and can fracture. Knots tend to spill unless tied and drawn properly. Five throws are recommended for security. Polypropylene is used extensively in general surgery (e.g. mass closure of the abdomen) and for vascular anastomoses. Subcutaneous knots must be buried as otherwise localized tenderness/sinus formation may occur.

Polyamide (nylon) is available as monofilament (Dermalon, Ethilon, Monosot) and braided (Nuralon). Polyamide combines strength and elasticity but is slowly biodegradable, retaining two-thirds of its strength for up to 6 months. In the monofilament form, it is a difficult material to handle and does not tie well, with a tendency for the knot to spill. Despite this, it is popular with many surgeons for mass closure of laparotomy wounds. The braided form (Nuralon) handles and ties well and is used extensively for single-layer GI anastomoses by many surgeons.

Polyester (Dacron) is the strongest of the non-absorbable polymers and has the best mechanical and handling properties. It knots and handles very well. Polyester is available as the uncoated braid (Mersilene) and as a braided suture coated with polytetrafluoroethylene (Ethibond, Surgidac).

Expanded polytetrafluoroethylene (Gortex) is an excellent suture and excites the least inflammatory reaction of all biomaterials used in surgical practice. Its microporous structure allows tissue ingrowth. Expanded polytetrafluoroethylene handles extremely well, although the knots tend to spill unless locked tightly. A minimum of four throws is recommended for knot security.

Synthetic absorbable materials

These are much less reactive than catgut, i.e. cause less inflammatory reaction after implantation. They are degraded slowly by hydrolysis rather than proteolytic digestion and exhibit a BSR of several weeks. The degradation by hydrolysis is important as this process releases hydrogen ions, thereby lowering the pH in the vicinity of the wound. This is thought to reduce bacterial colonization and infection. Synthetic absorbable suture materials can be monofilament or braided. The latter are available as coated and uncoated braids (Table 2.2).

Table 2.2 Synthetic absorbable suture materials

Monofilamen	Braided
PDS (polydioxanone)	Braided polydioxanone
Maxon (polyglyconate)	Dexon (coated polyglycolic acid)
Monocryl (poliglecaprone)	Vicryl (coated polyglactin)
Biosyn (glycomor)	Polysorb (coated lactomer copolymer)

Needles

Surgical needles are essentially penetrating devices designed to pass sutures through tissue with minimum trauma. As mentioned previously, most sutures are nowadays attached to the needle by crimping or swaging (atraumatic sutures) and the French eyelet needle is rarely used. The important characteristics of surgical needles are shape, size, tip and configuration of the shaft (body).

Shape

Needles can be straight, curved, compound curved and customized. The large, straight Keith needle is still popular for hand suturing and small, straight needles are used by some surgeons for laparoscopic suturing. The straight needle is not ideal for suturing, however, because it does not allow the smooth wrist-scooping movement. In addition, the straight needle results in a 'cutting' effect as the tissue is stretched on the shaft when the needle is picked and pulled out at the exit point. Curved needles do not have these problems. They are based on various sections of a circle (1/8, 1/4, 3/8, 1/2 and 5/8). The most commonly used curved needles in general surgery are the 1/2 and 3/8 circle configuration. The 1/2 circle needle is ideal for end-to-side anastomosis, whereas the 3/8 circle is better for tissue plane approximation and end-to-end anastomosis. The compound curved needles have different profiles at the tip and body and are exemplified by the J-shaped needle, fishhook needle and the endoski needle used in MAS (Figure 2.9).

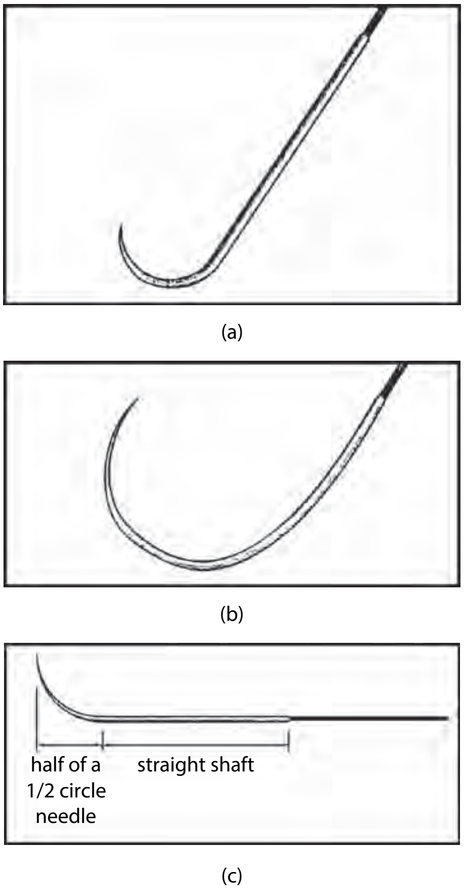

Figure 2.9 Examples of compound curved needles: (a) J-shaped; (b) fishhook; (c) endoski.

Size

This relates to the length and diameter of the needle. The length chosen is dictated by the distance between the entry and exit bites and by the length of the needle that needs to emerge from the exit point so that it can be picked up by the needle driver without damage to the tip. The gauge (diameter) chosen depends on the resistance of the tissue and its texture. In atraumatic sutures, the needle is always thicker than the suture and the ratio of the two is seldom below 2:1. The ratios of needle diameter to suture diameter for atraumatic sutures used in general surgery are shown in Table 2.3.

Tip

The sharpness of the tip and the tapering ratio determine the penetrating characteristics of the needle. The tapering ratio describes the extent of the taper from the maximal cross-section of the shaft (shoulder) to the needle tip and is calculated from:

$$\text{Tapering ratio} = \frac{\text{Distance between shoulder and tip}}{\text{Diameter of the shaft}}$$

The longer the taper, the more the needle penetrates atraumatically. Sharp needles with a long tapering ratio are used for suturing delicate tissues or those softened by inflammatory oedema. Sharp needles, however, increase the possibility of injury to the surgeons and operating staff. This is an important consideration in infected cases. Closure of the abdominal wound with blunt needles is advisable in these cases.

The tip of the needle is either conical, with a round cross-section (tapered), or cutting, in which the shape is pyramidal and the cross-section triangular, with either a cutting inside edge (conventional) or a cutting outside edge (reverse cutting), or both cutting outside and inner edges (cutting tip). Cutting needles are used for penetrating tough tissues, e.g. skin and cornea.

Body

The shaft or body of the needle is the longest section and extends from the shoulder to the join with the suture. Its cross-sectional shape determines: (1) the extent of trauma to the tissues during needle passage and (2) security of hold by the jaws of the needle driver (preventing deflection and swivel). The least traumatic configuration is the round-bodied needle, which should always be used for suturing delicate tissue, but this needle offers the least secure grip. The oval needle is fairly atraumatic and provides a better grip with fewer tendencies to swivel. It is preferable to the round-bodied variety in laparoscopic work. Various other shaft shapes are available for specialized work: ribbed, flattened hexagonal, triangular, etc.

Table 2.3 Atraumatic suture sizes and needle–suture ratios used in general surgery

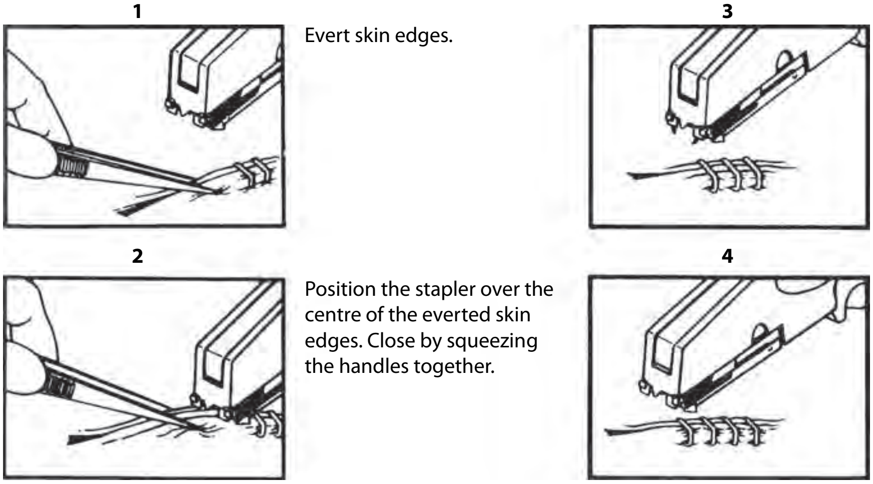
USP size	Needle diameter(mm)	Suture diameter(mm)	Needle–suture ratio
6/0	0.3	0.1	2.7:1
5/0	0.4	0.15	2.7:1
4/0	0.5	0.2	2.5:1
3/0	0.65	0.25	2.6:1
2/0	0.75	0.34	2.2:1
0	0.9	0.4	2.2:1
1	1.1	0.47	2.3:1
2	1.4	0.57	2.4:1

Approximation by clips and staples

Edge approximation by clips

Clips are often used instead of sutures to close skin wounds, for skin grafts and to attach prosthetic mesh in hernia repair. Clips used for this purpose are made of titanium alloys that are fully biocompatible and virtually non-reactive. The advantages of skin closure with clips include speed of application, good coaptation, minimal disturbance of the blood supply to the edges (constant occlusive force) and ease of removal. There are many clip applicators (disposable and reusable) but essentially they fall into two types: side and end applicators. The side applicators (Figure 2.10) are ideal for skin closures. They are used extensively in:

- head and neck surgery
- skin closure after peripheral vascular surgery
- skin grafting.



1 Evert skin edges.

2 Position the stapler over the centre of the everted skin edges. Close by squeezing the handles together.

3 Alternately, the skin stapler can be precocked to enable more precise placement of the staples. Simply squeeze the handles until the points of the staple are visible and the trigger is in the precocked position. The staple then can be placed exactly where desired and implanted by completing the squeeze.

4 Release the trigger to achieve staple release.

Figure 2.10 Disposable side-clip applicator for skin closure: step-by-step directions for use.

End-clip applicators deliver a clip at the end of the instrument and are ideal for the attachment of prosthetic mesh during hernia repair since they permit precise application. They are used extensively in laparoscopic hernia repair. The morbidity following use of clips for this purpose is related to the risk of nerve entrapment by the clip, especially during laparoscopic hernia repair. For this reason, in both transabdominal preperitoneal repair and extraperitoneal repair, clips are being used less frequently and only at the superior margin of the prosthetic mesh. The important factor in the prevention of recurrence is not the fixation but the size of the mesh, which must be large enough to overlap the defect by a significant margin.

Anastomosis by stapling

Anastomotic staplers are mechanical devices that enable the performance of anastomosis of hollow organs (side to side, end to end and end to side) by a single-layer technique using a treble row of evenly spaced titanium staples that join the approximated organs from the mucosal aspect while a central blade cuts out an opening inside the staple lines. In circular staplers, the blade is circular and cuts out a 'doughnut' inside the circular staple line; in linear staplers, the straight blades cut in a linear fashion the opposing walls of the two organs between the two rows of staples.

There is no doubt that staplers have been a significant technological advance since their introduction (first in Russia and Hungary) and subsequent development as fully loaded, disposable but multifire instruments in North America in the 1980s and 1990s.

The advantages of staplers, especially in surgical gastroenterology, include:

- the ability to perform safe anastomoses in surgically inaccessible or difficult areas; this is best exemplified in colorectal surgery, in which staplers have undoubtedly increased the number of sphincter-saving low anterior resections for cancer without compromising adequate distal margins
- uniform surgical results: the overall performance of low rectal and oesophageal anastomosis (effectiveness) has improved as stapling has evened out surgical skill in the execution of these difficult anastomoses
- compared with hand suturing, anastomotic stapling is considerably quicker to execute
- less risk of contamination
- avoidance of the need for occluding clamps.

The widespread use of staplers has not been an unmixed blessing. In the first instance, they have encouraged some surgeons to abandon hand-sutured anastomosis in all situations, thus being a disincentive to the acquisition and maintenance of suturing skills. Second, there are situations in which the use of staplers not only represents an unnecessary additional cost but also may enhance morbidity by an increased risk of postoperative suture-line bleeding. This is best exemplified by gastroenterostomy, where bleeding, usually from the gastric side of the staple line, is attributed to the prominent vascular supply of this organ. Finally, although stapler failure is uncommon, the integrity of the stapled anastomosis is dependent on the correct technique, which includes the correct size of stapler and staples, adequate preparation of the two anastomotic ends and anastomosis without tension. Some consider that stenosis is more common after stapled than hand-sutured anastomosis. With stainless-steel staples, corrosion and leaching of iron and other constituents of steel have been documented experimentally, although this problem has been solved with the use of titanium staples. Both types of staple produce confusing artefacts on subsequent MRI. Hand-suturing and stapling techniques are not mutually exclusive and, indeed, should be regarded as complementary since the vast majority of stapling techniques require some hand suturing for optimal results.

Underlying mechanism of tissue approximation by staples

Within the cartridge of the instrument, the staples are U-shaped. When fired, the staples grip the outer layers and assume the characteristic B-configuration that is essential for inverted coaptation of the edges without impairment of the capillary and nutrient blood flow to the anastomosis. This process works only if the surfaces of the two organs are in apposition throughout the intended anastomotic site. If extraneous tissue, e.g. fat, lies anywhere in between the stapling ring, fixation of the tissue at this point is defective and the anastomosis will leak. Thus, adequate preparation of the two ends is essential. As an additional precaution, the integrity of stapled low rectal anastomosis is tested by insufflation of air through the anus after submerging the anastomosis in isotonic saline. The selection of the correct cartridge deploying the appropriate size of staples (2.4–4.8 mm) is crucial for the execution of a safe anastomosis. The smallest staples should be restricted for the closure of blood vessels.

Types of stapling device

From the functional standpoint, staplers are either occlusive non-cutting or anastomotic cutting (linear or circular). Occlusive staplers (Figure 2.11) approximate the two walls of an organ without cutting it and are used extensively to close the stapler insertion site after a linear stapled anastomosis and in bariatric surgery.

Although circular staplers from different companies vary in detail, they are essentially of the same basic design. Circular staplers (Figure 2.12) have a detachable anvil that is inserted in one of the hollow organs and this is then closed tightly around the stem by a purse-string suture. The rest of the instrument is composed of the cartridge (containing staggered rows of staples), a docking mechanism (for the stem of the anvil), advancement mechanism for approximation of the two organs and a firing mechanism, which drives both the staples and the circular blade.

Linear staplers (Figure 2.13) consist of two docking limbs, one of which carries the cartridge containing the staplers and the other the knife mechanism. Most modern linear staplers are multifires, i.e. the cartridge can be replaced for multiple applications (up to six times). In most instances, the stapling length is fixed (e.g. 30 mm, 60 mm). Thus, if a long side-to-side anastomosis is needed (e.g. creation of an ileal pouch), sequential application of the linear stapler along the intended anastomosis is necessary. This is an entirely safe and well-validated technique. Some of the newer staplers permit adjustment of the stapling length (Figure 2.14).

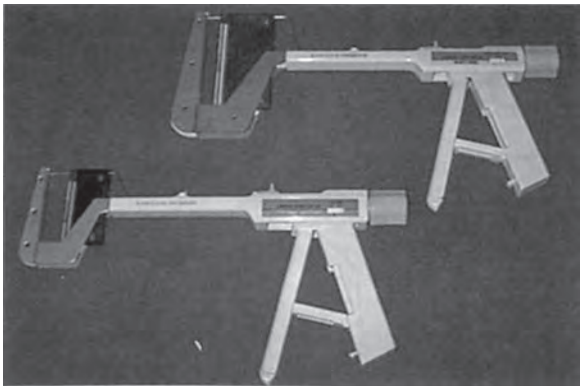


Figure 2.11 Occlusive disposable stapler: the device approximates and staples the two walls of an organ without cutting it.

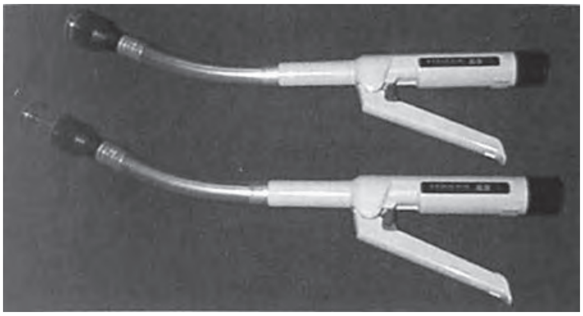

Figure 2.12 Circular cutting stapler used for oesophageal and colorectal anastomoses. The anvil is detachable.

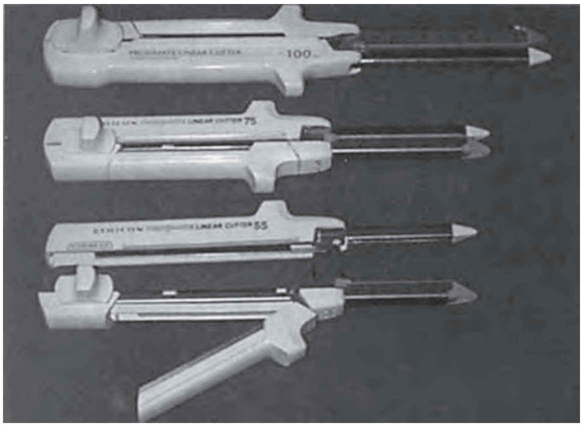

Figure 2.13 Linear cutting stapler. The instrument has two docking limbs, one of which carries the cartridge containing the staplers and the other the knife mechanism. Most modern linear staplers are multifires, i.e. the cartridge can be replaced for multiple applications (up to six times).

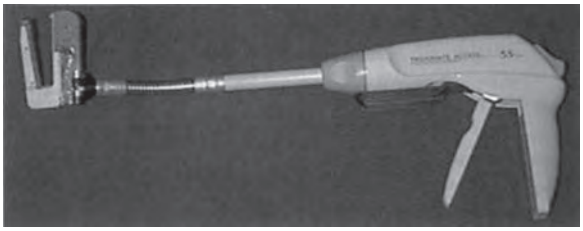

Figure 2.14 Linear occlusive stapler with adjustable stapling head.

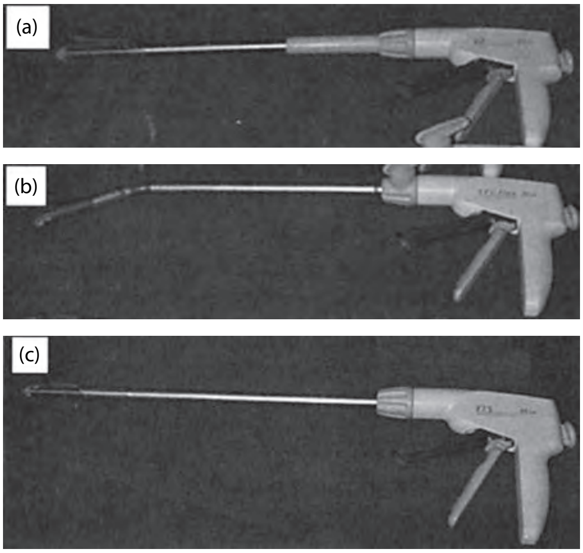

Figure 2.15 Endoscopic linear stapler: (a) occlusive stapler; (b) linear cutting anastomotic stapler with deflecting head; (c) linear cutting anastomotic stapler.

In some situations, both linear and circular staplers are used (double stapling). This is usually the case in low anterior resection in which, in the first instance, the rectum is stapled and transected by a linear cutting stapler and the stapled transected proximal colon is then anastomosed to the rectal stump by a circular stapler. This entails insertion of the anvil of the circular stapler through the antimesenteric taenia of the proximal colon and insertion of the stapler fitted with a perforating plastic trocar through the anus. The plastic trocar is made to perforate the closed rectal stump by the approximating mechanism. The plastic trocar is then removed and the two parts of the instrument are docked and approximated before the instrument is fired.

Both occlusive and anastomotic staplers have been developed for MAS (Figure 2.15). Some are powered and others have a deflecting staple head that facilitates precise application through the laparoscopic ports. Others have adjustable anastomotic lengths (Figure 2.16).

Surgical glues, adhesives and sealants

Although collectively referred to as surgical glues, a more precise nomenclature has become necessary in view of different usage/application of these biological and synthetic materials. In this context, *surgical sealants* are defined as absorbable materials used primarily to control bleeding or to seal anastomoses or skin wounds. *Surgical adhesives* denote substances with adhesive and cohesive properties stronger than sealants which are usually non-absorbable but biocompatible. *Surgical glues* have the strongest binding of all and are usually synthetic and slowly absorbable or non-absorbable. They are used for tissue approximation by binding as substitute to sutures or for mesh fixation (hernia surgery) and are exemplified by the cyanoacrylates. *Mucoadhesive polymers* stick to mucosal surfaces as they hydrate by absorbing water to form gels. Currently, they are largely used as buccal

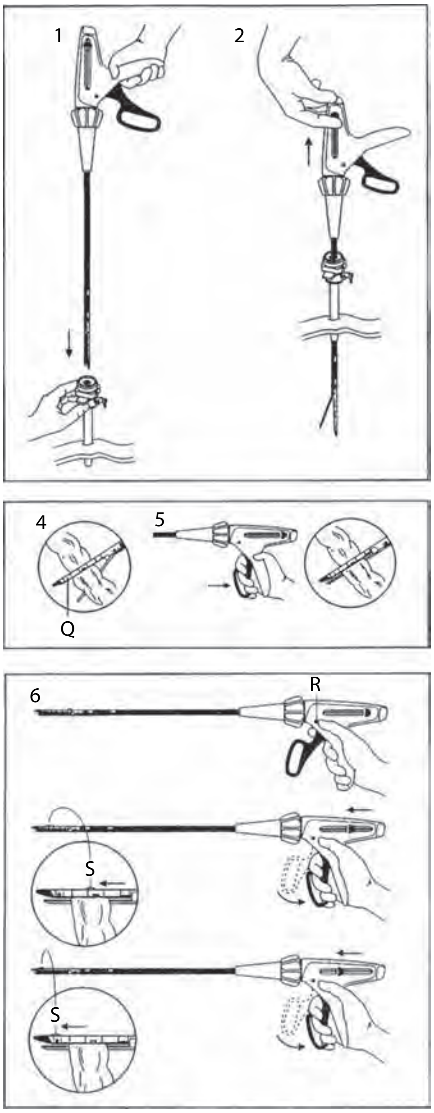

Figure 2.16 The newer generation of endoscopic cutting anastomotic stapler with adjustable anastomotic length.

mucosal drug carriers, which are assuming great importance in drug delivery. Thus a pharmaceutical drug or hormone which cannot be given orally as it is destroyed by gastric acid digestion can be incorporated in a mucoadhesive polymer that adheres firmly to the buccal mucosa, enabling absorption of the drug directly into the circulation before the polymer dissolves by hydration. There are other important emerging surgical applications involving the use of special mucoadhesive polymers, which are ferromagnetic by virtue of their iron content (as nano- or microparticles), e.g. magnetic retraction in interventional flexible endoscopy and SPLS.

The established and emerging indications for sealants, adhesives and glues indicate their widespread use and growing importance in surgical practice:

- control of bleeding during surgery (established)
- segmental solid organ resections – liver, spleen and kidneys (established)
- management of hepatic and splenic injuries (established)
- radiological embolic vessel occlusion (established)
- healing of fistulas (established)
- laparoscopic intestinal anastomosis (experimental)
- fixation of prosthetic material in hernia surgery (established)
- microanastomosis – vascular and non-vascular (established)
- repair of nerve injuries (established)
- laparoscopic vascular surgery (early clinical studies)
- skin closure (established)
- total wound closure (early clinical studies)
- endoscopic control of GI bleeding (established)
- reinforcement of suture and staple lines (established)
- sealing of pulmonary and cerebrospinal fluid (CSF) leaks (established)
- mucosal drug/hormone delivery (established)
- arthroscopic surgery – repair of cruciate and meniscus injuries (established)
- corneal surgery (established).

Fibrin-based systems

In the classic formulation, fibrin glues consist of two components – fibrinogen and thrombin plus calcium – with additives that vary with the preparation. When mixed at the point of application, the concentration of fibrinogen and thrombin influences the rate of polymerization of fibrinogen to fibrin and the strength of the final product. Some contain an antiproteinase (aprotinin), which is added with the intention of prolonging the integrity of the fibrin clot (ultimately dissolved by fibrinolysis) and increasing its adherence to the tissue. The two solutions have to be made up prior to use from the freeze-dried materials and then drawn into separate syringes that are connected to the applicator system. In essence, this consists of a Y-connection leading to a long double-lumen tube (one for each solution), with the two lumens joining at the tip where mixing of the two solutions occurs, i.e. at the point of application.

Tachocomb is a relatively new formulation of fibrin glue designed to avoid the need for making up the solutions of the procoagulant factors before use. It consists of a sponge-like membrane of equine collagen that is coated on one surface with the fibrinogen and thrombin plus calcium. The sheet is applied to the surface and then gently pressed with a saline-soaked swab until it adheres to the tissue. Tachocomb undergoes complete dissolution (phagocytosed by leucocytes and monocytes) within 6 weeks. FibFix is another formulation. It is a single-syringe formulation of fibrin glue that allows precise control of coagulation through light activation process.

The main disadvantage of all fibrin glues is the possibility of transmission of viral disease. Although all products are heat treated to destroy known viruses, there is the remote possibility of transmission of as-yet unidentified viruses. In some products, the thrombin is of bovine origin. This is a cause of some concern in view of the possibility of contamination with the bovine spongiform encephalopathy virus, and hence risk of new variant Creutzfeldt–Jakob disease.

The fibrin tissue sealants include cryoprecipitate, fibrinogen/thrombin formulations, light-activated (FibFix) and fibrin I monomer. Their advantages include elasticity and total biodegradability but they have certain disadvantages: weak adhesive polymers and a water-impermeable seal. Fibrin I monomer is now preferred to fibrinogen because it causes a minimal inflammatory response, as opposed to fibrin, requires much less thrombin for polymerization, does not require protease inhibitor and is totally biocompatible. Equally important, it produces a highly elastic fluid-repellent impermeable clot and is ready to use. Thrombin is available in two formulations: free thrombin and as thrombin nanoparticles, which are more stable, less inhibited by bacteria, pH and temperature, and have an increased storage time (6 months at room temperature).

Composite systems

The composite preparations include:

- French glue: gelatin resorcinol formalin glue
- BioGlue (CryoLife): bovine serum albumin + glutaraldehyde
- FloSeal matrix: pellets of bovine collagen coated with thrombin
- CoStasis: bovine fibrillar collagen + bovine thrombin in CaCl + fibrinogen (from patient)
- polyethylene glycol polymers: CoSeal (Baxter) and Focal Seal L and S (Genzyme)
- Tissuebond: porcine albumin + methylene blue + glycerol
- gelatin hydrogel polymer adhesives.

The polyethylene glycol polymers are totally absorbable and for internal use largely as sealants. They involve a two-stage application: primer followed by sealant which then polymerizes within 60 seconds on exposure to blue–green light (Figure 2.17). Focal Seal L is used in pulmonary resection and Focal Seal S for CSF leaks.

BioGlue is used as reinforcement of sutures/staple lines. It has been reported to cause nerve injuries and strictures in arterial surgery. Tissuemed (Tissuebond) is used as a sealant for anastomosis and consists of a dye–albumin mesh and an applicator containing porcine albumin, methylene blue (photophore to absorb light for polymerization), glycerol and water. A xenon arc lamp (Tissuemed 180 light source) is used to deliver filtered light by a fibreoptic handset activated by a footswitch. The light-activated albumin mesh then adheres strongly to tissue and grafts and is absorbable.

Cyanoacrylates

The cyanoacrylates are strong glues used extensively in flexible endoscopy to control gastric/duodenal bleeding and to fix meshes in hernia repair. They are based on 2-octyl cyanoacrylate monomer and produce heat as they polymerize (exothermic reaction), which may damage tissue and cause fibrosis. They include:

- Dermabond (Ethicon)
- Indermil (Tyco)
- Trufil (Cordis).

Their advantages include great bonding strength (tissue to tissue and tissue to prosthetic material), good vessel occlusion and excellent skin closure. They have some disadvantages, including toxicity to fibroblasts and epithelial cells, they are absorbed very slowly and thus may delay mesh incorporation, and they may carry an increased risk of infection, although this is not proven.

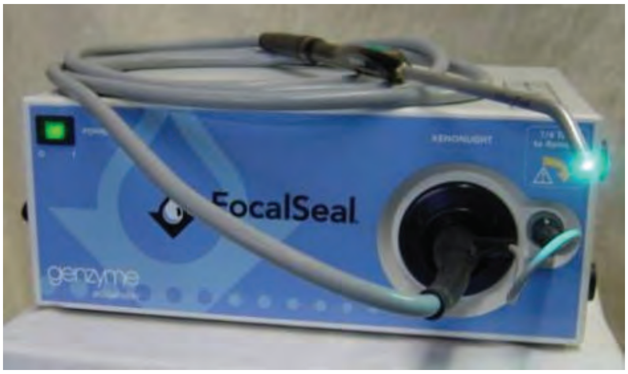

Figure 2.17 Blue–green light (xenon) for polymerization of a focal seal.

Topical materials used in surgery

These include Avitene (collagen sealant), Surgicel, Spongostan and Tacocomb. Surgicel is one of the most frequently used products in general surgery. It is a sterile, absorbable, knitted fabric prepared by the controlled oxidation of regenerated cellulose. In addition to its local haemostatic action, Surgicel is bacteriostatic *in vitro*.

Newer glues

These include biocompatible, biodegradable internal sealants based on proprietary protein engineering and consisting of a polymeric combination of synthetic silk and elastin with a cross-linking agent. They have good bonding properties, producing a flexible join. Animal studies have shown promising healing results. Photo-cross-linked hybrid ABA dendritic–linear copolyester ethers have been introduced clinically and are used in corneal surgery. CSIRO Biotechnology/University of Adelaide and spin-off company PolyNovo Biomaterials have developed a strong glue derived from the Australian frog (*Notaden*) that is biocompatible and has undergone successful clinical trials in knee joint surgery

Arrest of haemorrhage

The ability to arrest haemorrhage is an essential component of surgical skill. Haemorrhage can arise spontaneously as a result of disease or from blunt and penetrating trauma, or may be encountered during the course of an operation. The techniques for effective control of bleeding fall into three categories:

1. endoscopic: injection, thermal and photocoagulation, banding
2. radiological: embolization of bleeding vessels
3. surgical: techniques deployed during open surgery and MAS.

Control of surgical bleeding

Types of bleeding

Bleeding may be encountered during surgery or as a result of trauma (primary bleeding), within 24–48 hours after operation (reactionary bleeding) or be delayed for several days to weeks (secondary bleeding). *Reactionary bleeding* from small blood vessels within raw surfaces, minor capsular lacerations (liver, spleen) or from anastomotic suture or staple lines occurs as a result of the rise in the blood pressure after surgery. Reactionary bleeding is a special problem in laparoscopic surgery as small vessels compressed by the positive-pressure pneumoperitoneum may bleed following desufflation. Thus, careful haemostasis is essential throughout these procedures. A more serious cause of reactionary bleeding arises from a slipped ligature or clip used to secure an artery. Secondary bleeding is due to infection and is always a major problem. It is best exemplified by bleeding from infected vascular grafts, often requiring removal of the infected graft and some form of non-anatomical bypass through a non-infected region. *Internal* bleeding is defined as haemorrhage within closed body compartments or serous cavities with no visible external losses, and manifests externally as hypovolaemic shock. Occult bleeding (usually in the GI tract) refers to chronic blood loss, the exact cause of which can only be established by special investigations. It presents as iron-deficiency anaemia caused by a variety of benign and malignant disorders.

Bleeding during surgery

The primary objective is the execution of operative interventions in a bloodless field or with minimal blood loss. The advantages from this are several, the most important being reduced blood transfusion requirements, improved healing, maintenance of normal function of organ and systems, and reduction of infective complications. In many instances, bleeding during surgery is best prevented by careful dissection techniques. This is especially important in MAS, in which control of bleeding is more difficult than in open surgery and is a common indication for conversion. The following surgical methods are used for the control of haemorrhage:

- Packing: adequate packing of major or uncontrollable bleeding. During open surgery, when substantial bleeding is encountered in a deep cavity or inaccessible region, the first measure should be the application of compression by packs. This provides immediate control, allows the surgeon to obtain the necessary instruments and sutures and enables him or her to define the appropriate strategy. In addition, it gives the anaesthetist the opportunity to restore an adequate blood volume. In some situations, such as in major liver injuries, packing is the correct treatment and is preferable to hepatic resections, which carry a prohibitive mortality in this situation. Once bleeding is controlled by packs, the abdomen is closed and packs are removed or replaced 24–48 hours later. Packing is not possible in MAS, but control by compression can be achieved by grasping adjacent tissue with an atraumatic grasper, which is used to compress the bleeding area, or by pressure with a gauze swab or a tampon held by graspers. An additional port is inserted to enable application of suction and irrigation. As the assistant maintains soft-tissue/gauze compression, the surgeon approaches the bleeding area with a coagulating forceps or clip applicator in the dominant hand and suction irrigation in the assisting hand. If bleeding cannot be controlled within a few minutes, the case should be converted to the open approach, in which event soft-tissue compression is maintained while the abdomen is being opened.
- Vascular control (proximal and distal) to the operative field is a wise precaution for dissection of lesions adjacent to or adherent to major blood vessels. This entails insertion of a vascular sling around the vessels at the limits of the operative field, so that vascular clamps can be readily applied in the event of haemorrhage.
- During partial resection of solid organs (liver, spleen and kidneys), temporary occlusion of the inflow vessels is undertaken, e.g. Pringle manoeuvre during hepatic resection and management of bleeding hepatic lacerations. A careful note must be kept of the period of 'warm ischaemia' of the organ in question. The duration of warm ischaemia that the organ can tolerate should not be exceeded (45 minutes for the liver) unless the organ is cooled locally.
- Surface oozing over a wide area is best controlled by spray coagulation using the argon beam system (see Ion plasma beam).

Surgical vascular control and haemostasis

Vessels can be secured before division by a variety of techniques:

- thermal coaptation and sealing by energized systems: electrocoagulation, photocoagulation, ultrasonic sealing
- ligature and clipping
- transfixation
- vascular suturing or stapling
- application of fibrin glue.

The appropriate technique used depends on the size and the exact location. Energized coagulation by electrocoagulation, photocoagulation or ultrasonic systems (see below) is perfectly safe for vessels (arteries and veins) up to 2.0 mm in diameter but is not secure for larger vessels. Clips and simple ligatures (preferably with synthetic braided absorbable materials) are used for vessels between 2.0 and 3.0 mm in diameter. The correct application of clips, which must encompass the vessel totally and be applied at right angles to the long axis of the vessel, is crucial for safe vascular control by this technique, which is useful in deep cavity work and during laparoscopic surgery. The vessel should be divided at some distance (a few millimetres) from the clip or ligature, as the splayed-out cuff is the determining factor in preventing slippage by the force exerted by the systemic blood pressure. Overtightening of a ligature should be avoided as this will result in weakening of the vessel wall by the cheese-wire cutting effect. This is especially the case in the less pliant atherosclerotic arteries of older patients. The mechanism of closure of the lumen of an artery is a complex physical process but involves gradual reduction of the lumen (by infolding of the walls) such that blood flow ceases when the walls of the vessel collapse. When studied, the force needed to achieve this in blood vessels subjected to normal blood pressure is very small (approximately 5–7 N).

Larger arteries (3.0–4.0 mm) are more securely controlled by either transfixation or double ligature, especially if the artery arises directly from the aorta (e.g. inferior mesenteric). Vessels greater than 4.0 mm are best secured by vascular clamps on either side of the proposed section. The proximal end is then

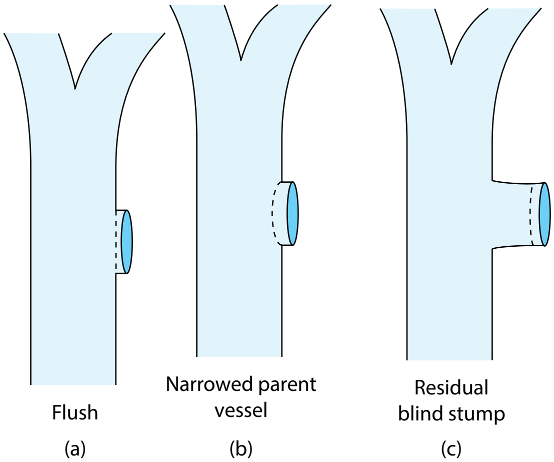

Figure 2.18 Vascular suture or a stapling of a tributary: (a) correct 'flush' control; (b) faulty because the parent vessel is constricted; (c) faulty because a blind outpouch is left. Both (b) and (c) predispose to thrombosis of the parent vessel.

sutured by 4/0 Prolene before the clamp is released. The distal end can be ligated as this will come out with the specimen. Vascular control of these large vessels by suture provides maximum security and also avoids narrowing and distortion of the parent vessel. This is especially important in securing large veins, e.g. the splenic vein at the junction with the portal vein. An alternative technique for securing large blood vessels is by vascular staplers. These are very commonly used for securing the pulmonary arteries and veins during lung resections. Whether a vascular suture or a stapling is used to secure large vessels, it is important that 'flush' control is achieved such that the parent vessel is not constricted or a blind outpouch is left. Either situation may result in thrombosis of the parent vessel (Figure 2.18).

Surgical technology

General considerations

Surgical intervention is becoming increasingly dependent on high-technology devices. This introduces new variables affecting the performance and outcome of an intervention, including malfunction of the equipment and misuse by the surgeon. The risk of errors for any particular procedure increases as the technology used becomes more complex. In addition, the technology itself is a potential source of hazard to both the staff and the patient.

Important considerations that relate to high-technology equipment used in surgical treatment include proper maintenance and training of the surgeons in safe and efficient usage. In this respect, it is essential that the surgeon understands the physics underlying the function of a particular device. Irrespective of its nature, all energized equipment that delivers energy to the patient is potentially harmful.

The power-density level reached during surgery with conventional instruments (scissors, scalpel) is a function of the sharpness of the instrument and the force applied by the surgeon. Power density is the amount of energy (mechanical, electrical, ultrasonic, photonic) applied per cm^2 of surface area of tissue and determines the effect, i.e. cutting or coagulation. In other words, the tissue effect depends on the power (W) and the surface area of contact, i.e. the effect of the same amount of energy will depend on the contact area between the instrument or probe tip and the tissue. The energy levels of the various technologies used in dissection and ablation in surgery are shown in Figure 2.19.

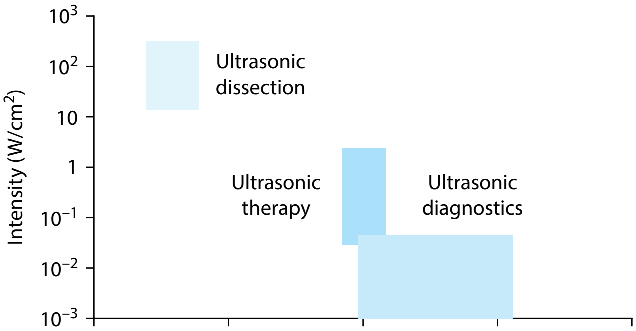

Figure 2.19 Energy levels of the various technologies used in dissection and ablation in surgery. (Reproduced from Muller and Fritzsch, *Endosc Surg Allied Technol* 1994;**2**:205–210.)

Categories of surgical technologies

Surgical technologies can be classified as follows:

- *Facilitative*: improve the efficiency of performance and reduce the level of difficulty of execution.
- *Additive*: bring technical sophistication and accuracy to surgical manipulations but are not considered essential.
- *Enabling*: make possible certain surgical procedures that would be impossible without them/open new therapeutic options.
- *Disruptive*: underpins real progress.

The designation 'disruptive technologies' was introduced by Christensen in 1997 in his book *The Innovator's Dilemma* to describe technologies that are disruptive in a positive sense because they drastically alter the way in which humans live, interact and do things. Examples of disruptive technologies in the past include the internal combustion engine, electric light bulb, railways, etc. Instances in more recent times include the internet and mobile phones. Initially disruptive technologies are more costly and less efficient than the technologies which they ultimately replace when they mature and become commonplace, such that we wonder how we managed without them. In surgery, MAS is an archetypal example of disruptive technology that, over two decades, has revolutionized surgical practice across the various surgical specialties and acted as a stimulus to radical changes in postoperative management of patients and to hospital stay, aside from being the main driver for the establishment of surgical skills laboratories. The problems with disruptive medical technologies are threefold: (1) long period between concept and realization, averaging 15–20 years, (2) maturation period and (3) training of surgeons in their safe and efficient use. Other practical issues include uptake by surgeons. The critical dynamics involved in the adoption and diffusion of new technologies are as follows:

- patients' demand for the technology (personal)
- low cost to surgeons of learning and using the procedure (professional)
- manufacturer's aggressive promotion of the technology (commercial)
- magnitude of benefit perceived by each stakeholder.

To which may be added restraint by the professional establishment and regulatory bodies such as the National Institute for Health and Clinical Excellence because of justifiable initial concerns that the new technology is both unproven and costly. This is no ready answer to this catch 22 situation as it takes time for proper assessment by appropriate clinical trials.

Image display technology

Visual perception

Human beings see the three-dimensional (3D) world with two retinas, each being two-dimensional (2D), but because of the phenomenon of retinal disparity resulting in slightly different retinal images, the brain by processing these two images enables us to enjoy true stereopsis. The human eyes perceive external electromagnetic waves of 400–700 nm (visible light) with a peak sensitivity near 555 nm. The visual apparatus sends the information from the eye to the brain after preliminary processing/coding of stimuli reaching the two retinas. The *cognitive stage* interprets the processed visual stimuli and creates an external model which enables perception. *Direct perception* relates to perception of objects in 3D space (normal everyday perception), whereas *indirect perception* is involved in viewing of pictures/images of objects. Indirect perception is thus of great importance in MAS, since the surgeon is operating from images of organs as distinct from open surgery, in which the normal direct perception is involved. The suggested mechanism involved in indirect perception is that the mind matches stimulus and memory and makes what seems to be the most likely identity and then presents this choice to consciousness. If the choice is valid this results in recognition (correct interpretation). If the choice made is incorrect, then misinterpretation results. What is important for endoscopic surgeons to realize is that the reality that is perceived is not absolute but individual, and that the correct interpretation of what is seen on the monitor by indirect perception is an acquired process which involves several factors including knowledge and experience of the displayed anatomy that essentially (irrespective of resolution and quality) remains an image and not reality.

Imaging modes

The imaging modes used in MAS are 2D, 3D and stereoscopic. 2D imaging is still the most widely used. It provides a flat image without any real depth, but, if the image quality is good (resolution, brightness and colour balance), the surgeon is able to operate safely because of pictorial (monocular) depth cues: overlapping, relative size, perspective, shadows and texture. 3D imaging is based on technologies that produce an apparently 3D image based on the after-image phenomenon (persistence of a retinal image for a few seconds using one special monitor) and the use of glasses that basically are shutting each eye alternately very quickly using polarized eyeware or liquid crystal glasses. Also there have been significant advances in 3D imaging; however, it is not true stereopsis as this requires separation of the two images and a separate telescope for each eye. In surgical practice there are only two stereoscopic systems: one used in the da Vinci robot (Intuitive Surgical) and the other in the TEM instrument (Wolfe).

A stereoscopic image contains more depth cues, enabling more accurate and efficient endoscopic manipulations. Monocular depth cues compensate somewhat for the lack of depth perception in 2D viewing and can provide comparable performance to stereoscopic (and 3D) viewing for some tasks (e.g. distance estimation). The published literature shows contradictory results on the benefits of non-stereoscopic 3D over 2D vision: some studies show better motor performances with non-stereoscopic 3D vision while others report no differences between the two imaging modalities. To some extent this controversy can be explained by the fact than all these reported comparative studies between 2D and non-stereoscopic 3D used first-generation systems, with lower resolution, brightness and inferior eye-shuttering technologies.

As the da Vinci system can toggle between stereoscopic and 2D imaging, it has enabled studies on performance by the two imaging modes. One such study demonstrated that performance using the stereoscopic imaging mode was significantly better than that achieved with 2D imaging. The time taken for the execution of all tasks was reduced by one-third and task quality improved by 25%. Dexterity was better by 25% when the surgeons used stereopsis. Accuracy based on error reduction rate improved by nearly 100%. However, other studies have reported that only the complex tasks are performed more easily and more quickly with stereoscopic viewing.

Imaging technologies: optics camera, display

The imaging chain in MAS consists of the laparoscope, the camera and the surgeon's eyes and the image display (monitor in most instances). An essential ancillary component is the light source, which is necessary for internal illumination of the body cavity and its contents.

Laparoscopes

There can be little doubt that the advent of MAS in its various forms in the early 1980s was made possible by the development of the rod–lens rigid telescope by H.H. Hopkins. Prior to then, rigid telescopes were based on the old Nitze configuration, with a series of double lenses that had to be positioned with great accuracy and the correct distance from each other in the barrel of the telescope (Figure 2.20a) with distal illumination provided by a small light bulb. These Nitze-type telescopes thus provided a dark image of poor quality without any depth of field and certainly would not have made laparoscopic surgery possible.

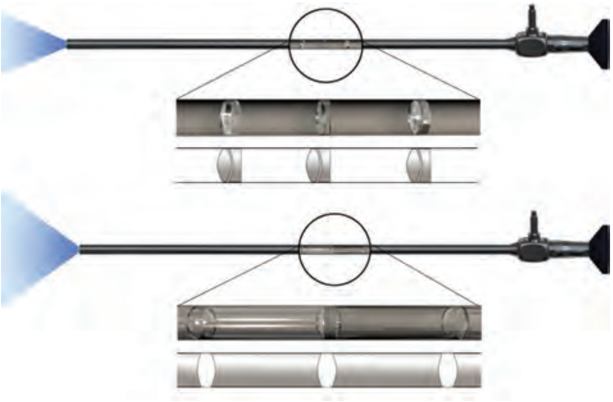

Figure 2.20 (a) Old Nitze telescope with several lens relays that had to be positioned accurately inside the barrel and had distal (bulb) illumination producing a dark often distorted image. (b) Hopkins rod–lens system that revolutionized rigid telescopes and made laparoscopic surgery possible as it produces a sharp high-quality image with depth of field.

The Hopkins system (Figure 2.20b) revolutionized endoscopy and enabled the introduction of MAS. Instead of the lens relay system, special glass rods separated by lenses placed strategically at regular intervals provide a much better aligned system capable of excellent light transmission and producing a high-resolution image with great depth of field. Moreover, the Hopkins system incorporates a light bundle that connects to a powerful light source (usually xenon) providing proximal illumination. The Hopkins rod–lens telescope is available in 10, 5 and 3 mm outer diameter. Obviously, the larger 10 mm optic produces a brighter image because of more illuminating bundles, but in practice the 5 mm telescope produces very good illumination and is used in both multiport laparoscopic surgery and SPLS. The 5 and 10 mm laparoscopes are available in three fixed viewing angles: 0°, 30° and 45°. The 0° telescope is forward viewing and is popular because it is easy to use – it sees where it points, i.e. straight ahead. Some surgeons (authors included) prefer the 30° optic because it looks down at the anatomy and, by axial rotation, either side of the median as well as up and down (normal viewing), but it does require familiarity by the camera person in its proper use. The 45° optic is rarely required in laparoscopic surgery, except perhaps in retroperitoneal operations, but it is very useful in thoracoscopic surgery.

A very recent novel laparoscope known as the Endocameleon (Storz) is capable of altering the viewing angle and is thus very useful (Figure 2.21); to date, it is only available as a 10 mm telescope.

Optoelectronic telescopes

These are different from the standard rigid laparoscopes (which couple to the camera) because the light sensor is inside the telescope, behind the lens, and indeed the telescope incorporates all other functions: light transmission through fibreoptic bundles, control of distal end, focus and zoom. All the modern flexible endoscopes belong to this category and produce high-quality imaging. They are used in NOTES and in SPLS, in which a flexible optic reduces internal collision between the telescope and the instruments. To date, they have not proved popular among surgeons in multiport laparoscopic surgery.

Cameras

The modern laparoscopic cameras are based on chip sensor devices of two basic types: charged-couple device (CCD) or complementary metal oxide semiconductor (CMOS).

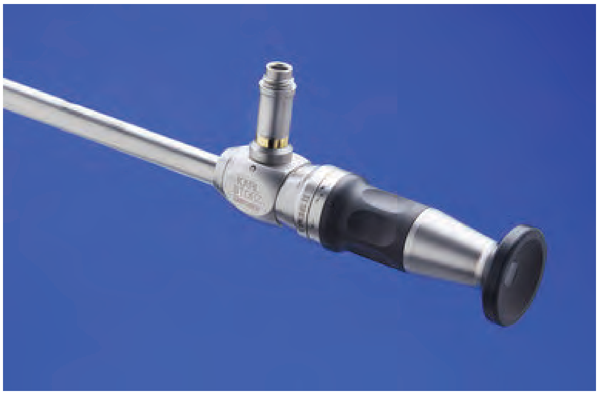

Figure 2.21 Endocameleon (Storz).

Boyle and Smith developed the CCD, for which they were awarded the Nobel Prize for Physics in 2009. Initially, the CCD was intended as a shift register (type of memory device). Tompsett *et al.* subsequently demonstrated that it could also accumulate charge via the photoelectric effect, thereby creating images. The CCD ushered in a new era of miniature high-resolution cameras that replaced all the existing imaging systems. CCD and, more recently, CMOS chips are used either at the distal end of an endoscope, forming digital (optoelectronic) endoscopes, or in a lightweight camera coupled to a Hopkins rod–lens telescope with output via a camera control unit to an external image display. Both CCD and CMOS chips are pixelated metal oxide semiconductors with an epitaxial layer of silicon as the photodetector. They accumulate signal charge in each pixel that is proportional to the illumination intensity. When exposure is complete, the CCD transfers each pixel's charge packet sequentially, as a shift register to a common output structure, which converts the charge to a voltage and sends it to the display. In a CMOS sensor, the charge-to-voltage conversion takes place in each active pixel sensor. CMOS chips have the advantages of high integration and functionality, small size and low power consumption – features which are particularly suited for small systems, mini-endoscopes, mini-robots and wireless capsule endoscopy (PillCam) introduced by Given Imaging in the 1990s.

The images from the CCD or CMOS sensors are black and white, and colour imaging is produced by filters. The first-generation CCD cameras had one chip overlaid by a Bayer

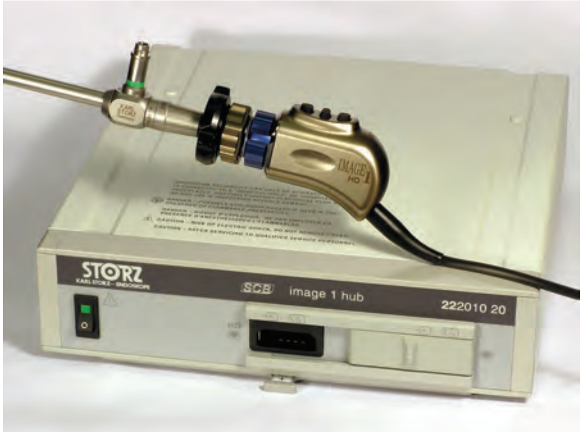

Figure 2.22 Modern progressive high-definition television camera producing progressive imaging at 1080 lines (Storz).

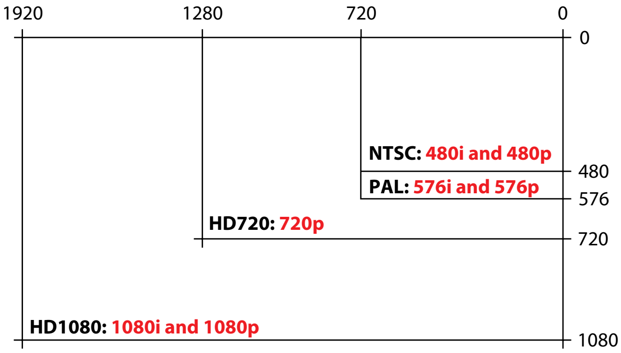

Figure 2.23 The higher resolution range of high-definition (HD) systems (camera and monitors). The HD systems range from 720 to 1080 lines. NTSC, American system; PAL, European system.

mask, which provided each square of four pixels with three filters: red, blue and two green (RGB). The second generation of laparoscopic cameras used nowadays have much better colour separation and luminance because they are equipped with three CCDs and a dichroic beam prism that splits the image into its red, green and blue components with each of the three CCDs being configured to respond to one colour. The three-chip camera has superior colour rendering and higher light sensitivity for a given aperture size. The best cameras are now equipped with three high-definition (HD) CCD chips and produce the best image quality (Figure 2.22).

Image display technology

Monitors

Standard

Cathode ray tube (CRT) monitors are being replaced by high-resolution back-lit liquid crystal display (LCD) monitors, and increasingly HD television (HDTV) systems are preferred because of their higher resolution. Although the aspect ratio (length to height) of HDTV monitors is usually 16:9, compared with 4:3 or 5:4 with standard definition (SD) monitors, there are low-end HDTV systems (720 lines) with aspect ratios in the SD range.

High definition

An HD image can contain up to five times the picture information contained in SD monitors. SD monitors consist of approximately 500–600 horizontal lines of pixels depending on the local transmission system used, whereas HD transmissions use at least 720 to over 1000 lines (Figure 2.23).

There are two HD systems: interlaced, denoted by the suffix ‘i’, and progressive, denoted by the suffix ‘p’. Each frame of the image display is made up of lines (in turn made up from pixels) that are built from above downwards on the screen and make up the picture, with the frames changing very rapidly (frame refresh rate is usually 30 Hz). In the interlaced system, the odd-numbered lines forming the picture are displayed first from above downward, e.g. 1–3–5–7 etc., until the bottom of the screen is reached, when the system starts again from the top and fills in the gaps with the even-numbered lines. The progressive system instead projects all the lines forming the screen picture simultaneously. The progressive system provides better quality imaging when the scene is changing rapidly and is sometimes referred to as full HD.

Organic light-emitting diode technology and displays

An organic light-emitting diode (OLED) is a light-emitting diode (LED) in which the emissive electroluminescent layer is a film of organic compounds/material that emit light in response to an electric current, the layer of organic semiconductor material being connected between two electrodes. There are two types of OLEDs: (1) those based on small molecules (quantum dots) and (2) those employing polymers, the latter being preferred for TV monitors. OLED displays can use either passive-matrix (PMOLED) or active-matrix (AMOLED) operating schemes. AMOLEDs require a thin-film transistor backplane to switch each individual pixel on or off, but enable higher resolution and larger display sizes.

Organic light-emitting diode and liquid crystal display systems

OLED displays do not need a backlight. In low ambient light conditions, such as in MAS operating rooms, OLED screens can achieve a higher contrast ratio than an LCD irrespective of whether this uses CRT or back-lit LED monitors. OLED displays have more control over colour rendition because they produce only pure colours when an electric current stimulates the relevant pixels. The OLED primary colour matrix is arranged in red, green and blue pixels, which are mounted directly onto a printed circuit board with each individual OLED element being housed in a special ‘micro-cavity’ designed to reduce interference from ambient light, thereby improving colour contrast. The thickness of the organic light-emitting layer is adjusted to maximize light for each of the primary colours (red, green and blue).

OLEDS require a low drive voltage and thus their power consumption is low. An LCD pixel works by applying different voltages to three electrodes, which each align to a small area of liquid crystal material to allow a certain amount of backlight to shine through a red, green and blue colour filter. These three subpixel colours then combine to form the final light output for one pixel, with the liquid crystal material acting as a variable shutter for each of these colour components. An OLED pixel works differently: light is generated directly in each subpixel when different currents are applied to the three diodes, each diode then emitting red, green or blue light. The final OLED light output results from the combination of the subpixel colours, similar to LCD.

Potential of organic light-emitting diode displays for minimal access surgery

OLED monitors provide superior quality for MAS than CRT and LCD systems for the following reasons:

- Energy efficient: use less power as they have fewer layers and no light is wasted by shining against non-transmitting liquid crystal material. Overall, OLED displays have average energy savings over LCD systems between 0% and 40% depending on use and type of LCD.
- Thinner lighter displays: as they dispense with liquid crystal, colour filter and associated layers required for LCD. The average thickness of OLED displays is 2.6 mm.
- Enhanced colour rendition: OLEDs give off a truer and wider range of colour than the LCD displays, which shine a backlight through a colour filter. OLED displays have much higher contrast ratios as a result of much richer blacks.
- OLED displays are flexible and can be transparent, and do not require glass layers to hold the liquid crystal intact.
- The colour quality of the image is the same regardless of viewing angle, as distinct from LCD systems in which the colour mix will change at wider viewing angles – they can be viewed from different angles.
- In low ambient light conditions, such as in MAS operating rooms, OLED screens can achieve a higher contrast ratio than LCD displays.
- Higher refresh rates than LCD displays, and thus more suitable for 3D viewing. The refresh rates (number of times per second a display redraws data) required for some 3D systems is twice that of an LCD to achieve the same image quality. The OLED pixels have a faster response rate as they are directly driven, whereas the LCD lighting element passes through the liquid crystal shutter.

Most OLED displays are currently used for entertainment and in higher end mobile devices, but Sony has just produced an OLED monitor for MAS that is undergoing clinical evaluation. It is likely that OLED displays will eventually replace LED and CRT systems for MAS and are likely to enable the development of image projection systems, dispensing with the need for ceiling-mounted or free-standing monitors.

Projection systems

These aim at projecting the image of the operating field on top of the patient in front of the patient, thus enabling 'gaze-down imaging' such that the surgeon can see his or her hands. Experimental studies have demonstrated that gaze-down frontal imaging on top of the patient improves both task efficiency (less time to complete the surgical task) and task quality (better execution). The first projection imaging system for MAS (ViewSite) failed and is no longer in production because of the poor quality of the projected image and indifferent ergonomic design. Since then, there have been significant developments in projector technologies and considerable research and development on disposable sterile screen material for image projection. Such a prototype system being developed in Dundee, UK, is shown in Figure 2.24.

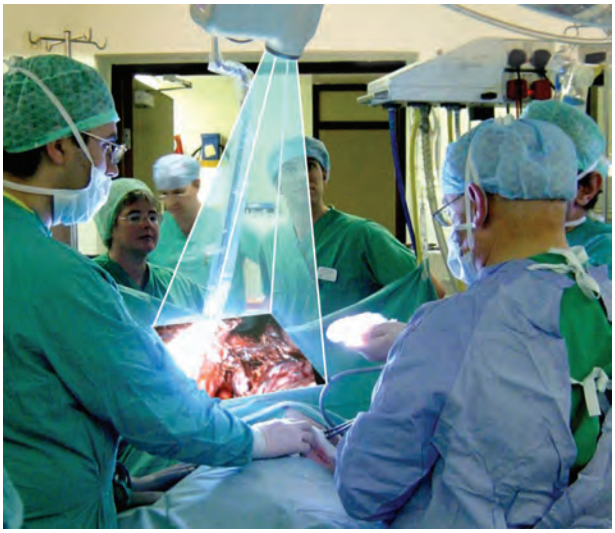

Figure 2.24 Projection image display for minimal access surgery. The image is displayed on a sterile screen on top of the patient, enabling gaze-down imaging.

It is likely that recent advances, including plastic OLED displays (2–3 mm) and laser holography capable of 'suspending' the image on top of the patient, will accelerate the development of image projection for MAS.

Ergonomics of imaging

Aside from the quality of the image display, there are important considerations that pertain to the ergonomics of viewing by the surgeon that are often overlooked but that are important because they affect both the quality and efficiency of the execution of the operation. These ergonomic principles have three components: (1) viewing position of the surgeon, (2) eye gaze and stance of the surgeon and (3) distance from the monitor.

Viewing position of the surgeon

As stressed at the start of this section, the surgeon is an integral, and indeed the most important, component of the imaging chain of MAS. Surgeons must be positioned such that they face the monitor directly and do not have to turn their head to either side for viewing the image on the screen. They must have clear vision immediately ahead with no obstacles in the viewing path.

Eye gaze and stance

Humans perform precision tasks best when they look down at the task, and this applies to all professions with MAS being no exception. Experimental studies have confirmed that the best execution of surgical endoscopic tasks is achieved when the surgeon looks down at the image (gaze-down viewing), and performance deteriorates when the surgeon operates looking up, or to the left, or to the right, to see the image of the operating field on the screen. With the current monitor-based image display systems, gaze-down viewing is problematic, especially for short individuals, but these surgeons are advised to stand on a platform. Optimal gaze-down viewing can only be achieved by projection imaging on the patient (see above).

Until such systems come on stream, the best arrangement is by an LCD display adjustable to the individual height of surgeon so that he or she can look down at it.

Distance of surgeon from monitor

This of course varies with the size of the monitor (conventionally measured as the diagonal of the image display in inches), but there is in addition great variation between surgeons. In studies with a 21 inch SD monitor, the maximal viewing distance among trained laparoscopic surgeons with corrected vision ranged from 139 to 303 cm, the minimum viewing distance (how close the surgeon is to the monitor and still see the image clearly) ranged from 90 to 183 cm, and the individual monitor optimal view distance (the distance the surgeon preferred for optimal viewing) ranged from 90 to 303 cm. This study demonstrates that each surgeon has his or her optimal viewing distance, with some preferring close-up viewing and others not.

Energized surgical dissection technology

High-frequency electrosurgery

The underlying principle involves the passage of an electric current through the tissue by means of a potential difference (voltage). The resultant flow of electrons excites the tissue molecules, notably water, creating heat energy, which causes water evaporation and tissue coagulation. High-frequency (HF) currents (greater than 100 000 Hz) are used to minimize the risk of electrical shocks. The characteristic of the applied current can be varied from sine wave to modulated, to favour cutting or coagulation, respectively (Figure 2.25). HF electrosurgery can be monopolar, bipolar or quasibipolar.

Monopolar high-frequency electrosurgery

Here, the current escapes from the electrode tip, dissipates into the receptive tissue and exits through the grounding pad (patient neutral electrode; Figure 2.26). The neutral grounding pad should have a large, even surface and is applied to the patient's upper thigh, covering a large area of clean, hairless skin to ensure a low current density. Special efforts should be made to ensure that the patient's skin does not come in contact with metal components of the operating table, chucks and restraining devices, and damp clothing. The connecting cables to the neutral and active electrode (appliance used by the surgeon) must be in perfect condition with respect to their insulation and connector plugs.

The potential hazards of HF electrosurgery include unwanted discharge and absorption of low-frequency currents (shocks), HF current burns (to patient and staff), sparking to unwanted areas (collateral damage) and capacitive coupling. Electrical current leakage can also cause malfunction of pacemakers and monitors. The monopolar HF unit must not be operated in the vicinity of an electrocardiogram electrode (minimum distance of 15 cm). Modern electrosurgical generators are smart devices in that they incorporate a microprocessor with sensor electronics that provide the necessary feedback from the electrode–tissue interface to the computer inside the generator. Used correctly, these smart generators adjust the power output to the lowest level necessary to achieve the effect. In addition, the strict limitation to the purposeful voltage range (200–500 Vp) preserves the integrity of the electrodes and increases the safety margin.

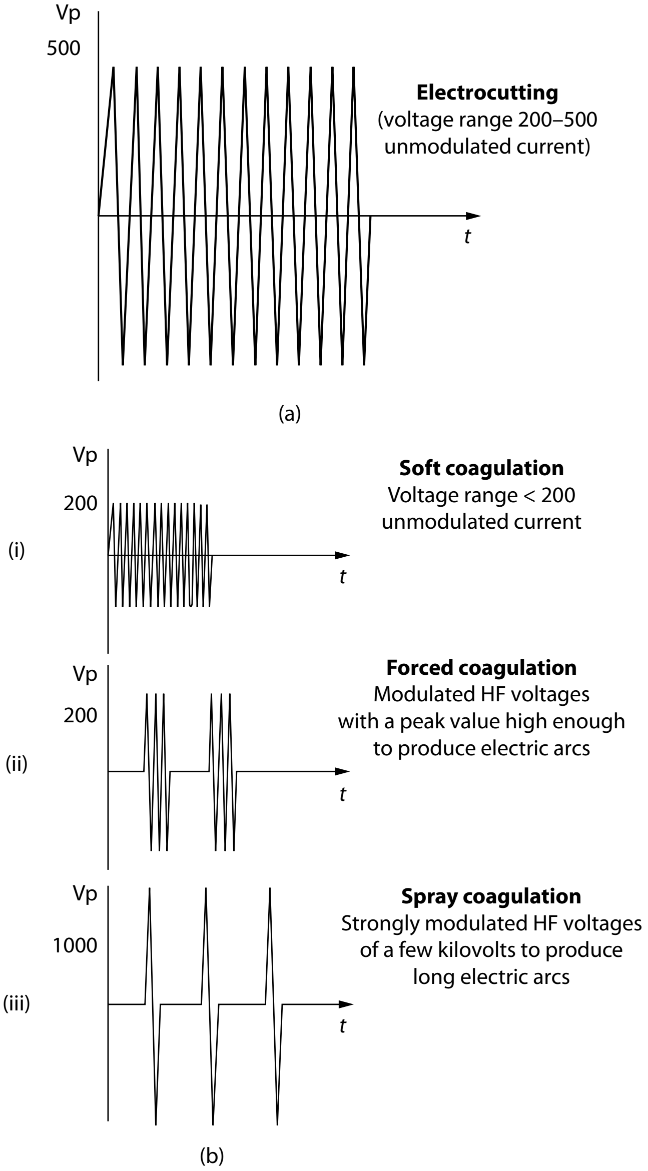

Figure 2.25 Characteristics of the applied currents in high-frequency (HF) electrosurgery. (a) Unmodulated continuous sine wave in the voltage range 200–500 V for electrocutting. (b) (i) Unmodulated current with a voltage output below 200 V for soft coagulation; this voltage does not generate electric arcs. (ii) Modulated HF voltages with a peak value high enough to produce electric arcs for forced coagulation. (iii) Strongly modulated HF voltages of a few kilovolts to produce long electric arcs for spray coagulation.

Electrocutting

HF monopolar electrocutting is achieved by the use of a continuous sine wave (unmodulated) current (Figure 2.27) of sufficient voltage (200–500 V) to produce electric arcs at the tip of the active electrode. These arcs cause an immediate vaporization of tissue in contact with the electrode, creating a series of 'cellular mini-explosions' that collectively result in cleavage. If the voltage drops below 200 V, tissue cutting cannot be achieved since electric arcs are not generated. Conversely, if the voltage rises above 500 V, the electric arcs produced are so intense that

the tissue is carbonized and the electrode may be damaged. Within the safe operating range, the depth of coagulation of the cut edges increases with increasing voltage and intensity of the electric arcs. In practice, the depth of coagulation during electrocutting is determined by the setting of the HF output power and the degree of modulation of the current (blend or mix). It is also influenced by three other factors:

1 thickness of the cutting electrode
2 rate and depth of cutting
3 impedance of the generator.

With a conventional HF unit having an impedance of 250 W, fluctuations in the current or output voltage and intensity of the electric arcs are produced by variations in the depth and rate of cutting. This may lead to carbonization of the tissue along the cut edges, particularly at the beginning and end of the cut. This problem is obviated by smart HF generators that incorporate microprocessor-controlled automatic circuits with sensory electronics referred to previously.

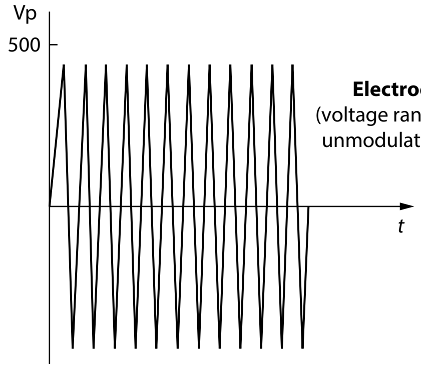

Figure 2.27 Characteristics of the applied currents in high-frequency electrosurgery. Unmodulated continuous sine wave in the voltage range 200–500 V for electrocutting.

Electrocoagulation
When an HF-modulated alternating electric current is applied specifically for heating living tissue, the temperature rise is proportional to the specific electrical resistance of the tissue, the duration of current flow and the square of the root-mean-square of the electrical current density. Largely because of the irregular current density distribution in the tissue, the temperature rises at different rates in various zones within the tissue. As the current density is largest in the zone of contact between the tissue and the electrode, the maximum temperature is reached

there, with the temperature decreasing proportionately with the distance from the contact area. The safe deployment of monopolar electrocoagulation depends on this phenomenon, since the further away the tissue from the contact area, the less likely the damage.

When the temperature of the tissue near the contact surface reaches boiling, a layer of vapour forms between the tissue and electrode, impeding current flow. Thereafter, the sequence of changes depends on the peak voltage. If this is less than 200 V, the coagulation process slows down until the tissue next to the electrode has dried out, when current flow ceases. If the current is not switched off, the coagulum becomes adherent to the electrode. When this happens, removal of the electrode will dislodge the coagulum and precipitate renewed bleeding. If the peak voltage exceeds 200 V, once the tissue next to the contact area has dried out, electric arcs are produced that carbonize and puncture the coagulum, thereby causing the coagulation process to continue unabated until the generator is switched off or the dried-up coagulum becomes so thick that it resists further puncture by the electric arcs.

There are three coagulation modes that can be used:

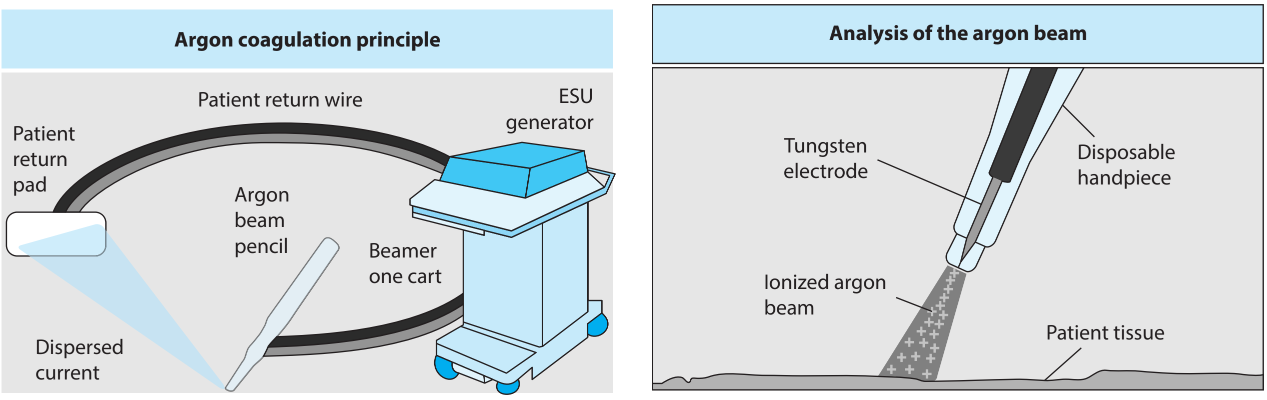
1 soft
2 forced
3 spray.

Soft coagulation is the safest for both open and laparoscopic surgery. As the peak voltage is less than 200 V, no electric arcs are generated between the electrode and the tissue. It results in desiccation of the tissue with shrinkage and no charring. *Forced coagulation* deploys high peak voltages (>500 V) to generate electric arcs to achieve deep coagulation. This may be needed in vascular areas but the risk of collateral damage is substantially higher. Forced coagulation should never be used in close proximity to important structures such as the bile duct or ureter. *Spray coagulation* is a non-contact mode in which long electric arcs are intentionally generated by strongly modulated HF voltages (a few kilovolts) to surface coagulate raw and bleeding areas or to achieve haemostasis from inaccessible vessels. Spray coagulation is used in urology during transurethral resection of the prostate.

Ion plasma beam coagulation

This is a modification of monopolar HF electrocoagulation. It utilizes a plasma of ions of an inert gas (most commonly argon) to deliver the electrical current and is directed as a focused beam to the desired target. The argon gas beamer works with certain specific generators, which are capable of providing a spray coagulating current. The electrical arcs from this current produce a conductive channel of argon ions (the plasma) in the centre of the gas cone. It thus provides non-contact coagulation with minimal charring and depth of tissue necrosis under the coagulum. The argon ion plasma appears as a blue lightning flame that darts to other wet areas of the tissue surface once the incident zone has been desiccated, hence the limited depth of coagulation. Other advantages of the system include the displacement of blood by the gas spray, thereby permitting a more direct application of current to the bleeding area, and cooling around the coagulating zone by the outer layers of the gas, thereby minimizing lateral thermal damage. There is an optional setting of the gas flow in litres in relation to the generator power output, i.e. the greater the power, the greater the gas flow required. When operating on vascular organs such as the liver, spleen and kidneys, the argon flow rate must not exceed 10.0 L/min because of the risk of gas embolism.

The delivery hand piece (disposable or reusable, flexible or rigid) essentially consists of a tube containing the energizing copper wire or tungsten wire electrode (Figure 2.28). Ion plasma coagulation can be used in open surgery, MAS and interventional flexible endoscopy to control bleeding from surface lesions, and is especially useful in arresting haemorrhage from large oozing surfaces, during liver resections and partial splenectomy or nephrectomy. During laparoscopic and thoracoscopic surgery, one of the ports must be kept open during deployment of ion plasma coagulation, to avoid a dangerous rise in the intra-abdominal and intrathoracic pressures, respectively.



(a) (b)

Figure 2.28 (a) The argon gas beamer works with certain specific monopolar generators, which are capable of providing a spray coagulating current. A ground pad is essential for the return current and the patient must be insulated from any metal component or wet surface. (b) The electric arcs from this current produce a conductive channel of ionized argon gas in the centre of the gas cone, resulting in non-contact precise coagulation with minimal charring and depth of tissue necrosis underneath the coagulum.

Bipolar electrocoagulation

Some dedicated bipolar generators operate only with bipolar probes, whereas others are capable of operating in both the monopolar and bipolar modes. In bipolar electrocoagulation, the current crosses between the two prongs of the electrode and returns to the generator without flowing through the patient. Thus, a patient ground (neutral) pad is not required and bipolar electrocoagulation is undoubtedly safer than the monopolar variety. Heating of the tissue in bipolar electrocoagulation is confined to the area between the two ends of the probe and thus collateral thermal damage is not possible. When using bipolar electrocoagulation, the minimum power necessary is used and every precaution must be taken to avoid contact between the active electrode and metal instruments. The tips of the bipolar electrode must be kept clean, as fouling with encrusted coagulum impairs the coagulation efficiency.

Although bipolar generators do not require a neutral patient ground pad, combined machines, which incorporate monopolar and bipolar circuits, do, and the safeguards described previously with regard to the safe application of the neutral ground pad must be strictly adhered to.

Quasibipolar electrocutting

This is designed to achieve electrocutting without the unmodulated current passing through the patient. Although standard monopolar/bipolar generators are used, specially designed cutting probes, which incorporate active (cutting) and return elements, are employed to apply the unmodulated current (Figure 2.29). The system is not, strictly speaking, bipolar and some current leakage to the patient is possible, especially if the return component of the electrode is fouled by charred tissue debris. A neutral ground pad is thus advisable.

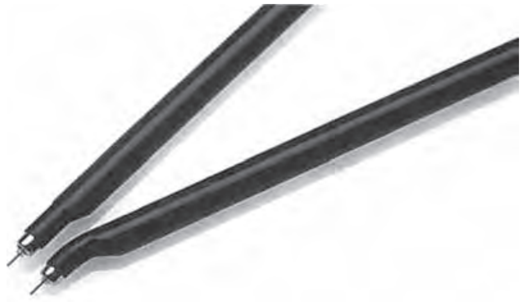


Figure 2.29 Bipolar electrocutting knife. The cutting needle can be retracted inside the instrument and the 'return' electrode.

Chemical composition of electrosurgical smoke

Electrosurgical smoke contains charred debris, cell-sized fragments, breathable aerosols and various complex organic molecules. Electrosurgical smoke used to be considered sterile but this has been questioned, particularly in relation to viral agents. The same applies to the smoke (plume) caused by lasers. At least 21 toxic or carcinogenic compounds have been positively identified in electrosurgical smoke (Table 2.4).

The use of smoke-evacuation devices and safety precautions against inhalation by theatre staff has been recommended. In endoscopic surgery, compounds produced by the high-temperature pyrolysis of protein and fat are absorbed into the systemic circulation of the patient and lead to an increased level of carboxyhaemoglobin and methaemoglobin in patients after prolonged laparoscopic operations. *In vitro* studies have shown that high concentrations of electrosurgical smoke are cytotoxic and low (sublethal) concentrations stimulate white cells and the vascular endothelium.

Ultrasonic dissection

Ultrasound waves are mechanical waves that are not audible by the human ear, i.e. have a frequency above 20 000 cycles per second (20 kHz) and propagate in matter but not in air (hence the need for acoustic coupling by conductive gel during contact diagnostic ultrasound). Ultrasonic dissectors impart a higher power density than mechanical non-energized dissection but utilize less energy than HF electrosurgery or laser surgery. As a result of this, they cause less heating of tissue with reduced penetration. The ultrasonic frequency range used for surgical dissection ranges between 20 and 60 kHz. The tissue effects (separation, cutting, coagulation) are due to the high power density (around 100 W/s) compared with diagnostic ultrasound, which, because of the low power density (0.01 W/s), has no discernible effect.

Basic design of ultrasonic dissectors

All ultrasonic dissectors, irrespective of make, consist of (1) an electrical generator, (2) a piezoelectric transducer and (3) the dissection instrument (disposable or non-disposable). The transducer and dissection instrument are incorporated in the hand piece, which is connected to the generator by an electrical cable. The generator supplies the electrical energy to the system.

Piezoelectric transducers

These are ferroelectric ceramic crystals that vibrate (expand and contract rapidly), thereby producing ultrasound waves

Table 2.4 Chemicals identified in electrosurgical smoke

Ethynyl benzene			Benzaldehyde	4-Methyl phenol
Ethyl benzene				
Toluene				

when energized by an electric current. The vibration frequency (Hz) varies with the extent of polarization of the crystals. By contrast, when piezoceramic crystals are compressed, they generate an electrical current, i.e. convert mechanical into electrical energy. It is this latter effect that is used in many household and car appliances, e.g. ignition systems. The former effect, conversion of electrical to mechanical (ultrasound) energy, is used in both diagnostic ultrasound and ultrasonic dissection.

The vibrations generated by the piezoelectric transducer are conducted by a metal rod, the length, diameter and shape of which influence the conducting efficiency to the tip of the instrument. A number of silicon rings fixed at specific vibration nodal points (Figure 2.30) prevent the rod from touching the outer protective sheath. Alternatively, the rod is covered in a Teflon sheath. An efficient system transmits most of the vibration energy to the tip of the instrument (hook knife, shears, ball, etc.) with little heating of the shaft of the instrument.

Low-power ultrasonic dissectors

These operate at a frequency of around 25 kHz and the hand piece, consisting of the transducer and free (unsheathed) rod, is non-disposable. The system allows irrigation and suction during activation, and hand pieces for both open and laparoscopic surgery are available (Figures 2.31 and 2.32). Low-power ultrasonic dissectors are the safest form of energized dissection. They do not coagulate or cut, but only cleave cells with a high water content by a process called cavitation: the intracellular water, when subjected to the pressure waves, vaporizes, forming vacuoles, which then resonate with the vibrating rod, leading to implosion of the cell. These low-power ultrasonic dissectors cannot cut fibrous organized structures (arteries, veins, ureters, etc.) and impart very little, if any, collateral damage. They are used extensively for hepatic resections, where they cleave the hepatic parenchyma, exposing the intrahepatic ducts and vessels for clipping or ligation.

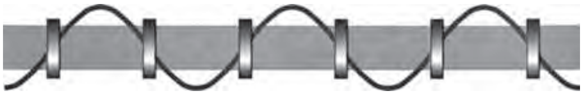

Figure 2.30 A number of silicon rings fixed at specific nodal points prevent the vibrating rod from touching the outer protective sheath of the hand piece of the ultrasonic dissector.

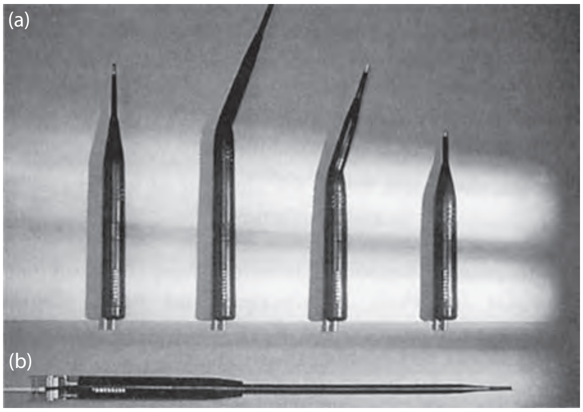

Figure 2.31 Selector probes for low-power ultrasonic dissection: (a) for open surgery; (b) for laparoscopic surgery.

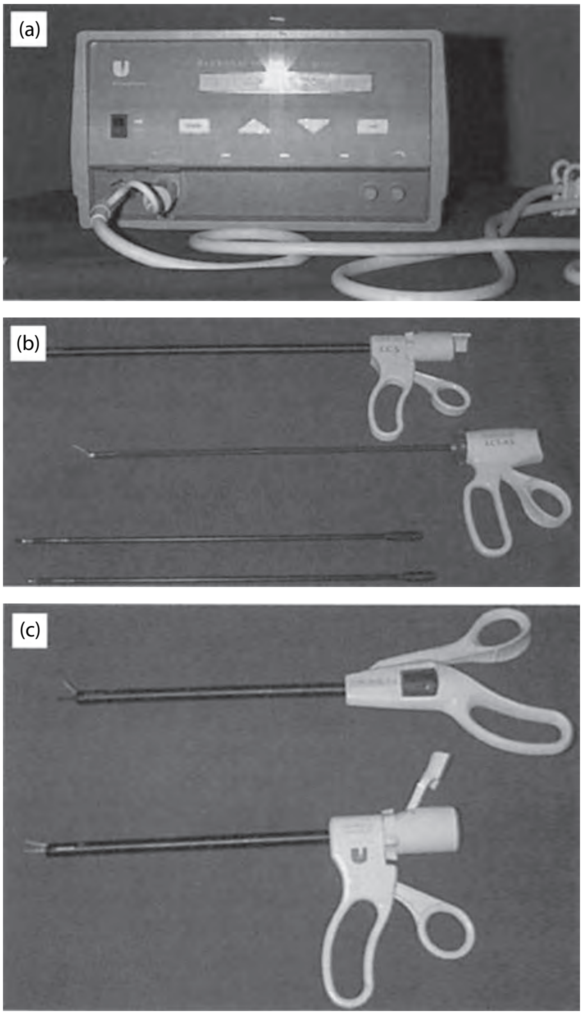

Figure 2.32 High-power ultrasonic dissection system (Ethicon). (a) Generator; (b) transducer and hand pieces for endoscopic surgery; (c) hand pieces for open surgery.

High-power ultrasonic dissectors

High-power ultrasonic dissectors have become very popular for both laparoscopic and open surgical interventions in view of their efficiency in effective coagulation and cutting, thus reducing the instrument traffic and the duration of the procedure. Instead of smoke, they produce mist that can obscure the view in laparoscopic work, especially when the sprayback fouls the lens of the telescope.

These devices operate at a frequency of 55.5 kHz and thus deliver a very high vibrational energy to the tissue such that significant heating (as much as 120°C at the instrument tip), deformation and friction effects occur at the instrument–tissue interface. Cutting is mainly due to 'tissue sawing' (high-speed frictional deformation) coupled with linear compression of the tissue (by the surgeon). Although very efficient, these high-power ultrasonic dissectors can cause collateral tissue damage, especially when the generator is used at maximum power. Animal experiments have demonstrated significant damage (on subsequent histology) to the walls of the aorta, bile duct, etc., after high-power ultrasonic dissection in the vicinity of these structures. Each generator has five power levels (1–5). Although the vibration frequency is unaltered, the excursion at the tip of the instrument varies from 50 μm at power setting 1 to 100 mm at power level 5 (Figure 2.32). Collateral damage to vital structures is diminished by operating at a maximum power setting of 3. The trade-off is slower cutting, but safety is increased. For coagulation, the power setting should be minimal (level 1) and pressure is applied gently to coapt the vessel walls and create a seal over a wide area before cutting it.

Lasers

Laser is an acronym for 'light amplification by stimulated emission of radiation' and essentially consists of a beam of highly collimated (waves are in synchrony) monochromatic light (of a single wavelength). Visible light is the relatively small range of wavelengths of the electromagnetic spectrum (380–700 nm) that can be detected by the human eye (Figure 2.33). Electromagnetic radiation of wavelengths below (ultraviolet, X-rays and γ-rays) or above (infrared, microwaves and radiowaves) this range is invisible. Laser beams can be generated of wavelengths that cover the entire visible portion of the electromagnetic spectrum (380–700 nm) as well as the ultraviolet and infrared regions.

Production of laser beams

The three components of a laser device are the lasing medium, a power source, often referred to as pump source, and a resonator or optical cavity (Figure 2.34). The lasing medium may be solid (crystals, e.g. ruby, or semiconductor diodes, e.g. gallium arsenide), gas (CO_2, helium, argon, metal vapours) or liquid (usually organic dyes in suitable solvents, e.g. rhodamine 6G in methanol). The lasing medium is energized by the pump source (electric current or light) inside the resonator. This is essentially a vacuum tube with a mirror at either end, one being totally reflective, i.e. bounces back all incident photons (light particles), and the other partially reflective, i.e. lets some photons through, and thus provides the exit point of the laser beam.

Within the resonator, the atoms of the lasing medium are excited from their resting or ground state to a higher energy level by absorption of the electrical or light energy from the power source. When the lasing medium has been excited sufficiently, a stage is reached when more of its atoms are at the upper energy level than at the ground state. This population inversion of the molecules of the lasing medium is essential for the lasing action to begin. Then, some of the excited atoms return spontaneously to the ground state, releasing this extra energy as photons of light of a wavelength characteristic of the lasing medium used (spontaneous emission of radiation). These photons interact with other excited atoms, which then return to the ground state, releasing more photons (stimulated emission of radiation). The net result is the production of waves of the same wavelength (monochromatic) travelling in the same direction and in phase with one another (spatially coherent). These photons are reflected backwards and forwards between the two mirrors, causing further stimulated emission of radiation from other excited molecules of the lasing medium. The partially reflective mirror allows some of this radiation to escape from the resonator, forming the laser beam.

Properties of laser beams

Most lasers produce collimated light; that is, the beam is parallel with minimal divergence with distance. This property enables high irradiance of tissue (power per unit area irradiated or power density). The semiconductor diode-array lasers are an exception as the light output from these solid-state devices is poorly collimated and requires focusing by suitable optics.

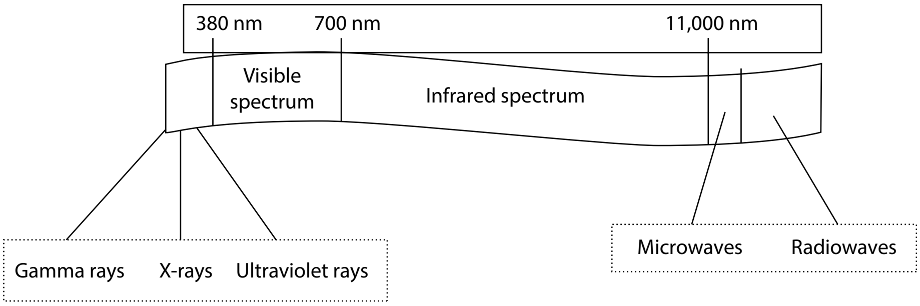

Figure 2.33 The electromagnetic spectrum.

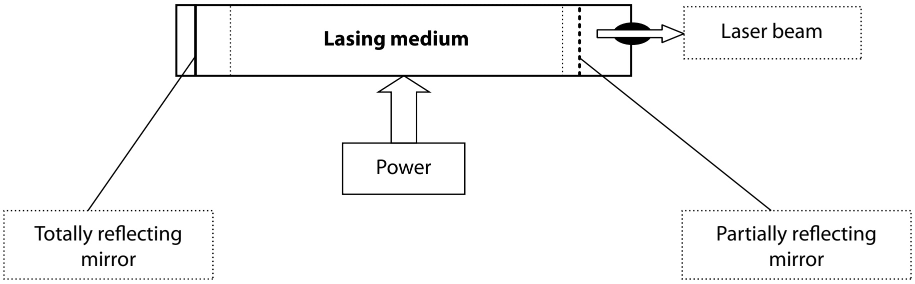

Figure 2.34 Components of laser devices: the lasing medium, a power source, often referred to as pump source, and a resonator or an optical cavity.

The second property is being monochromatic (single or very narrow lines at characteristic wavelengths). Therapeutically, this enables the choice of laser for a given effect, coagulation, cutting or activation of specific chemicals. The third property of laser beams is spatial coherence of the component waves (in phase), although this is reduced to some extent when laser light is transmitted through an optical fibre and is rapidly lost as the light penetrates the tissue.

Classification

Lasers can emit light continuously (continuous-wave lasers) or in the form of discrete multiple pulses of higher energy around 1 ms (pulsed lasers). Both types can be Q-switched. Essentially, this consists of a very fast shutter in the resonator cavity between the lasing medium and partially reflecting mirror. When the shutter is closed, there is a tremendous build-up of light energy in the chamber, which is released as a giant high-energy pulse when the shutter is open (Figure 2.35).

The majority of medical lasers operate at specific wavelengths depending on the lasing medium. Thus, if a different wavelength is needed, another laser system has to be used. This has been the main limitation of lasers in medical therapy. A tunable laser, i.e. one that enables the clinician to select different output wavelength beams for a wide range of specific applications, does not currently exist, although the dye lasers and the more recent solid-state diode-array lasers are tunable over a narrow range. Diode-array lasers will probably replace all other types in view of their portability and because they are largely maintenance free.

From the safety aspects (potential damage to the eye and skin), lasers are classified as 1, 2, 3A, 3B and 4, with class 1 being the safest and 4 the most hazardous, requiring strict safety procedures. The vast majority of medical lasers fall into class 4 because of the power needed. For this reason, laser safety management is mandatory within the UK National Health Service.

Laser safety management

This involves:

- A laser protection adviser: a physicist certified for competence in laser radiation protection.
- Provision of local rules for each specific application of a laser. These address the nature of hazards, training, user's responsibilities, methods of safe working, personal protective equipment, especially eyewear, etc.
- Laser protection supervisor: to ensure that the local rules are implemented and is usually the clinician responsible for the use of the laser.
- Laser controlled area: the operating environment of the laser. The occupancy and activity of all persons in this area are subject to control and supervision to prevent exposure to radiation in excess of the maximum permissible exposure (MPE). This is the level of laser radiation to which the eye and the skin may be exposed without suffering adverse effects. The MPE varies with the wavelength of the radiation, the pulse duration or exposure time and, for lasers operating in the 400–1400 nm range, the size of the retinal image. The distance at which the radiation exposure from the laser equals the corneal MPE is defined as the nominal ocular hazard distance. This is taken into account when specifying the boundaries of the laser controlled area. Warning signs are provided at every entrance to the laser controlled areas that medical lasers that fall within class 3B or 4 should only be operated by authorized users and a register kept of all authorized users for each laser installation.

Examples of medical lasers and their characteristics are shown in Table 2.5.

Medical applications of lasers

Lasers are used to achieve (1) therapeutic effects, (2) stimulation of healing, (3) diagnosis and (4) optical alignment.

Therapeutic effects

These are achieved by the deposition of laser energy at a radiant exposure of 10^5–10^7 J/m^2 and may be (1) photochemical, (2) photothermal, (3) photoablative or (4) photomechanical.

Photochemical effect

In clinical practice, this is referred to as photodynamic therapy (PDT). The basis for the treatment is the prior administration of a photosensitizer, e.g. haematoporphyrin derivative (HpD, Photophrin II) or various chlorin compounds, to the patient.

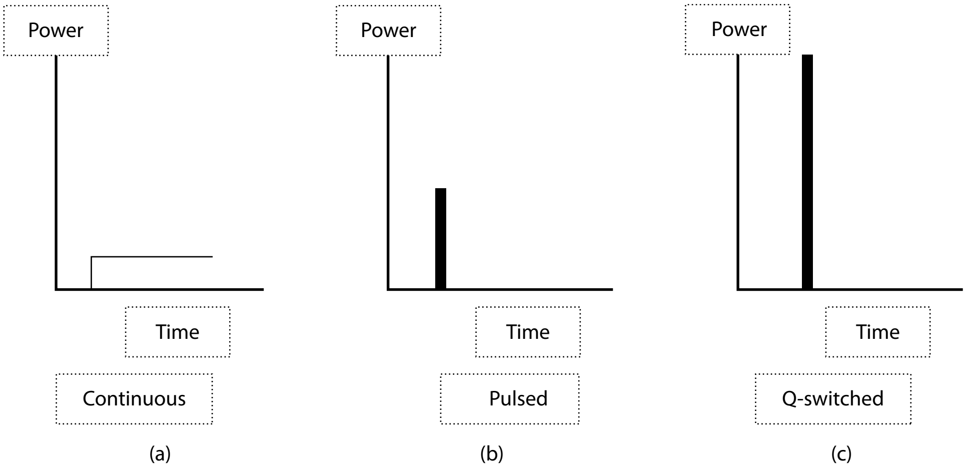

Figure 2.35 Representation of power output of (a) continuous-wave lasers; (b) pulsed lasers; (c) Q-switched lasers. The last releases a giant high-energy pulse when the shutter is open.

Table 2.5 Examples of medical lasers in current usage

Laser type	Wavelength (λ) (nm)	Output power	Beam output	Class 1–4	Beam transport
Helium/neon	630 (red)	0.5–10 mW	CW	1, 2, 3A, 3B	Fibreoptic or mirrors
Argon ion	490–510 (blue–green)	3–10 W	CW and pulsed		
Q-switched	4	Fibreoptic			
Nd:YAG	1060 (infrared)	70 W	CW and pulsed	4	Fibreoptic
Carbon dioxide	10 600	5–30 W	CW and pulsed		
Q-switched	4	Mirrors			
Dye lasers	400–700	15 J	Pulsed	4	Fibreoptic
Excimer	200 (ultraviolet)	0.1 J	Pulsed	4	Direct
KTP	532	15 W	Q-switched	4	Fibreoptic
Diomed diode-array laser	730		4	Fibreoptic	

CW, continuous wave; J, joule (watt-second); KTP, potassium titanyl phosphate; W, watt.

The photosensitizer is taken up and retained by the tumour or dysplastic tissue. If this is irradiated by the appropriate laser light (630 nm in the case of HpD), the light interacts with the photosensitizer (photochemical reaction), leading to the production of highly toxic reactive species such as singlet oxygen with necrosis of the tumour. The actual destruction is far more complex and involves both a direct cytotoxic effect on the tumour cells and destruction of the tumour circulation. With HpD, the major factor in the necrosis of the tumour is destruction of its blood supply. The problem with PDT centres on the prolonged time it takes for the body to clear the photosensitizer. This may vary from several days to weeks (depending on the photosensitizer used). During this time, the patient has to avoid exposure to sunlight because of the risk of a major burn. PDT has been used in palliation, e.g. inoperable oesophageal and bronchial carcinomas, in the ablation of mucosal cancer of the GI tract and urinary bladder, and in the destruction of Barrett's mucosa in association with medical (proton-pump inhibitors) or surgical treatment of the acid reflux. Following this treatment, regeneration with squamous epithelium may occur in some but not all cases.

Photothermal effects

These are used to obtain photocoagulation, cutting and ablation by vaporization. Some 90% of the CO_2 laser radiation is totally absorbed by tissue water within a depth of 0.2 mm. This laser is, therefore, ideal for surgical cutting and for vaporization of tissues. Argon laser penetrates more deeply before absorption (0.5 mm) and neodymium:yttrium aluminium garnet (Nd:YAG; 2 mm). The argon laser is used extensively in ophthalmology and in photocoagulation because of the high absorption of the blue–green light by haemoglobin and melanin. However, for endoscopic control of bleeding the Nd:YAG laser produces more effective coagulation and shrinkage of blood vessels in view of its greater penetration. The addition of a sapphire tip at the end of the conducting fibre or sculptured fibre tips enable contact mode laser delivery, permitting more precise endoscopic application with less smoke than the free beam mode. Interstitial laser hyperthermia produced by implantation of fibres conducting laser light into the tumour is an established modality of *in situ* ablation of tumours in solid organs such as the liver. The pulsed dye laser is the most effective laser for the treatment of port wine stains and has replaced the argon laser for this purpose.

Photoablative effects

Ultraviolet light is highly absorbed in tissue. Excimer lasers (argon fluoride, xenon chloride), which output in the ultraviolet range, are used in ophthalmology for controlled precise ablation, e.g. band keratoplasty and to refashion the corneal curvature for refractive correction. Experimentally, excimer lasers have been used to remove atherosclerotic plaques from peripheral blood vessels.

Photomechanical effects

These require giant pulsed laser energy with power densities of around 10^{16} W/m^2, such as that produced by a Q-switched Nd:YAG laser. These pulses generate localized shock waves and are used in ophthalmology for capsulotomy and iridotomy. Intraluminal stone fragmentation (e.g. impacted ductal calculi) is achieved by creating these shock waves with the end of the optical fibre touching the stones. Other lasers used for intraluminal lithotripsy are the holmium:YAG (2100 nm) and pulsed dye (504 nm) laser systems.

Stimulation of healing

Low-power laser energy (10–100 mW) produced by helium–neon (HeNe), gallium arsenide (GaAs), etc., emitting at the red end of the spectrum or near infrared region, has been shown to stimulate healing and is used in soft-tissue trauma, wound healing and relief of chronic pain due to musculoskeletal disorders.

Diagnosis

The photochemical effect can be used in the early diagnosis of severe dysplasia and *in situ* cancer of mucosal tumours accessible by endoscopy (GI tract, bronchus and urinary bladder). For this purpose, the naturally occurring substance α-amino-levulenic acid (ALA) is administered intravenously or by mouth. ALA is not itself a photosensitizer, but, following administration, it is converted into protoporphyrin ix (Ppix), which fluoresces bright pink when irradiated with violet light (410 nm). The dose given and the power density of the light used are minimal, thereby a photoablative effect is not achieved. The procedure is known as fluorescent endoscopy and has the potential for increasing the earlier detection of severe dysplasia and *in situ* cancer. Initial experience with fluorescent endoscopy using ALA has demonstrated a much higher detection of *in situ* cancer of the oesophagus, bronchus and urinary bladder than ordinary white-light endoscopy. Other photosensitizers can be used for fluorescent endoscopy but ALA is the ideal substance for this purpose because it is rapidly cleared from the body (within 24 hours) and is thus free of the problem of delayed cutaneous sensitivity to sunlight.

Laser Doppler velocimeters incorporating low-power HeNe or diode lasers (up to 2 mW) are in routine use to measure skin blood flow, blood pressure and oxygen saturation (pulse oximeters) during surgery and in high-dependency and intensive care units.

Optical alignment

Low-power lasers emitting in the red are used routinely in optical alignment systems for patient positioning in radiotherapy and also as a light-guide for invisible lasers (Nd:YAG) during photocoagulation.

Cryosurgery

Cryosurgery is a long-established modality for tissue destruction by rapid freezing followed by slow thawing. It has been used in the treatment of skin, head and neck, prostate and liver tumours (primary and secondary cancer). Recent technological developments include laparoscopic probes that enable cryoablation through the laparoscopic approach. The advantage of this is twofold:

1. The procedure can be repeated several times: this is particularly important in the management of patients with secondary hepatic tumours.
2. There is experimental evidence that cryosurgery, carried out through the laparoscopic approach with positive-pressure pneumoperitoneum, results in a greater immediate tumour cell kill. This is probably related to the reduced liver perfusion consequent on the reduction of the portal blood flow by the positive intra-abdominal pressure.

Basis of cryoablation

Rapid cooling of cells to below −40°C results in supercooling and the formation of intracellular ice crystals that disrupt cell membranes and intracellular organelles. In addition, osmotic damage occurs with rapid freezing and slow thawing. During the freezing stage, blood flow ceases completely in the iceball and, when scanned by the contact ultrasound probe, the lesion does not transmit ultrasound waves. These are reflected from the surface of the iceball, giving a characteristic hyperechoic white margin overlying an area of acoustic shadowing (Figure 2.36). As the lesion thaws, blood flow returns for several hours. During this period, fixed tumour antigens, intracellular enzymes, etc., leak into the circulation. The escape of the fixed tumour antigens is thought to initiate an immunological response, although its significance in humans remains uncertain. The serum lactic dehydrogenase level correlates most closely with the extent of cryodestruction on the day after cryosurgery, but transaminases and carcinoembryonic antigens (in the case of secondary deposits from colorectal cancer) are elevated for several days. The revascularization accounts for the 'systemic stress' syndrome after hepatic cryosurgery and limits the extent of freezing possible during any one session (to approximately 12 cm^3). During this period there is a degree of disseminated intravascular coagulation with a fall in platelets, which is maximal between the second and third postoperative day. For this reason, when large volumes of liver are frozen, haematological support is necessary. The revascularization of the cryolesion is only temporary and is invariably followed by occlusion of the blood vessels. The haemorrhagic necrosis becomes encapsulated and undergoes liquefaction over a period of several weeks. Eventually, the lesion shrinks down to a scar.

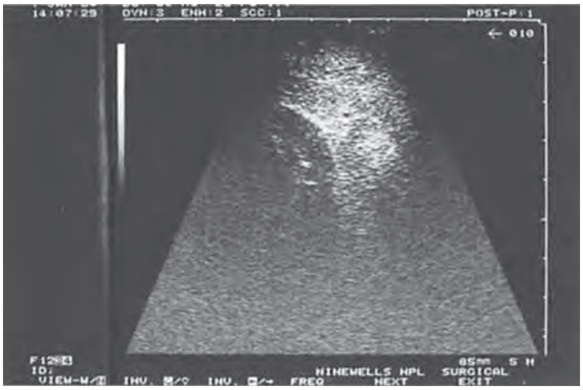

Figure 2.36 Ultrasound appearance of a hepatic iceball during laparoscopic cryotherapy. The ultrasound waves are reflected from the surface of the iceball, giving a characteristic hyperechoic white margin overlying an area of acoustic shadowing.

Modern equipment for cryosurgery of tumours

Although many cooling systems are available, the appropriate coolant used in cryosurgery for *in situ* ablation is liquid nitrogen as this has a boiling temperature of -190°C. All modern cryosurgical machines used for cryoablation of tumours use implantable rather than surface probes. These are shaped like blunt needles and those for laparoscopic use are 2.0 mm and 3.0 mm in diameter. They produce pear-shaped iceballs measuring 4–6 cm in diameter. More than one probe can be inserted into big lesions simultaneously such that the two iceballs merge to encompass the tumour. The objective is to create an iceball that is larger than the lesion by at least 1.0 cm. Modern cryosurgery machines have a gantry into which the cryoprobes dock (Figure 2.37). The cryosurgery process is monitored with ultrasound and thermocouples placed at the periphery of the lesion.

Freezing regimens

Currently, there are two schools of thought. Some practise repeated freeze–thaw cycles, on the basis that the first freeze–thaw cycle alters the thermal conductivity and thus a larger frozen volume is achieved with the second freeze. Other surgeons practise a single freeze, usually of about 20 minutes' duration, on the grounds that there is no material evidence

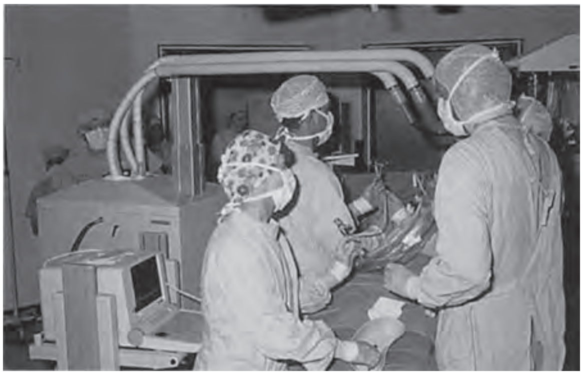

Figure 2.37 Modern cryosurgical unit with a gantry that accepts up to three cryoprobes simultaneously.

that a multiple-freeze cycle regimen produces a larger iceball than a single freeze of the same duration. In addition, the procedure is shorter.

Treatment options

Currently, hepatic cryosurgery is limited to patients who are considered inoperable either because the hepatic reserve is compromised by cirrhosis (primary liver tumours) or because the disease is bilateral and extensive (secondary deposits). However, in the latter instance, cryosurgery may be used in conjunction with resection of a liver lobe. As previously indicated, laparoscopic cryosurgery is preferable to open cryosurgery as it permits repeated application at intervals of 6–8 weeks. Repeated cryotherapy combined with systemic chemotherapy (raltitrexed with high-dose 5-early clincal) is being investigated in phase II trials.

Radiofrequency thermal ablation

In situ thermal ablation of inoperable hepatic tumours is an alternative to cryosurgery since tumour cells are susceptible to temperatures over 45°C. Experimentally, there is a documented synergistic tumour cell kill between hyperthermia and chemotherapy or radiotherapy. Thermal ablation can be achieved by interstitial laser hyperthermia, high-intensity focused ultrasound (HIFU), microwave energy and radiofrequency (RF) current. Interstitial laser hyperthermia requires expensive technology and costly maintenance. HIFU is still at the early clinical stage.

Mechanism of action

RF localized heating is currently the most feasible and cost-effective means of achieving targeted precise thermal ablation and is in established use in cardiology (e.g. treatment of arrhythmias) and neurosurgery. During RF *in situ* tissue thermal ablation, the HF alternating electric current (200 000–500 000 Hz) flows from the non-insulated tip of an electrode into the tissue. This current flow induces ionic agitation within the tissue surrounding the electrode, resulting in frictional heating, which is quite different from electrocautery, in which the current heats the probe. As a result, a localized ellipsoid lesion centred round the non-insulated tip of the probe forms. The thermal lesion is hyperechoic and its generation and size can thus be monitored by ultrasound scanning. The heat generated in the lesion depends on the current intensity (I) and its duration (T) and is described by I^2T. Although current intensity has a much greater effect on lesion volume, a minimum duration of application is needed to achieve the maximum lesion size. During application, heat is continuously generated and lost (by tissue conduction, by convection by the circulating blood and by shunting of RF current along low-resistance electrical paths) until equilibrium, determining the size of the thermal lesion, is reached. Tissue heating decreases rapidly with distance from the tip of the probe ($1/r^4$).

Modern equipment for radiofrequency *in situ* ablation of tumours

The long axis of the ellipsoid thermal lesion is approximately twice the length of the bare tip and its diameter approximates to two-thirds of the long axis. This has meant that until recently the largest thermal lesion that could be achieved *in vivo* by RF thermal ablation was approximately 2.5–3.0 cm and this limited its efficacy. Technological developments in recent years have led to (1) a new generation of microprocessor-controlled RF generators, and (2) multielectrode probes that permit the insertion of an array of single electrodes conducting RF current into the lesion following a single puncture (Figure 2.38). This configuration enables the creation of thermal lesions of up to 4.0 cm in diameter. The new RF generators provide information on the resistance of the tissue surrounding the probe, the temperature of the electrode tip, the RF current intensity passing from the electrode and the RF voltage producing the current. Thus, the control on the size of the lesion is much more precise. A neutral ground pad (electrode) is essential as current travels through the patient. Cooling of the electrode during use improves ablative power.

RF ablation has been mostly used in the treatment of secondary hepatic tumours. It can be applied percutaneously under ultrasound or CT guidance. The laparoscopic approach with contact ultrasound scanning provides a more precise and controlled approach (Figure 2.39).

Other forms of *in situ* ablation

These include high-intensity ultrasound ablation, microwave and nanohyperthermic ablation.

High-intensity ultrasound ablation

Ablation of tumours by HIFU, also known as focused ultrasound surgery, is a totally non-invasive thermal ablation

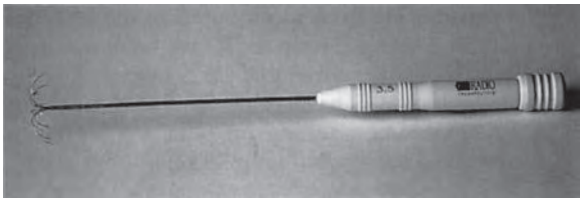

Figure 2.38 Multielectrode probe that permits the insertion of an array of electrodes conducting radiofrequency current into the lesion following a single puncture.

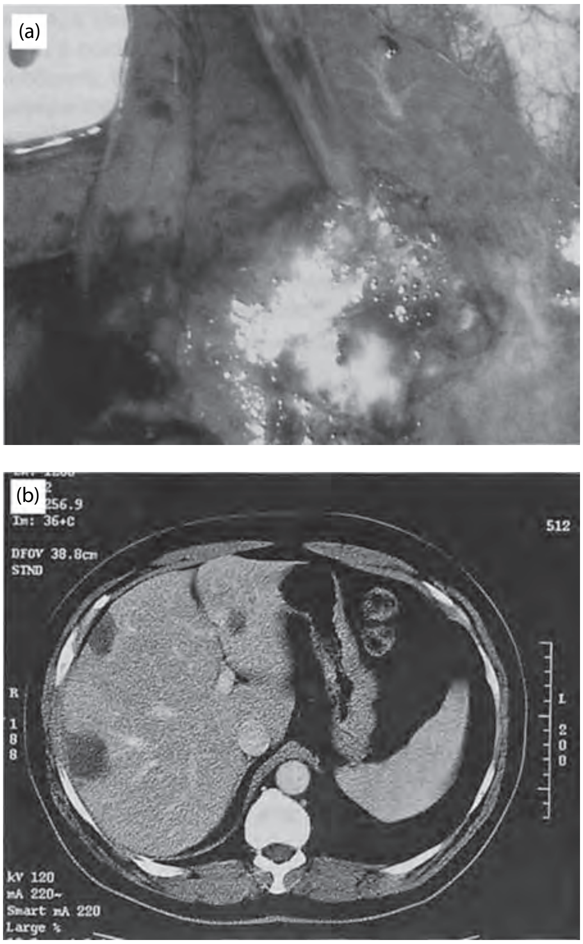

Figure 2.39 (a) Laparoscopic radiofrequency ablation of a secondary hepatic tumour; (b) appearance of the thermally ablated lesion 1 week after treatment: the lesion has a necrotic fluid centre with surrounding fibrosis.

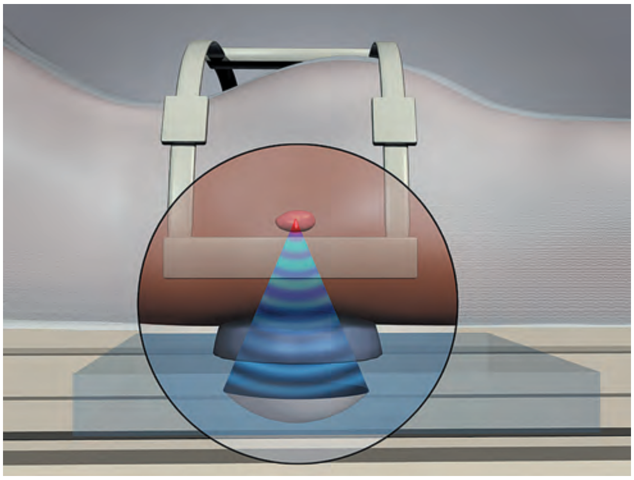

Figure 2.40 High-intensity focused ultrasound (HIFU) totally non-invasive ablation of internal tumours. The transducer is incorporated in a special operating table in the illustration. HIFU probes are also available for ablation of prostate cancer. HIFU systems are guided either by ultrasound (Chinese HIFU system) or by MRI (Insightec system).

of solid tumours. Ultrasound offers two advantages over microwave and radiofrequency techniques for *in situ* ablation: (1) deep penetration through tissues with low attenuation of the beam during transit to the intended ablation site and (2) ability to configure transducers with large dimension (50–100 mm) relative to the wavelength, thereby allowing precise focusing on the ablation zone. The clinical HIFU systems use transducers comprising an array of many elements, each controlled individually for rapid and precise alteration of the beam (Figure 2.40).

There are three forms of HIFU arrays: (1) an annular array comprising 10–20 rings arranged on the surface of a bowl; (2) an annular array divided into eight sectors; and (3) a matrix array with hundreds or thousands of tessellated elements. An annular array can move its focus electronically only along its axis and requires cumbersome mechanical motion for other directions. A sector array additionally allows a small amount of electronic control around the axis, and a matrix array allows full electronic beam control throughout a volume related to the aperture and penetration depth of the array. HIFU arrays have been developed to operate at frequencies from 250 kHz ($\lambda \approx 6$ mm) for transcranial applications to more than 3 MHz ($\lambda < 0.5$ mm) for prostate treatment. Recent developments have enhanced the efficacy of the HIFU system itself but also integrated it with MRI and ultrasound imaging systems for treatment planning and real-time guidance during the ablation.

A major advantage of MRI guidance is that it offers accurate direct temperature measurement for monitoring and control of the hyperthermic ablation in combination with excellent 3D spatial resolution and update rate. *In situ* ultrasound ablation operates mainly by heating and to a lesser extent by cavitation (microbubble formation and implosion). The tumour or pathological tissue is heated rapidly to a temperature above 56°C, often as high as 80°C, causing immediate cell necrosis. One of the advantages of HIFU is the sharply defined nature of the lesion with minimal collateral damage to surrounding normal tissues.

China has more than one HIFU systems manufacturer and has carried out procedures on the largest number of patients, now exceeding 10 000. In the West, HIFU has been used to date in:

- treatment of benign disorders: uterine fibroids, benign prostatic hyperplasia, chronic neuropathic pain
- treatment of small renal carcinomas, especially in renal transplant patients
- treatment of prostate cancer
- palliative care in malignant disease: bone metastases and pancreatic cancer
- primary treatment of solid cancers (phase II clinical trials): breast, kidney, liver, prostate.

Nanohyperthermic ablation

The potential impact on healthcare of nanotechnology is immense and has ushered a new era aptly labelled as ‘nanomedicine’. The EU Technology Platform on Nanomedicine defines nanomedicine as 'the application of nanotechnology to achieve breakthroughs in healthcare'. It exploits the improved and often novel physical, chemical and biological properties of materials at the nanometre scale.

In essence, nanotechnology entails the manufacturing and manipulation of matter at a scale ranging from single atoms to micron-sized objects. From the biological standpoint, nanomaterials match the size of naturally occurring functional units or components of living organisms and, for this reason, enable more effective interaction with biological systems.

Nanoscale and nanomaterials

A nanometre (nm) equals one thousand millionth of a metre and, for comparison, one single human hair measures 80 000 nm across and the diameter of a red blood cell is 7000 nm. By definition, the nanoscale ranges from 100 nm down to the size of atoms (approximately 0.2 nm). At this scale, the properties of materials are very different from their bulk equivalents, i.e. nanomaterials have a relatively larger surface area than bulk material and, for this reason, are more chemically reactive. Additionally, the nanoscale has a marked effect on the strength and electrical properties as the quantum effects dominate the behaviour of materials with respect to their optical, electrical and magnetic properties. Nanomaterials fall into three categories:

1. unidimensional: nanoscale in one dimension, e.g. very thin surface coatings
2. 2D, e.g. nanowires, nanotubes
3. 3D, e.g. nanoparticles, liposomes, buckey balls, etc.

In terms of their complexity and current/future evolution, nanomaterials are classified as passive, active, nanosystems and molecular nanosystems:

- *passive nanomaterials* (first generation): dispersed and contact nanostructures (aerosols, colloids), products incorporating nanostructures (coatings, nanoparticle composites, polymers, ceramics)
- *active nanostructures*: bioactive (targeted drugs, biodevices), physicochemically active (transistors, amplifiers, actuators)
- *nanosystems*: 3D networking and new hierarchical architectures, robotics
- *molecular nanosystems*: molecular devices, machines, biogenerators.

Nanohyperthemic *in situ* ablation

This is still largely experimental but holds great promise for image-guided targeted *in situ* thermal ablation of tumours. The two systems that have attracted considerable research interest both *in vitro* and *in vivo* (animal studies) are carbon nanotubes (CNTs), which may be single or multiwalled and gold nanoshells. One important property of CNTs is their strong absorbance of near infrared light with heating and release of this heat for destruction of cells – nanohyperthermic ablation of tumours. As many solid tumour overexpress surface receptor for folate, CNT-based nanohyperthermic ablation can be made selective by using folate-functionalized CNTs and then producing heating of the tumour by continuous near infrared radiation.

Gold nanoparticles can also be engineered for ablation of tumours and tumour cells most commonly as gold nanoshells, usually coated with polyethylene glycol. They react to near infrared light by the plasmon and photothermal effects. Both techniques are, however, still experimental and it will be some years before they are translated into clinical oncology.

Magnetism

Magnetism is a property by which certain materials respond at an atomic level to an applied magnetic field and are referred to as *magnetic* with *ferromagnetism* exhibited by permanent magnets being the strongest. In turn, permanent magnets produce their own persistent magnetic fields. Some materials assume magnetic behaviour only when exposed to an external magnetic field and lose this when the magnetic field is removed. These materials are called *paramagnetic* and include magnesium, molybdenum, lithium and tantalum. Other materials with very weak magnetic moments are repulsed by magnetic fields and are referred to as *diamagnetic*. Other substances, e.g. copper, aluminium, gases and plastic, are not affected by magnetic fields to any measurable extent and are categorized as *non-magnetic*.

Superparamagnetism is exhibited by certain materials in the nanocrystal scale (1–10 nm) and with temperature below the Curie temperature, when the thermal energy becomes sufficient to change the direction of magnetization of the nanocrystals, when the material assumes paramagnetic behaviour, except that instead of each individual atom being independently influenced by an external magnetic field, the magnetic moment of the entire nanocrystal aligns with the magnetic field. A pertinent example used extensively in MRI as contrast is superparamagnetic iron oxide.

A magnetic domain describes a region within a magnetic material that has uniform magnetization, i.e. where the individual magnetic moments of the atoms are aligned with one another and point in the same direction. When heated above a certain temperature (known as the Curie temperature), ferromagnetic materials undergo a phase transition, and their uniform magnetization within a domain disappears since the magnetic domain structure is responsible for the magnetic behaviour of ferromagnetic materials. The magnetic moment of a magnet is a quantity that determines the force and torque that the magnet can exert on electric currents. Both the magnetic moment and the magnetic field may be considered to be vectors with both magnitude and direction. The direction of the magnetic moment points from the south to north pole of a magnet; and the magnetic field produced by a magnet is proportional to its magnetic moment.

Other useful properties of magnets include:

- *anisotropic magnet*: has a preferred direction of orientation, i.e. magnetic properties are optimal in one direction
- *isotropic magnet*: does not have a preferred direction of magnetic orientation

- *coercive force*: the demagnetizing force necessary to reduce induction *B* to zero from the saturation state of the magnet
- *Curie temperature*: at which material loses its permanent magnetic properties
- *magnetic flux*: total magnetic induction over a given area
- *Gauss*: lines of magnetic flux/cm^2, measured in tesla (SI system)
- *length of air gap* length of the central flux path across the gap
- *remenance*: residual magnetic induction in a magnetic circuit after removal of magnetizing force.

The various types of permanent ferromagnetic materials are:

- *Al–Ni–Co–Fe (alnico)*: anisotropic along one axis – directional properties
- *ferrite*: pressed and fired strontium ferrite; immune to magnetic change with handling and high corrosion resistance
- *Nd–Fe–B*: highest performance magnets but the maximum operating temperature is 100°C; has a low resistance to corrosion but may be coated; anisotropic
- *samarium cobalt* (rare earth cobalt): substantially higher flux densities than alnico and ferrite
- *magnetic sheets*: flexible bonded sheet consisting of fine magnetic powder (barium ferrite) loaded in a flexible thermoplastic binder.

The most commonly used is Nd–Fe–B, followed by samarium cobalt.

Surgical applications

The surgical application involving the use of external magnets includes (1) retraction of hollow viscera to the anterior abdominal wall during laparoscopic surgery and SPLS; (2) external magnetic displacement of laparoscopic intraperitoneal free micro-robots and small CMOS cameras; (3) magnetic instruments for laparoscopic/endoscopic interventions based on prior localized ferromagnetization of tissues needing retraction; (4) magnetic probes, which may be permanent or electromagnetic, the latter with the use of advanced sensor technology can provide both contact and non-contact retraction; and (5) magnetic compression anastomosis.

Ferromagnetization of tissues

Technologies are being developed for localized ferromagnetization of tissues such that these can be manipulated or retracted by magnetic probes. The localized ferromagnetization is achieved in two ways:

1. surface: uses glue-based ferromedia or ferromagnetic mucoadhesive polymeric films
2. injection: special ferrofluids (intramural injection) or glue-based ferromedia (intraluminal injection).

Ferrofluids and ferromagnetic media

Ferrofluids are stable colloidal suspensions of subdomain magnetic nanoparticles (10 nm) coated with a stabilizing dispersing agent (surfactant) that prevents nanoparticle agglomeration even when a strong magnetic field gradient is applied across the ferrofluid. Following injection, even a small 3.0 cm permanent magnet at the tip of a plastic probe can provide excellent contact retraction (Figure 2.41).

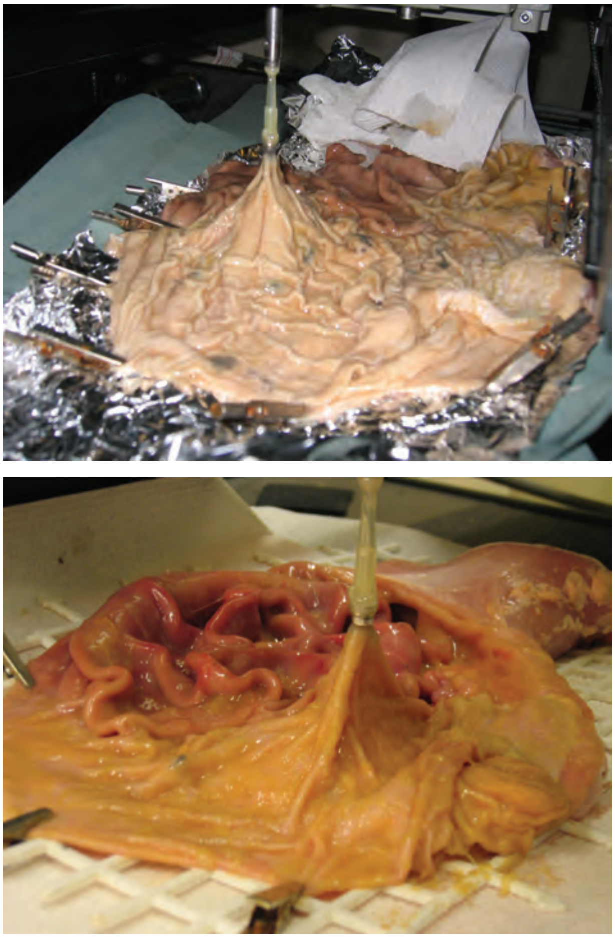

Figure 2.41 (a) Experimental magnetic retraction following submucosal injection of ferrofluid. (b) Mucosal retraction by a polymerized pellet of ferromagnetic glue medium.

Ferromagnetic media are similar suspensions in surgical glues (biological or synthetic) that are either layered on the surface of the organ to be retracted or injected into the bowel lumen. The ferromagnetic glue-based medium (usually cyanoacrylate based), when layered by applicator, binds on polymerization to the surface or serosa and the resultant pellet serves as an attracting point to the magnetic probe.

Magnetic compression anastomoses

The concept of suture less magnetic anastomosis is not new, and various technologies, such as polymer constructs (Valtrac for colonic anastomosis) and much more recently superelastic Ni–Ti (50:50), have been used to achieve intestinal anastomosis. In magnetic compression anastomosis, a magnetic dipole, consisting of two circular or oval magnets (may be ring shaped) with one magnet placed in each of the two hollow organs or intestinal loops to be anastomosed, results in immediate approximation of the two hollow organs as

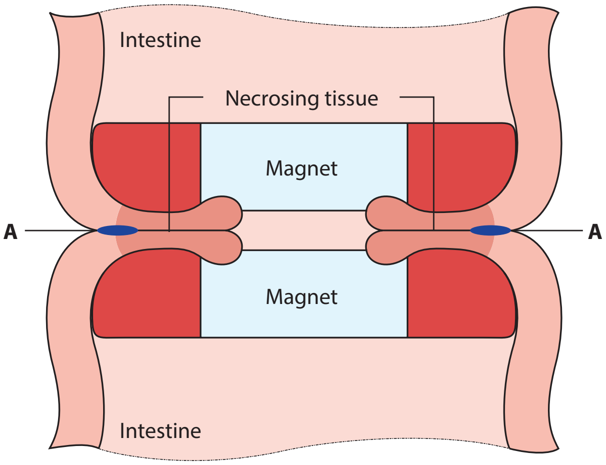

Figure 2.42 Magnetic compression anastomosis.

magnets are attracted to each other forming the dipole. What is different from other types of compression anastomoses is that the dipole exerts uniform compression with pressure necrosis over the area encompassed by the opposing surfaces of the magnets (Figure 2.42). In addition, there is stimulation of fibroblast proliferation with fibrous union between the two walls of the opposed hollow organs surrounding the magnetic dipole (points A in Figure 2.42) over a period of 5–6 days, when usually the magnetic dipole falls through the perfectly circular anastomosis and is eliminated per anus.

Magnetic compression anastomosis is used clinically for end-to-side coronary anastomosis (Ventrica Inc.), colorectal anastomosis (magnetic rings embedded in polyester) and bilioenteric anastomosis. One seminal reported case indicates the immense potential of the technique. The patient developed a stricture of the bilioenteric anastomosis after hepatic transplantation. Under total radiological control, one magnet was inserted in the hepatic duct transhepatically and the other in the jejunal loop distal to the stricture. The patient obtained total relief of jaundice following the magnetic compression hepatojejunostomy without recourse to an operation.

Robotically assisted surgery

Although often referred to as robotic surgery, this term is incorrect as the surgeon operates a sophisticated master–slave manipulator (MSM) system that reproduces the surgeon's hand movements and, through electronic processing, scales down the movements as directed by the surgeon providing great precision and abolishing tremor. In surgery there has been two such operating MSMs: Zeus (Computer Motion) and da Vinci (Intuitive Surgical), but the former is no longer in use. Thus, in essence, over the last 15 years the only system available has been the da Vinci system, although a new Canadian operating MSM (Titon Medical) is due to be launched for phase I clinical examination.

Surgical robots

There are several types of robotic devices used in various clinical scenarios in surgical practice:

- robotic arms with voice control used as camera holders in laparoscopic surgery (Aesop)
- robots used in CyberKnife (gamma-knife) radiotherapy for brain and spinal cord tumours
- robot used in orthopaedic surgery for pinning of fractures to avoid radiation exposure to the surgeon and staff
- RP7 Tele-rounding robot, which enables ward rounds of patients by a specialist from a distance
- operating MSMs for robotic-assisted MAS operations
- robotic systems for single-port/incision laparoscopic surgery
- mini-intracorporeal robots (still experimental).

Master–slave manipulator operating systems

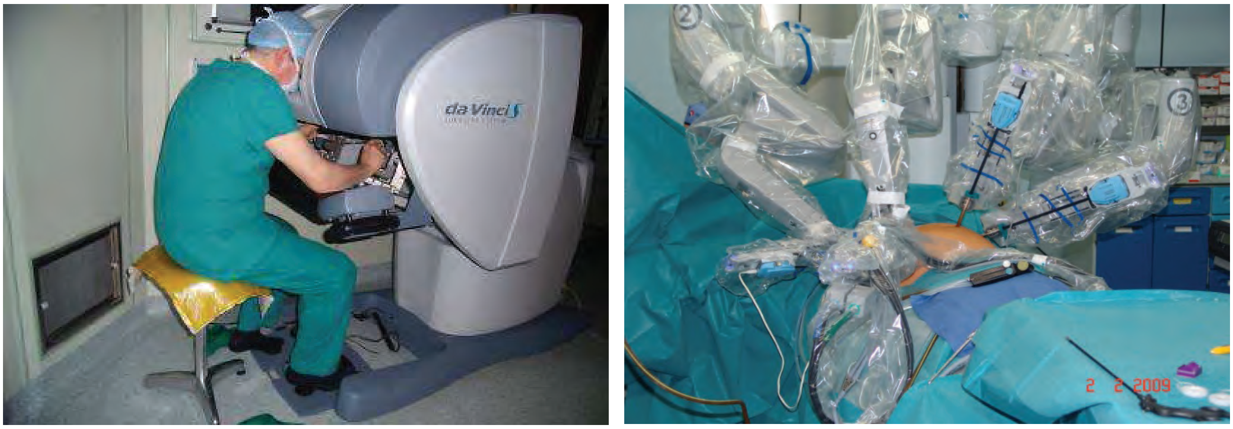
These provide an electronic platform that translates electronically the hand movement of the surgeon via robotic manipulator arms to the movement of the functional tip of the instrument (known as the end-effector) inside the patient and are used largely in complex MAS operations. They greatly facilitate the execution of complex tasks such as intracorporeal suturing by restoring all six DOFs and thereby abolishing the restricted manipulation that the surgeon has to overcome in direct manual laparoscopic surgery. In addition, the system permits motion scaling, whereby the hand movements are faithfully reproduced but scaled down to order. This has two advantages: (1) abolition of transmitted hand tremor of the surgeon and (2) vastly increased precision. Currently, there is only one MSM in well-established use in surgery – the da Vinci (Intuitive Surgical) – as the other competitor (Zeus) is no longer in production or clinical usage. The da Vinci robot has been in clinical use for 20 years and there is a considerable published literature on its use in the various surgical specialties: cardiovascular surgery, general surgery, gynaecology and urology; to date, it has enjoyed a total monopoly, but this is likely to change as several rival systems are due to be launched in 2014 when the patents owned by Intuitive Surgical will run out.

Although often referred to as robotic surgery, this term though commonly applied to these operations is incorrect and the appropriate terminology is robotically assisted surgery.

da Vinci surgical operating robot

The robot was introduced in the USA in 1995, but its first clinical use dates back to 1997 and the first version became available for purchase in 1998. Currently, there are over 2000 installed systems in the USA and another 1000 in other countries. Since 2007, the number of operations performed worldwide with robotic assistance has tripled, increasing from 80 000 surgical procedures to 205 000 cases.

The da Vinci is a teleoperated robotic system based on a master–slave control. It consists of two major subsystems. One subsystem consists of the surgeon's console, housing: (1) the image display, (2) the surgeon's master interfaces,



(a)

(b)

Figure 2.43 (a) Robotic arms covered with sterile plastic drapes with end-effectors (instruments) introduced through ports inside the insufflated peritoneal cavity. (b) Surgeon operating from da Vinci console.

(3) the surgeon's user interface and (4) the electronic controller. The second subsystem is the patient-side cart, consisting of four slave manipulator arms: three for telemanipulation of surgical instruments and a fourth dedicated to the endoscopic camera. The da Vinci system creates an immersive operating environment for the surgeon by providing both high-quality stereoscopic imaging and a man–machine interface that directly connects the surgeon's hands to the motion of the surgical instrument tips. The surgeon visualizes the stereoscopic images by display located above hand level (gaze-down viewing), thereby restoring hand–eye coordination and providing an intuitive correspondence with manipulation. Furthermore, the controller transforms the spatial motion of the instruments into the camera reference frame, such that the surgeon feels as if the hands are inside the patient's body cavity. Lastly, the da Vinci system restores the DOFs lost in direct manual laparoscopic surgery by placing a three-DOF wrist at the distal (internal) end of the instruments, enabling natural wrist pronation/supination, and providing a total of seven DOFs for control of the instrument tip (three orientation, three translation and grip). The system also uses its control system to filter out surgeon tremor, and allows a variable motion scaling from each master to each master–slave arm.

The cart consists of a moveable base with four mounted arms: one for the endoscope and three for instrument manipulation. All four arms are attached to a central column through vertical prismatic joints. Each arm has a set of non-actuated joints that position a distal set of active joints. The passive joints are adjusted manually by releasing the associated brakes. The active joints are controlled by the surgeon.

The surgeon controls the MSM seated on a stool at the computer console, which is positioned remotely from the patient. The console serves as the interface between the surgeon and the robot. The surgeon views the operation through binoculars housed in the console and an infrared beam immediately deactivates the robotic tower whenever the surgeon removes his or her eyes from the binoculars. Several mechanisms permit the surgeon to adjust specific functions of the video system and robotic arms through a panel of buttons on the armrests. The surgeon can also control motion scaling between movements of the masters and the translated motions of the robotic surgical instruments by selecting 1:1, 3:1 or 5:1 motion scaling. The surgeon is also able to control other da Vinci functions with five foot pedals (Figure 2.43a,b).

The da Vinci console provides immersive stereoscopic viewing of the operating field through the binoculars. The imaging is true stereoscopic in nature because of the retinal disparity provided by the optic as distinct from 3D imaging provided by other systems used in laparoscopic surgery, and helps the surgeon considerably in orientation and manipulation within complex operative landscapes.

Robot work space: importance of an optimal port placement

Optimal positioning of the robot and trocar sites is crucial to the expeditious performance of the surgical procedure. Port positioning has to be such as to minimize/avoid collision between the arms of the robot (external to the patient), other obstacles in the operating room and the patient. Other considerations include collision avoidance between the surgical instruments (inside the patient's body) and clashing between the instruments and/or the camera. When work space is large, the ports can maintain an adequate distance between the robotic arms, thereby avoiding external collision when both arms are in active use; in situations of restricted work space, the distance between the ports is reduced, and hence hinders optimal manipulation because of collision.

Advantages offered by the robot

Robotically assisted laparoscopic technology provides a solution to the ergonomic restrictions imposed on the surgeon by direct manual laparoscopic surgery. Several studies have confirmed that the da Vinci robot enhances the surgeon's dexterity as well as provides an ergonomically efficient and user-friendly working environment. Most of the advantages of da Vinci robotic surgery stem from the wristed instrument motions with seven DOFs, scaling for precise movements, elimination of hand tremor, stereoscopic vision and improved ergonomics.

Limitations of the da Vinci robot

Although system malfunctions are well documented in the literature, especially in relation to failures during urological interventions, these are rare and the system is very robust, as demonstrated by a malfunction rate of less than 1%. However, the complete lack of haptic feedback remains a major unresolved problem. The two important adverse consequences of this loss of haptic feedback during laparoscopic robotically assisted surgery are the inability for the surgeon to identify tissue consistency, which enables discrimination between tumour and normal tissue, and the execution of intracorporeal suturing and knot tying, especially with fine suture material, with frequent breakages of the suture material. Although several studies have concluded that operative time is slightly prolonged (because of set-up time), this has been overstated as, when the setting up of the robot is performed by designated and well-trained teams, the increase in operating time becomes insignificant. Other disadvantages of the da Vinci system include its large size which occupies precious space in the OR and restricts access to the patient, distances the surgeon from the patient on the operating table and immerses the surgeon such that he is not aware of what is happening in the OR.

SPRINT robot for single-port laparoscopic surgery

Intuitive Surgical has launched its da Vinci Single-Site kit, and initial clinical results with this system have been reported. However, enhanced dexterity in terms of instrumentation tip manoeuvrability remains unresolved with this kit and, moreover, the large size of the robot and the high cost of the da Vinci will limit its uptake among surgeons. A novel teleoperated robotic platform, SPRINT (Single-Port lapaRoscopy ImaNual roboT), has been developed (Figure 2.44) by a European consortium coordinated by the Pisa group (P. Dario and A. Cuschieri). This is a true multiarm robot aimed at enabling bimanual interventions through a single access port or incision. The manipulator arms of the SPRINT robot are introduced individually through a modified EndoCone into the insufflated peritoneal cavity by means of a cylindrical introducer and then connected to the transverse section. The SPRINT robot is thus assembled internally, and the surgeon is able to control the robot in a master–slave configuration through a dedicated console, allowing the translation of the natural movements of the surgeon's hands to the end-effectors. The SPRINT robot has equivalent functionality and DOF to the da Vinci system.

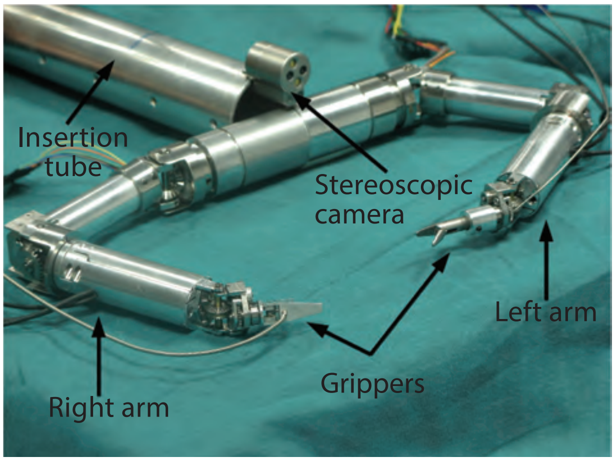


Figure 2.44 Prototype of the SPRINT (Single-Port lapaRoscopy ImaNual roboT) bimanual robot for single-port laparoscopic surgery, which is undergoing laboratory testing at the CRIM laboratory of the Scuola Superiore S'Anna, Pisa, Italy.

Preliminary laboratory tests with the SPRINT robot for SPLS have confirmed its precise functionality and work space necessary for laparoscopic operations, and preclinical animal studies are planned.

CHAPTER 3

Risk assessment and prognostic indices in surgery

OMAR FAIZ

Introduction

> Take calculated risks. That is quite different from being rash.
> George S. Patton, United States General (1885–1945)

Risk assessment is a fundamental component of contemporary surgical practice. It is important for three reasons. First, appropriate selection of surgical patients depends upon the balance between the benefit likely to be derived from the surgical procedure and the risk posed by that intervention. Second, an assessment of risk will guide the surgeon and anaesthetist as to the degree of supportive care that will be required in the postoperative period. Sometimes risk assessment will also identify factors amenable to optimization in the immediate preoperative phase. Last, adjustment for surgical risk is essential for accurate performance evaluation. Increasingly, surgeons' outcomes are subjected to professional and public scrutiny. Adjustment of outcome measures for risks that are outside the surgeon's control are essential for meaningful representation of morbidity and mortality rates in this context.

Risk assessment can take various forms. At its most subjective, the surgeon's perception, or 'gut feeling', may offer a crude prediction of outcome. This method is, however, highly dependent on the individual's experience and perception of risk. In order to overcome subjective variation in risk evaluation, quantification is necessary. A number of risk-scoring systems have been developed. Many of these combine patient demographic, comorbidity and physiological parameters along with operative factors to quantify risk. There are many different disease-specific risk assessment scores, and a smaller number of generic scoring systems.

This chapter comprises four sections. In the first, the important risk factors that influence outcome in surgery are described. In the second, methods of preoperative assessment are considered, and the third section describes some of the commonly used risk-scoring systems The fourth section describes methods of patient optimization and risk reduction in surgery.

Risk factors

Risk factors relate to age, comorbid disease, the nature of the operation, the surgeon and the patient's medication:

- age
- comorbidity
  - cardiovascular disease
  - respiratory disease and smoking
  - gastrointestinal: malnutrition, adhesions, jaundice
  - renal disease
  - haematological conditions
  - obesity
  - diabetes mellitus
  - drugs
- surgeon, operative severity and mode of admission (i.e. emergency surgery)
- gender
- social deprivation.

Age

Older patients are at increased risk of death and serious complications following major surgery. Most surgeons would agree that no patient should be denied an operation on the basis of age alone. An understanding of how the risks and benefits of surgical intervention change with advancing age is however important for informed decision-making. In the elderly population limited mobility, frequent presence of intercurrent disease and diminished reserve of cardiac, respiratory or renal function may potentially impede recovery.

It has been demonstrated in many differing specialties that outcome is inferior following surgery in older patients when compared with results from younger counterparts. For example, wound infection rates tend to be higher in elderly patients. Furthermore, postoperative stroke occurs in 1% of patients above the age 65 years and in 3% of those above 80 years. There does not appear to be an increased incidence of postoperative stroke in patients with a history of old stroke or in those with a symptomatic carotid bruit. However, a recent stroke (within 2–3 months of the operation) is thought to increase the risk of a recurrent episode. As the autoregulation of the cerebral circulation becomes impaired with age, extremes of hypotension and hypertension must be avoided throughout the perioperative period.

It is debated whether the increased risk of mortality presented to older patients undergoing major surgery is dependent on chronological age *per se* or rather that this cohort are more likely to have associated comorbidities. Certainly, elderly patients undergoing major planned surgery for colorectal cancer are more likely to die following surgery than younger patients with a similar comorbidity burden. In addition, their risk of mortality in the months that follow surgery is significantly higher than that of age-matched population controls. These mortality risks are even greater when patients present as emergencies. Patients aged older than 80 years who undergo emergency surgery for large bowel obstruction have a 30 day mortality rate that exceeds 20%.

Elderly patients therefore require careful preoperative evaluation to assess their cardiac, respiratory and renal function. An understanding of the patient's exercise tolerance, social circumstances and cognitive function are also essential. Increasingly, a multidisciplinary approach, involving surgeons, anaesthetists, elderly care physicians and physiotherapists, is being adopted to optimize perioperative care and rehabilitation in this potentially vulnerable cohort. Commonly undertaken ward interventions, such as intravenous fluid administration and blood transfusion, offer potential risks of circulatory overload in patients in whom cardiac reserve is often limited. Elderly patients also require smaller doses of narcotic analgesics or sedatives, as these are likely to precipitate confusion, both as a result of a direct action on the central nervous system (CNS) and from resulting hypoxia as a consequence of respiratory depression.

Future research will need to identify whether risk assessment in the elderly can be extrapolated beyond mortality measures to include patient-centred outcomes. Factors such as loss of independent living or quality of life that can be brought about through surgery may represent an important decision factor for many patients. In addition, the role of perioperative interventions such as prehabilitation, minimal access techniques (that incur less tissue trauma) and multimodal rehabilitation packages require further study.

Comorbidity

Cardiovascular disease

Overall, myocardial infarction and congestive heart failure are the most common causes of perioperative death in patients undergoing non-cardiac surgery. Lee and colleagues studied over 4000 patients at a tertiary centre undergoing elective non-cardiac surgery. They identified that major cardiac complications occurred in 2% of patients. Six factors were identified as independent predictors of cardiac complications: high-risk surgery, prior history of ischaemic heart disease, congestive cardiac failure, prior history of cerebrovascular disease, preoperative insulin treatment and an elevated creatinine. These factors collectively represent the Revised Cardiac Index. Rates of major cardiac complication occurred at 0.4%, 0.9%, 7% and 11% when 0, 1, 2, 3 or more factors were present respectively.

The Committee of Perioperative Cardiovascular Evaluation for Non-cardiac Surgery [American College of Cardiology (ACC) and American Heart Association (AHA) Task Force] has provided a framework for considering the management of patients with cardiac risk undergoing non-cardiac surgery. The guidelines identify three broad categories, including major, intermediate and minor clinical predictors of increased perioperative cardiovascular risks such as myocardial infarction, congestive cardiac failure and death (Box 3.1). When present, major predictors necessitate intensive management and delay or cancellation unless the condition requires emergency surgery to save life. Intermediate predictors enhance the risk of perioperative cardiac complications and require careful assessment by objective testing of the patient's cardiac performance. It should be noted that a history of myocardial infarction (occurring more than 30 days previously) or pathological Q waves on the ECG are considered as intermediate risk factors, compared with a recent myocardial infarction, which is listed as a major predictor. Minor predictors are recognized markers for cardiovascular disease that have not been proven independently to increase perioperative risk.

BOX 3.1 Clinical predictors of increased perioperative cardiovascular risk (myocardial infarction, congestive heart failure, death)

Major:
- Unstable coronary syndromes
  - Recent myocardial infarction with evidence of important ischaemic risk by clinical symptoms or non-invasive study
  - Unstable or severe angina (Canadian class III/IV)
- Decompensated congestive heart failure
- Significant arrhythmias
  - High-grade atrioventricular block
  - Symptomatic ventricular arrhythmias in the presence of underlying heart disease
  - Supraventricular arrhythmias with uncontrolled ventricular rate
- Severe valvular disease

Intermediate:
- Mild angina pectoris (Canadian class I/II)
- Prior myocardial infarction by history or pathological Q waves
- Compensated or prior congestive heart failure
- Diabetes mellitus

Minor:
- Advanced age
- Abnormal ECG (left ventricular hypertrophy, left bundle branch block, ST–T abnormalities)
- Rhythm other than sinus (e.g. atrial fibrillation)
- Low functional capacity (inability to climb one flight of stairs)
- History of stroke
- Uncontrolled systemic hypertension

In practice, these guidelines translate into the following management pathway:

- *Major predictors present*: surgery cancelled unless the condition is immediately life threatening. Intensive cardiological management takes priority. Some may require myocardial revascularization (when the stress of elective non-cardiac surgery is likely to exceed the stress of daily life) in the first instance.
- *Intermediate predictors present*: objective performance of cardiac status (e.g. echocardiography, stress ECG) undertaken, on which is based the individual risk that should influence the decision to proceed with surgery.
- *Minor predictors present*: surgery can proceed with adequate monitoring and postoperative support.

Although moderate hypertension is not an independent risk factor, its presence is often an indictor of coexisting coronary artery disease (CAD) and intraoperative fluctuations of the blood pressure in hypertensive patients are associated with myocardial ischaemic episodes. Furthermore, patients with preoperative hypertension are more likely to develop hypotension during surgery than normotensive patients, especially when blood volume is decreased. Thus, hypertension should be controlled prior to elective surgery. The exact details of any antihypertensive therapy that the patient is taking must be recorded, so that the anaesthetist can avoid adverse drug interactions and hypotensive episodes. Dysrhythymias are also important and patients with heart rates of less than 40 beats/min should be considered for pacemaker insertion preoperatively, even as an emergency. Likewise, patients with Stokes–Adams attacks have a great risk of developing complete heart block during anaesthesia and should also be paced preoperatively.

Respiratory disease and smoking

The incidence of respiratory disease in surgical patients varies with the population and in Western countries this ranges from 25% to 50%. The presence of either obstructive or restrictive pulmonary disease increases the risk of postoperative pulmonary complications and carries an adverse effect on the cardiovascular system. Thus, hypoxaemia, hypercapnia, acidosis and the increased work of breathing can cause further deterioration in patients with compromised cardiac function. Chronic obstructive airways disease is followed by a higher incidence of postoperative pulmonary complications than is restrictive airway disease. In patients with significant pulmonary disease, estimation of functional capacity (spirometry and blood gas analysis) forms part of the preoperative evaluation. Wherever possible, surgery in patients with acute respiratory infections should be postponed until 2 weeks after the resolution of the infection. The timing of elective surgery in patients with chronic respiratory disease should coincide with remission and after a period of intensive physiotherapy and appropriate treatment with antibiotics and bronchodilators. Postoperative problems, particularly chest infections and segmental or lobar collapse, are exceedingly common in patients with chronic bronchitis and in heavy smokers.

Smoking increases the risk of surgery and anaesthesia as a result of its adverse effects on the cardiovascular and respiratory systems. Carbon monoxide and nicotine are responsible for the immediate cardiovascular effects. Consequent on the formation of carboxyhaemoglobin, carbon monoxide reduces the amount of haemoglobin available for combination with oxygen and alters the oxygen dissociation curve such that the affinity of haemoglobin for oxygen is enhanced. It also has a weak negative inotropic action on the heart. Nicotine causes an increase in heart rate and blood pressure; thus, it enhances the demand of the myocardium for oxygen while carbon monoxide decreases the supply. Elimination of both carbon monoxide and nicotine with improvement in the cardiovascular fitness is complete following a 12–24 hour abstention from smoking.

There is a sixfold increase in the postoperative respiratory morbidity among patients who smoke more than 10 cigarettes per day. The responsible factors include small airways disease, hypersecretion of a thick viscid mucus and impairment of tracheobronchial clearance. Smoking also depresses the immune system. It induces reduction in immunoglobulin levels, natural killer cell activity, neutrophil chemotaxis and pulmonary alveolar macrophage activity. It is therefore recommended that smokers should abstain from smoking for about 3 months prior to surgery, as this will result in an improvement in pulmonary function, a reduction in the likelihood of postoperative respiratory morbidity and the return towards a normal immune response. Those who find it impossible to stop smoking for this period will derive some benefit in terms of improved cardiovascular function from a short period of abstinence (12–24 hours before their operation).

Gastrointestinal

Malnutrition

The malnourished patient is at increased risk of postoperative morbidity. However, assessment of nutritional status can be difficult. In essence, it is important to obtain an accurate history. There is evidence that loss of 15–20% of body weight is likely to be associated with impairment of physiological function and increased postoperative complications. Physical examination should be directed towards determining body stores of fat and protein. Inspection of the temporalis, spinatus and interosseous muscles is a good indication of muscle wasting and the presence of oedema is suggestive of protein (kwashiorkor-like) malnutrition. Contrary to popular belief, the level of plasma albumin is not a particularly good index of malnutrition. Albumin is most useful as a negative acute phase reactant and in a patient who is metabolically stressed, usually by sepsis, a low serum albumin can be expected. Thus, in the patient who is suspected of malnutrition and has a low plasma albumin, a focus of sepsis should be sought.

In malnourished patients with benign disease in whom surgery may be delayed it is common practice to attempt a period of supplemental nutrition prior to surgery. As a general guideline, body weight loss of 15–20% below the patient's ideal weight, accompanied by clinical evidence of muscle weakness and wasting, is still a reasonable indication for nutritional repletion before undertaking surgery. If possible, this should be carried out using the enteral route, thereby preserving gut immunological function. In patients with severe gastrointestinal malfunction parenteral nutrition may be required.

Adhesions

Another important gastrointestinal problem, which may affect the outcome of surgery, is the presence of intra-abdominal adhesions. Postoperative adhesions are dealt with elsewhere. Previous laparoscopy is unlikely to be associated with significant adhesions, but in the patient who has undergone a laparotomy there is a high likelihood of intra-abdominal adhesion formation. Reoperative surgery is usually lengthier and associated with greater blood loss than primary laparotomy. When multiple dense adhesions are found within the abdominal cavity, great care should be exercised in dissection as accidental enterotomies lead to a significant risk of postoperative intestinal fistulation.

Jaundice

The patient with jaundice is at significant risk of postoperative complications, particularly sepsis, disorders of clotting, renal failure, liver failure, and fluid and electrolyte abnormalities. In addition, the conjugation and metabolism of drugs and anaesthetic agents are impaired secondary to hepatocyte malfunction.

Contrary to popular belief, there is no evidence to support the view that wound healing is impaired in the presence of jaundice. Wound-healing problems are usually confined to patients who have jaundice as a result of underlying malignancy and are the result of the disease and its association with poor nutrition.

Nutritional deficits in jaundiced patients are variable and parenteral nutrition should only be used very selectively because of the risk of infection. A high intake of carbohydrate is essential and amino acid solutions containing aromatic amino acids should be used sparingly as these may precipitate encephalopathy in susceptible patients. The oral route for nutritional supplementation should be used whenever possible.

Infective complications are usually due to the fact that most patients with jaundice undergoing surgery have an obstructed biliary tree and the bile in these patients may be infected by aerobic Gram-negative organisms. Coagulation disorders are usually due to a prolonged prothrombin time resulting from a deficiency of vitamin K-dependent factors consequent on the malabsorption of this vitamin that occurs in cholestatic jaundice. Under normal circumstances the patient with jaundice who is about to undergo surgery merely requires an intramuscular injection of vitamin K. This will reverse the multifactorial clotting deficiency over 1–3 days. With severe hepatic disease, the prothrombin time may remain abnormally prolonged despite this treatment and in this case administration of fresh-frozen plasma is necessary to cover the perioperative period.

Renal

It is important to obtain an assessment of renal function prior to surgery. The patient with renal failure may require haemofiltration throughout the perioperative period and it is particularly important to establish acid–base as well as the potassium levels as acidosis and hypo- or hyperkalaemia increase the risk of cardiac dysrhythmias. Renal failure is commonly associated with heart disease and complicates its management. Correction of prerenal failure is particularly important in the emergency situation.

Haematological conditions

Anaemia

Preoperative anaemia multiplies mortality risk in patients undergoing major surgery with other associated renal and cardiac illness. The patient with profound anaemia should have this corrected preoperatively as the reduced oxygen-carrying capacity of the blood can put undue strain on the cardiovascular system as well as increasing the likelihood of chest infection and confusion. Allogenic blood replacement carries risks of transfusion-transmitted infections although these risks are substantially lower than they were three decades ago. In patients with iron-deficient anaemia, this should ideally be corrected by means of oral iron therapy if asymptomatic. A range of preoperative options including intravenous iron therapy, erythropoietin, cell salvage, acute normovolaemic haemodilution and autologous blood transfusion now exist when patients are asymptomatic or mildly symptomatic and there is sufficient time to achieve restoration. Most anaesthetists would consider preoperative allogenic blood transfusion in patients with a haemoglobin level less than 8 g/dL, with a lowered threshold when cardiac comorbidity coexists. Ideally, any patient requiring a blood transfusion should have this performed at least 1–2 weeks prior to surgery for elective conditions to allow for haemodynamic stabilization and not disadvantage oncological outcome. In addition, it must be emphasized, however, that correction of mild anaemia is neither necessary nor desirable perioperatively. In fact, some observational and randomized studies suggest a disadvantage to liberal transfusion in the perioperative period. It is, however, difficult to establish whether the poor outcome identified in the latter studies was attributable to anaemia or as a consequence of surgical blood loss *per se*. Most patients in this category have adjusted to the reduced haemoglobin load and the associated haemodilution may be beneficial in ensuring adequate tissue perfusion in the perioperative period. Indeed, controlled haemodilution down to a packed cell volume of 30–35% has been reported to reduce morbidity.

Polycythaemia, thrombocytosis and other conditions that increase blood viscosity enhance the risk of thromboembolism or haemorrhage or both. Sickle cell disease must also be recognized before surgery. The condition can occur as the homozygous state (SS), resulting in the full-blown disease with attacks of sickle cell crises and haemolytic anaemia, or as the heterozygous condition (sickle cell trait). This rarely causes problems and is associated with a normal lifespan. Although the abnormal haemoglobin S is soluble when oxygenated, it polymerizes and crystallizes out when it loses oxygen. As a result of this conformational change, the red cells become elongated, sickle shaped and rigid, leading to increased blood viscosity and an abnormal rheological state. The rigid cells block the microcirculation to various organs, inducing episodes of pain and infarction (joints, small bones of the hands and feet, spleen, etc.). Attacks of vaso-occlusive crises are precipitated by dehydration, infection, hypoxaemia (during surgery and anaesthesia), severe physical exertion, childbirth and high altitude. Repeated attacks of splenic infarction can lead to an increased susceptibility to infection by encapsulated bacteria. If sickle cell disease is suspected, the patient must be screened and special anaesthetic and perioperative precautions taken if surgery and general anaesthesia are required (adequate hydration, avoidance of hypoxaemic episodes, oxygen therapy).

In patients with a suspected bleeding disorder, a full coagulation screen must be carried out.

Diabetes mellitus

Diabetes is associated with increased need for surgery as well as enhanced perioperative risk. Patients with diabetes mellitus require special management**.** An important feature in the management of the diabetic patient is to avoid dehydration and perioperative instability of blood glucose levels. Patients with diabetes mellitus are predisposed to CAD and, when present, myocardial ischaemia is more likely to be silent than in the general population.

Obesity

Obese patients have an increased risk of respiratory complications, deep vein thrombosis, wound infection and wound dehiscence. In addition, they have a higher incidence of intercurrent disease and restricted mobility. The technical difficulty of the operative procedure is also increased, making the risks of failure of attempted minimally invasive techniques and iatrogenic injury during surgery more likely. Whenever possible, controlled weight reduction is recommended before elective surgical treatment. A significant proportion of obese patients have sleep apnoea, and are at risk of postoperative pulmonary failure. Some patients may require pre-empted respiratory support on the intensive care unit (ICU) perioperatively.

Drugs

Many patients coming to surgery are on prescription medication. Some drugs (e.g. antihypertensives) should be continued right up to the time of operation. Oral contraceptives pose the specific risk of postoperative deep vein thrombosis. In women using the combined pill (oestrogen plus progesterone), the risk of thromboembolic complications is double that of non-users. This is related to a reduction in the activity of antithrombin III induced by the additive affect of the contraceptive and general anaesthesia. This enhanced risk is not seen with the progesterone-only pill, which need not be stopped over the time of elective surgery. Current guidance suggests that oestrogen-containing contraceptives or hormone replacement therapy should be discontinued 4 weeks before major elective surgery and alternative contraceptive arrangements made. In the emergency situation, prophylactic low-dose heparin and graduated compression stockings should be used and early mobilization encouraged. Patients on warfarin are at risk of haemorrhagic complications. These patients should have the warfarin discontinued at least 3–7 days prior to surgery if the risk of venous thromboembolism is low. Surgery can be conducted safely once the international normalized ratio is <1.5. If anticoagulation is considered vital, the warfarin should be converted to a low-molecular-weight heparin or unfractionated intravenous heparin. This can be continued up to 4–6 hours before operation and recommenced about 12 hours postoperatively. The American College of Chest Physicians has issued guidance on antithrombotic prophylaxis in specific circumstances. In some emergencies acute reversal of warfarin is necessary. Under such circumstances liaison with haematologists and administration of reversal agents (vitamin K, prothrombin concentrate complex and fresh-frozen plasma) is necessary. In patients with bare metal or drug-eluting coronary stents requiring surgery within 6 weeks or 12 months of placement, respectively, it is recommended that antiplatelet therapy (aspirin and clopidogrel) is continued throughout the perioperative period.

Operative severity and operating surgeon

The magnitude of an operation as well as whether it is carried out on an elective or expedient basis represent important risk factors for subsequent outcome. Various schedules of operations exist. Operations are often classified into four grades as minor, intermediate, major and major+. Examples of such grades include:

- *minor*: local anaesthetic procedures, excision of skin lesion, drainage of breast abscess
- *moderate*: uncomplicated groin hernia repairs, uncomplicated varicose vein operations, tonsillectomy
- *major*: total abdominal hysterectomy, cholecystectomy with choledochotomy, major amputation
- *major+*: any aortic procedure, total joint replacement, colorectal resection, pancreatic or liver resection, oesophagectomy.

These classifications are used in the operative severity scoring systems described below.

Several studies comparing postoperative mortality and cardiac complications in elective versus emergency operations have concluded that mortality risk and cardiac complications are two to five times more likely to occur following emergency surgical procedures than following elective operations. Emergency presentation is often accompanied by substantial physiological and biochemical derangement. Thus, emergency surgery is itself an important risk factor across a wide range of differing surgeries.

It is also an important, if unpalatable, fact that the individual surgeon is a significant risk factor. It is now generally recognized that the outcome of similar operations can vary widely according to the skill of the operating surgical teams and it is important for all surgeons to be aware of their own results and to ensure that they conform to a reasonable standard. In the future, training must ensure that all surgery is carried out to an acceptable standard.

Preoperative assessment

Preoperative assessment is an essential aspect of surgical care. Eventual outcome will be largely dependent on measures taken as a result of the assessment of operative risks and fitness for general anaesthesia. Preoperative patient evaluation offers an opportunity for

- assessment of operative risks; appropriate patient selection
- assessment of fitness for general anaesthesia and tolerance of indicated surgery
- adequate explanation to the patient of the nature of the operative procedure, so that fully informed consent can be obtained
- optimization of nutritional, blood volume, fluid and electrolyte deficiencies when possible
- institution of prophylactic measures against common postoperative complications
- general preparation of the patient for surgery
- estimation of the amount of blood required to cover the operation
- assessment of the likely postoperative course and probable need for high-dependency or intensive care after the operation.

Careful patient selection involves balancing the relative benefits from a given surgical procedure against the known risks and complications. This decision is taken against the background knowledge of the natural history of the untreated disease from which the patient is suffering as well as the life expectancy and estimated quality of life gains achievable via operative or non-operative courses. In some circumstances a consensual decision is obvious to both patient and clinician. At other times the most appropriate course of action is less clear. Certainly, in the elective setting there is a greater amount of time to allow full consideration. A historic paternalistic approach to decision-making, in which clinicians decide the best option for their patients, is being replaced by shared decision-making models in which mutual agreement is achieved.

Good selection of patients for surgery also entails an early decision that the medical or conservative management has failed since, other risk factors being equal, the overall operative mortality is lower for procedures undertaken under elective conditions. Thus, for example, the mortality following colectomy for ulcerative colitis is highest when this is performed as an emergency because of colonic perforation, intermediate when undertaken urgently for toxic megacolon and lowest when the procedure is performed electively because of failure of medical treatment.

Another aspect of patient selection is referral for specialized treatment. The impact of surgeon case load and subspecialization has been shown across a broad range of surgical interventions. Improved outcome has been demonstrated in patients undergoing oesophagectomy, gastrectomy, thoracotomy, proctectomy and ileoanal pouch when undertaken by high-volume surgeons with appropriate expertise.

History

When assessing a patient for surgery a comprehensive history must be taken. Particular attention must be paid to the following:

- cardiac and vascular disease, including deep vein thrombosis; recent myocardial infarction is a significant risk factor
- respiratory disease and smoking habits
- other medical disorders, particularly hypertension, diabetes, bleeding diatheses and previous stroke
- detailed account of all drugs being taken
- alcohol intake
- previous experience of anaesthetics, especially intractable vomiting, volatile agents used and specific anaesthetic complications, apnoea and malignant hyperpyrexia.

Physical examination

Again, a full physical examination must be carried out. The following are particularly important:

- cardiovascular system
- respiratory system
- nutritional status, body mass index (BMI)
- mental state
- abnormalities of the face, jaw and neck
- presence of dentures.

Investigations

Investigation can be divided into routine preoperative investigations and special investigations.

Routine investigations

When carrying out routine preoperative investigations it is important to ensure that adequate information is obtained, but not at the expense of carrying out large numbers of unnecessary investigations. For this reason it is useful to think of preoperative investigations as mandatory, discretionary or unnecessary in terms of the type of operation or the status of the patient. National guidance is available in the UK for the use of preoperative tests. The requirement for individual tests is based upon the grade of surgery undertaken in addition to American Society of Anesthesiologists (ASA) grade (see below). The standard (or commonly utilized) investigations are haemoglobin, haemostasis, urea and electrolytes, urinalysis (pH, ketones, protein, blood), random blood glucose, liver function tests, sickle cell screening, chest radiograph and ECG. For ASA 2 and 3, investigations include arterial blood gases, echocardiogram and lung function tests.

In general preoperative tests are not required in children undergoing minor or intermediate complexity procedures. Young healthy adults undergoing such procedures require limited preoperative investigation. Older patients and those with significant comorbidity undergoing major or major+ grade surgery require individualized preparation. Assistance on this issue is available in the form of evidence-based ‘look-up’ tables in the UK from the National Institute for Health and Clinical Excellence.

A respiratory opinion, pulmonary function tests and blood gas analyses are advisable in patients with respiratory disease that limits function and in patients undergoing thoracotomy. Forced expiratory volume in 1 second and forced vital capacity are good indices of obstructive and restrictive airways disease and can easily be measured. Similarly, a cardiology opinion and tests of cardiac function (24 hour ECG monitoring for arrhythmia, stress ECG, echocardiography, thallium scanning) are required in patients with intermediate predictors of risk for perioperative cardiac morbidity. The exact assessment for estimation of risk in the individual patient is left to the discretion of the cardiologist.

Risk assessment scoring systems

For the majority of patients, assessment of risk is based largely on clinical assessment. In essence, this is a judgement based on history and examination of the clinical, physiological and nutritional state of the patient. If carried out by an experienced clinician, this overall assessment may be as reliable as any complex scoring system. Usually, the clinical assessment is supplemented by taking into consideration the influence of individual factors (variables) that are known to have a documented adverse effect on outcome, e.g. old age, respiratory disease, cardiac disease and renal impairment. This type of additional assessment of risk is known as univariate, as the individual risk factors are considered one at a time. By contrast, multivariate (multifactorial) assessments provide a cumulative account (score) made up of the collective contributions of various data (clinical and laboratory), which reflect the overall risk and therefore the likely outcome. Some of these are generic, i.e. they can be used across a wide range of disease states, and others refer to specific disease processes and are relevant only in specific settings.

Generic scoring systems

American Society of Anesthesiologists grade

The term ASA refers to the scoring system described in the 1960s by the American Society of Anesthesiologists to assess fitness before surgery. It provides a measure of the preoperative physical status and is summarized in Table 3.1. Initially, the system was introduced to describe and select patients for clinical trials, but it has now been adopted for routine clinical use. It has the advantage of simplicity as it does not employ specific parameters. As such, grading of the patient relies on a certain degree of subjectivity. Furthermore, ASA grades may fail to adequately describe either patients with local, as opposed to systemic, disease (e.g. myocardial infarct) or those with multiple comorbidities of differing severity. This system is, however, used widely in surgical practice.

Table 3.1 Physical status scale of the American Society of Anesthesiologists (ASA)

Class	Physical status
1	A normally healthy individual: no organic, physiological, biochemical or psychiatric disturbance
2	A patient with mild to moderate systemic disease: this may or may not be related to the disorder requiring surgical treatment, e.g. diabetes mellitus, hypertension
3	A patient with severe systemic disease that is not incapacitating, e.g. heart disease with limited exercise tolerance, uncontrolled hypertension or diabetes
4	A patient with incapacitating systemic disease that is a constant threat to life with or without surgery, e.g. congestive cardiac failure, severe and persistent angina
5	A moribund patient who is not expected to live and where surgery is performed as a last resort, e.g. ruptured aortic aneurysm
E	A patient who requires an emergency operation

APACHE II

Assessment of outcome is an important consideration in patients requiring ICU treatment, for several reasons. First, intensive care is an extremely costly resource. The cost–benefit ratio cannot therefore be ignored and it is generally agreed that intensive care is inappropriate when the probability of survival is negligible. Within any society, the facilities for intensive care treatment are finite. If a selective policy is not adopted, the available resource becomes readily exhausted and salvageable patients who become acutely ill and require intensive care support may be denied this treatment. Thus, a policy of admitting inappropriate patients to the ICU, aside from being wasteful, is counterproductive.

There has been considerable clinical research into methods that afford reliable estimates for outcome in ICU patients. The method that has been most validated and is now widely accepted is the Acute Physiology and Chronic Health Evaluation (APACHE) system. It measures the severity of the acute disease by quantifying the degree of abnormality across multiple physiological variables. The APACHE system gives a score, which is the sum total of:

- acute physiological score (APS)
- age points
- chronic health points.

The maximum possible score with a revised APACHE system (APACHE II) is 71. In practice, no patient exceeds 55, and scores in excess of 35 are associated with a mortality exceeding 85% (Table 3.2).

Acute physiological score

The original APACHE I system comprised 34 potential physiological variables, making up the APS. As this was found to be impracticable, the infrequently measured and redundant variables have been dropped in the revised APACHE II, so that the APS is now made up from 12 variables (Table 3.2). The weighting system is based on a scale of 0 (normal range) to 4 (high or low abnormal). In practice, the APS is assessed on these variables over a 24 hour period, when the most deranged physiological value for each parameter for that day is used to calculate the score, e.g. the lowest blood pressure recording, lowest pH and highest respiratory rate.

Age points

Chronological age is an independent variable in its own right and, for this reason, points are assigned to the age in years as follows: 44 and below (0), 45–54 (2), 55–64 (3), 65–74 (5), 75 and over (6).

Chronic health points

As outcome is also adversely influenced by previous history of severe organ or systemic disorders and immunodeficiency states, points are allocated for these chronic disease problems. The latter disorders must have been present before the current severe illness in order to merit inclusion. The risk of death is higher when acutely ill patients with these previous chronic health problems require emergency surgical or non-operative treatment and when they undergo elective surgical operations and are electively admitted to the ICU directly from the recovery room. For this

Table 3.2 The Acute Physiology and Chronic Health Evaluation (APACHE) II severity of disease classification system

Physiological variable	**Score**									
	High abnormal range					**Low abnormal range**				
	+4	**+3**	**+2**	**+1**	**+0**	**+1**	**+2**	**+3**	**+4**	
Temperature; rectal (°C)	≥41	39–40.9		38.5–38.9	36–38.4	34–35.9	32–33.9	30–31.9	≤29.9	
Mean arterial pressure (mmHg)	≥160	130–159	110–129		70–109		50–69		≤49	
Heart rate (ventricular response)	≥180	140–179	110–139		70–109		55–69	40–54	≤39	
Respiratory rate (non-ventilated or ventilated)	≥50	35–49		25–34	12–24	10–11	6–9		≤5	
Oxygenation: A–aDO_2 or PaO_2 (mmHg)										
(a)	FiO_2 ≥0.5, record A–aDO_2	≥500	350–499	200–349		<200				
(b)	FiO_2 <0.5, record only PaO_2				PO_2 >70	PO_2 61–70		PO_2 55–60	PO_2 <55	
Arterial pH	≥7.7	7.6–7.69		7.5–7.59	7.33–7.49		7.25–7.32	7.15–7.24	<7.15	
Serum sodium (mmol/L)	≥180	160–179	155–159	150–154	130–149		120–129	111–19	≤110	
Serum potassium (mmol/L)	≥7	6–6.9		5.5–5.9	3.5–5.4	3–3.4	2.5–2.9		<2.5	
Serum creatinine (mg/100 mL) (double point scored for acute renal failure)	≥3.5	2–3.4	1.5–1.9		0.6–1.4		<0.6			
Haematocrit (%)	≥60		50–59.9	46–49.9	30–45.9		20–29.9		<20	
White blood count (total/mm^3) (in 1000s)	≥40		20–39.9	15–19.9	3–14.9		1–2.9		<1	
Glasgow Coma Scale (GCS) score										
Score = 15 minus actual GCS score										
(A) Total Acute Physiology Score (APS): sum of the 12 individual variable points	≥52	41–51.9		32–40.9	22–31.9		18–2.9	18–2.9	15–17.9	<15
Serum HCO_2 (venous; mmol/L) (not preferred, use if no ABG)										

(B) Age points: assign points to age as follows:

Age (years)	Points
≤44	0
45–54	2
55–64	3
65–74	5
≥75	6

(C) Chronic health points

If the patient has a history of severe organ system insufficiency or is immunocompromised assign points as follows:

(a) for non-operative or emergency postoperative patients: 5 points or

(b) for elective postoperative patients: 2 points

Definitions

Organ insufficiency or immunocompromised state must have been evident *prior* to this hospital admission and conform to the following criteria:

Liver	Biopsy-proven cirrhosis and documented portal hypertension: episodes of past upper GI bleeding attributed to portal hypertension; or prior episodes of hepatic failure/encephalopathy/coma
Cardiovascular	New York Heart Association class IV
Respiratory	Chronic restrictive, obstructive or vascular disease resulting in severe exercise restriction, i.e. unable to climb stairs or perform household duties; or documented chronic hypoxia, hypertension (>40 mmHg) or respirator dependency
Renal	Receiving chronic dialysis

Table 3.2 (Continued)

Immunocompromised	The patient has received therapy that suppresses resistance to infection, e.g. immunosuppression, chemotherapy, radiation; long-term or recent high-dose steroids, or has a disease that is sufficiently advanced to suppress resistance to infection, e.g. leukaemia, lymphoma, AIDS

APACHE II score

Sum of (A) + (B) + (C)

(A) APS points ....

(B) Age points ....

(C) Chronic health points ....

Total APACHE II..

ABG, arterial blood gas; GI, gastrointestinal.

reason, five points are awarded to non-operative or emergency postoperative patients as opposed to two points for elective postoperative patients with the same chronic health problems.

Mortality and APACHE II scores in patients treated in intensive care units

The relationship of the APACHE II system with mortality in patients admitted to ICUs is illustrated in Figure 3.1. There is a clear-cut inverse correlation between APACHE scores and survival; when scores exceed 29, the mortality increases sharply, and above 35 the chances of survival are so small as to be negligible. Within a given APACHE score range, the overall risk of hospital death varies in accordance with the underlying aetiology of the acute disease. Thus, in the score range 10–19, ICU patients with gastrointestinal bleeding or septic shock have a mortality of 27–30%, as distinct from 13% in patients with congestive cardiac failure.

POSSUM

While the APACHE II system is ideal for predicting mortality in the ICU, it is not so useful for the prediction of mortality and morbidity across the general surgical spectrum. The reasons for this are that it requires 24 hours of observation and the analysis of a large number of variables. As such, a simple scoring system for general surgical patients whose main use would be in surgical audit was developed. To start with, 62 factors were assessed by multivariate discriminate retrospective analysis. Of these, 35 covariates were then assessed prospectively to produce a system that has been termed Physiological and Operative Severity Score for the Enumeration of Mortality and Morbidity (POSSUM). This is divided into two sections: the physiological score, to be scored at the time of surgery, and the operative severity score. These are detailed in Tables 3.3 and 3.4.

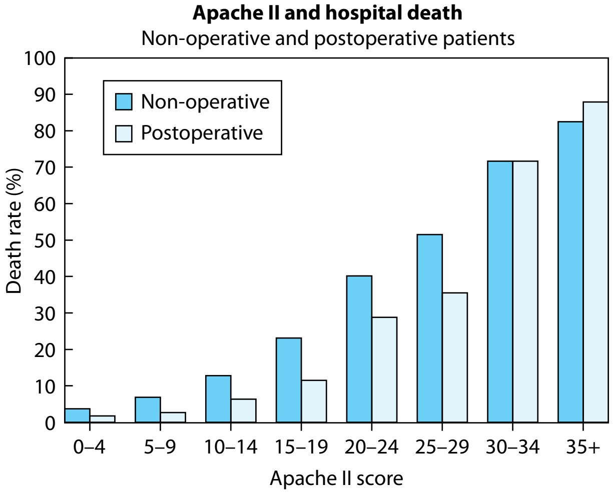

Figure 3.1 Relationship between Acute Physiology and Chronic Health Evaluation (APACHE) II scores and hospital mortality ($n = 5815$). (From Knaus *et al.*, *Crit Care Med* 1985;13:818–829.)

Thus, POSSUM requires scores from 12 physiological and six operative severity variables to estimate the risk of postoperative morbidity or mortality. For morbidity, the equation is:

$$\ln[R/(1-R)] = -5.91 + (0.16 \times \text{physiological score}) + (0.19 \times \text{operative severity score})$$

For mortality, the risk equation is:

$$\ln[R/(1-R)] = -7.04 + (0.13 \times \text{physiological score}) + (0.16 \times \text{operative severity score})$$

Prospective studies have shown POSSUM to be accurate in predicting both morbidity and mortality. Early criticism that POSSUM overpredicted mortality in low-risk groups have not been substantiated in later studies. These concerns did, however, lead to subsequent development of the Portsmouth, or P-POSSUM, predictor of mortality. Similar reports of overprediction of death in surgical subspecialties have also led to the development of individualized vascular (V-POSSUM) and colorectal (CR-POSSUM) scoring systems.

Disease-specific scoring systems

Over the years many scoring systems for different disease states or forms of trauma have been developed. In order to provide a representative example, the commonly used scoring systems for cirrhosis of the liver, pancreatitis, head injury, general trauma and tumour prognosis are described below.

Table 3.3 Physiological and Operative Severity Score for the Enumeration of Mortality and Morbidity (POSSUM): physiological score (to be scored at the time of surgery)

Parameter	Score			
	1	2	4	8
Age (years)	<60	61–70	>71	
Cardiac signs	No failure	Diuretic, digoxin, antianginal or hypertensive therapy	Peripheral oedema; warfarin therapy	Raised jugular venous pressure
Chest radiograph		Borderline cardiomegaly	Cardiomegaly	
Respiratory history	No dyspnoea	Dyspnoea on exertion	Limiting dyspnoea (one flight)	Dyspnoea at rest (rate >30/min)
Chest radiograph		Mild COAD	Moderate COAD	Fibrosis of consolidation
Blood pressure (systolic) (mmHg)	110–130	131–170	>171	–
		100–109	90–99	<89
Pulse (beats/min)	50–80	81–100	101–120	>121
		40–49		<39
Glasgow Coma Scale score	15	12–14	9–11	<8
Haemoglobin (g/100 mL)	3–16	11.5–12.9	16.1–17.0	10.0–11.4
		17.1–18.0	<9.9	>18.1
White cell count ($\times 10^{12}$/L)	4–10	10.1–20.0	>20.1	
		3.1–4.0	<30	
Urea (mmol/L)	<7.5	7.6–10.0	10.1–15.0	>15.1
Sodium (mmol/L)	>136	131–135	126–130	<125
Potassium (mmol/L)	3.5–5.0	3.2–3.4	2.9–3.1	<2.8
		5.1–5.3	5.4–5.9	>6.0
Electrocardiogram	Normal		Atrial fibrillation (rate 60–90)	Any other abnormal rhythm or >5 ectopics/min; Q waves or ST–T wave changes

COAD, chronic obstructive airways disease.

Table 3.4 Physiological and Operative Severity Score for the Enumeration of Mortality and Morbidity (POSSUM): operative severity score

Parameter	Score			
	1	2	4	8
Operative severity	Minor	Moderate	Major	Major+
Multiple procedures	1		2	>2
Total blood loss (mL)	<100	101–500	501–999	>1000
Peritoneal soiling or blood	None	Minor (serous fluid)	Local pus	Free bowel content, pus
Presence of malignancy	None	Primary only	Nodal metastases	Distant metastases
Mode of surgery	Elective		Emergency resuscitation of >2 hours possible	Emergency (surgery <2 hours needed)

Definitions of surgical procedures with regard to severity are guidelines; not all procedures are listed and the closest should be selected.

Cirrhosis of the liver

In cirrhosis of the liver, the prognosis is largely dependent on liver function. This is particularly important in assessing the risk of surgical procedures on patients with cirrhosis. Various grading systems have been devised. The most widely used is that of Child, modified by Pugh (Table 3.5). Grade A indicates a good prognosis, grade B a moderate prognosis and grade C a poor prognosis. An alternative classification is that of the Paul Brousse Hospital devised by Bismuth (Table 3.6).

Acute pancreatitis

In acute pancreatitis the diagnosis is confirmed by a rise in the serum amylase. Although amylase levels can be used for diagnosis they are not prognostic. It is also important in this context to estimate disease severity in order to rationalize treatment. Decisions relating to whether or not high-dependency or intensive care placement is indicated, use of antibiotics and whether early endoscopic retrograde cholangiopancreatography in patients with gallstone disease is indicated can be made upon the basis of whether patients are predicted to be at substantial risk of mortality or septic complications. For this reason, scoring systems have been developed using biochemical parameters. In 1992 the Atlanta classification was introduced. Although its limitations are widely reported, it permits classification of pancreatitis into mild and severe disease. Systems that predict for severity and the development of complications are the Ranson and Glasgow criteria. These scoring systems were developed using US and UK populations, respectively. They are summarized in Table 3.7. Ranson/Glasgow scores ≥3 define severe (necrotizing) pancreatitis and predict a protracted clinical course along with a higher mortality risk.

Scoring system for the assessment of head injury

One of the most frequent problems encountered by the clinician in the emergency department is to decide whether a patient is responding appropriately and is fully aware of their surroundings.

Table 3.5 Pugh modification of Child's classification system for assessing severity of hepatic dysfunction in cirrhosis

Parameter	Points awarded for abnormality		
	1	2	3
Encephalopathy	None	1–2	3–4
Ascites	Absent	Slight	Moderate
Albumin (g/L)	35	28–35	<28
Prothrombin time (seconds; prolonged)	14	4–6	6+
Bilirubin (mmol/L)	15–30	30–45	45+
Bilirubin patients in primary biliary cirrhosis	15–60	60–150	150+

Grade A, 5–6 points; grade B, 7–9 points; grade C, 10+ points.

Table 3.6 Paul Brousse Hospital classification of severity of chronic liver disease

Parameter	Number of criteria
Albuminaemia <3.0 g/100 mL	1
Hyperbilirubinaemia >30 mol/L	1
Encephalopathy	1
Clinical ascites	1
Coagulation factor II and V 40–60%	1
Coagulation factor II and V <40%	2

A, none of the criteria; B, one or two criteria; C, three or more criteria.

Table 3.7 Prognostic grading systems for acute pancreatitis

Ranson	Glasgow/Imrie
At admission/diagnosis	Within 48 hours
Age >55 years	Age >55 years
WBC >16 000/mm^3	WBC >15 000/mm^3
Blood glucose >10 mmol/L	Blood glucose >10 mmol/L (not diabetic)
AST >250 SF units/dL	Serum albumin <32 g/L
LDH >350 IU/L	Blood urea >16 mmol/L (no response to i.v. fluids)
Within 48 hours	LDH >600 IU/i
Haematocrit fall >10%	PaO$_2$ <60 mmHg
Blood urea nitrogen rise >5 mg/dL	AST/ALT >100 IU/L
Serum calcium <2.0 mmol/L	Serum calcium <2.0 mmol/L
PaO$_2$ <60 mmHg	
Base deficit >4 mEq/L	
Estimated fluid sequestration >61	

Three or more positive criteria in either system predicts a severe attack of acute pancreatitis.

ALT, alanine aminotransferase; AST, aspartate aminotransferase; i.v., intravenous; LDH, lactate dehydrogenase; WBC, white blood cells.

Table 3.8 The Glasgow Coma Scale

Parameter	Score
Eye opening (E)	
Spontaneous	4
To speech	3
To pain	2
Nil	1
Best motor response (M)	
Obeys	6
Localizes	5
Withdraws (flexion)	4
Abnormal flexion	3
Extensor response	2
Nil	1
Verbal response (V)	
Orientated	5
Confused conversation	4
Inappropriate words	3
Incomprehensible sounds	2
Nil	1

Coma score: (responsiveness sum = 3–15 (E + M + V)).

In addition, difficulty in describing a patient's condition prohibits clear communication. The terms 'semiconscious', 'semicomatose' and 'stuporose' have different meanings to different people and so it is important to be as precise as possible regarding clinical findings. Fully conscious implies being fully aware of and interacting in an appropriate fashion to one's environment. If the patient is not fully conscious, the clinician must be able to describe the degree of consciousness.

The Glasgow Coma Scale (Table 3.8) uses (1) eye opening, (2) best motor response and (3) verbal response to define the level of consciousness. This has the advantage of providing an objective means of assessing the level of consciousness that is highly reproducible. It can therefore be used to monitor a patient's progress.

Injury severity score

In trauma patients the extent of injury and the probability of survival can be defined using the Injury Severity Scoring (ISS) system. The ISS system is based upon the Abbreviated Injury Score. In the ISS system, the body is categorized into six regions. Points are assigned to major organ systems depending on the type and severity of injury, i.e. minor = 1, moderate = 2, severe but not life threatening = 3, life threatening but survival probable = 4, and survival not probable = 5. Maximal injuries (currently untreatable cardiovascular, CNS or burn injuries) are allocated a score of 6. The three highest injury scores are then squared and summated. The ISS system scores range between 1 and 75. If any of the injuries score 6, the overall score defers to 75. Scores of around 25–40 are associated with a 50% mortality, depending on the patient's age.

Risk reduction and patient optimization

In recent years attention has focused on mechanisms that may reduce perioperative risk. The benefit of these strategies is likely to be greatest in high-risk groups.

β-blockade

β-adrenergic blockade in the weeks preceding elective surgery may confer postoperative outcome benefit in very high-risk patients. Influential trials have shown that pre-emptive β-blockade may reduce the risk of myocardial infarction and death in the context of vascular and non-cardiac surgery. These studies led to widespread use of this approach in the USA among high-risk patients. However, subsequent trials have suggested that the findings from initial studies should be interpreted with caution. In fact, the results from the Perioperative Ischemic Evaluation (POISE) trial showed that commencing β-blockers acutely on the day of surgery may in fact be harmful. National guidelines in the USA now recommend that β-blockade may be advantageous in patients at high risk of cardiac complications undergoing vascular and certain types of non-cardiac surgery.

Statins

A number of recent studies have demonstrated a possible mortality benefit to preoperative statin therapy in patients with ischaemic heart disease undergoing vascular surgery. One such retrospective observational study reported improved clinical outcome and resource utilization in patients receiving statin therapy and undergoing elective abdominal aortic aneurysm repair. Not all studies have, however, substantiated this cardiovascular effect.

Goal-directed fluid therapy

Previous studies have debated optimal perioperative fluid volume and type. Evidence in favour of both liberal and restrictive regimes utilizing either colloid or crystalloid fluid therapy are reported. Recent attention has, however, sought to improve understanding of the haemodynamic changes that occur during surgery.

An appropriate physiological response to the stress of surgical intervention is to increase cardiac output. Shoemaker and colleagues demonstrated that patients incurring a significant oxygen debt during surgery are at high risk of postoperative complications. Patients who sustain a large and persistent oxygen debt are at greatest risk of mortality. The aim of goal-directed therapy is to maintain adequate tissue perfusion. Correction of physiological variables to within desirable target ranges is feasible with judicious use of fluids, oxygen and inotropic agents [dobutamine, dopexamine and norepinephrine (noradrenaline)]. Perioperative monitoring modalities offer real-time information on heart rate, urine output, oxygen saturation, stroke volume, arterial blood pressure, central venous oxygen saturation and cardiac output, thereby permitting manipulation. Oesophageal Doppler is one such method of measuring intraoperative cardiac output during abdominal surgery that has gained significant popularity. Goal-directed therapy has been associated with reduced mortality and shorter length of stay among high-risk groups undergoing major surgery. It has been advocated that high-risk patients (i.e. those at considerable risk of postoperative mortality) benefit most from goal-directed therapy. Therefore, some degree of patient selection in this context seems appropriate.

Perioperative nutrition

In recent years perioperative Enhanced Recovery of patients After Surgery (ERAS) has been incorporated into mainstream clinical practice. Nutritional aspects of care are central to such multimodal rehabilitation protocols. The severely malnourished patient (weight loss of ≥10–15% body weight, BMI <18.5, albumin <30 g/dL) should be offered nutritional support for at least 10–14 days even if this results in delayed surgery. Even patients who are not malnourished but are anticipated to not be able to feed normally for 1 week should be considered for nutritional support. The key principles of perioperative nutrition management include: minimization of the catabolic response to surgery, avoidance of long periods of starvation with reinstitution of feeding as soon as possible after surgery. It is now common practice to permit patients to drink clear fluids until 2 hours before surgery and the avoidance of solids is limited to 6 hours preoperatively. In addition, patients undergoing major surgery are offered carbohydrate loading drinks in the hours preceding the intervention. After surgery, patients should be encouraged to resume normal food intake or enteral feeding as soon as possible. The majority of patients can be fed early by mouth even after major gastrointestinal procedures. Certain groups, however, including those undergoing head and neck surgery, severe trauma patients, patients who are malnourished at the time of surgery and those who will not manage oral intake for 7–10 days, will require enteral tube or parenteral nutrition. The enteral route is preferred. Enteral feeding formulas comprising standard protein regimes are used commonly. Perioperative supplementation with immune-modulating substrates such as arginine, ω-3 fatty acids and nucleotides is beneficial in certain circumstances (severe trauma and surgery for upper gastrointestinal malignancy).

CHAPTER 4

Care of the patient in the perioperative period

HELGI JOHANNSSON AND VAFA MANSOUBI

The preoperative preparation of a patient for surgery

The perioperative period is a time of increased risk for every patient undergoing an operation. This risk is caused by the effects of anaesthesia, the operation itself and its complications, and the stress response to surgery affecting the patient's immune and coagulation status. Balancing the risk of the surgery and the benefit to the patient can be a difficult task that will involve the surgeon, anaesthetist and often the patient's physician, as well as the patient themselves.

Factors affecting the risk of surgery

These include:

- the nature of the surgery
- pre-existing medical conditions
- the patient's physical fitness
- whether the surgery is planned or an emergency
- presence of a coagulation disorder
- obesity
- age
- smoking.

Preassessment of patients presenting for surgery

The Association of Anaesthetists of Great Britain and Ireland (AAGBI) recommends that anaesthetists should assume a central role in the preoperative preparation of patients for operations. Preassessment clinics have been set up in most hospitals in the UK using anaesthetists and specifically trained nurses to screen for conditions that may increase the patient's perioperative risk. Their aim is not only to pick up these conditions but to give patients information about their operation and anaesthetic, as well as discontinue relevant drugs and advise patients on starvation times.

Cardiovascular disease

The perioperative period places unique stresses on the cardiovascular system. Anaesthesia itself causes great changes in blood pressure, systemic vascular resistance and myocardial contractility. As a consequence, blood pressure routinely falls on induction of anaesthesia owing to vasodilation and suppression of myocardial contraction. Intubation and the start of the operation often increase the heart rate and blood pressure, putting further stress on the system. Cardiovascular disease is common in the general population. Pre-existing cardiac disease increases the risk of perioperative myocardial infarction, heart failure and even complete loss of cardiac output.

Cardiovascular issues affecting surgery

The cardiovascular issues affecting surgery include:

- ischaemic heart disease
- previous angioplasty
- anticoagulation and antiplatelet therapy
- hypertension
- heart failure
- atrial fibrillation and other arrhythmias
- valvular heart disease.

Table 4.1 Tests used in diagnosing and assessing the severity of heart disease

Test	Use
ECG	Previous MI, hypertrophy, conduction defects, arrhythmias
Echocardiogram	Heart failure, hypertrophy, valvular heart disease
Stress echocardiogram	Above plus inducible cardiac ischaemia
24 hour ECG monitoring	Paroxysmal arrhythmias
Exercise ECG	Inducible cardiac ischaemia
Angiogram	Coronary artery disease and intervention
Cardiopulmonary exercise testing	Global fitness and oxygen usage. Heart failure, respiratory failure. Often difficult to interpret

MI, myocardial infarction.

Ischaemic heart disease

Plaque in the coronary arteries causes a restriction in oxygen supply to the myocardium, particularly at times of high demand. The heart muscle is perfused in diastole owing to the high pressures in the myocardium during systole, and oxygen supply is therefore reduced if the heart rate increases significantly. High heart rates and shear forces on the arteries brought about by increased contractility may cause a coronary plaque to rupture and consequently myocardial infarction. In addition, the hypercoagulable state in the perioperative period can increase the risk of infarction.

Risk factors for ischaemic heart disease

These are:

- smoking
- diabetes
- family history
- hypercholesterolaemia
- ethnic groups (e.g. Indian subcontinent)
- male sex.

Detecting and optimizing ischaemic heart disease

The history and an appreciation of the patient's risk factors are vital in the detection of coronary arterial disease. The patient may dismiss the symptoms as trivial and concentrate more on the reason for surgery. Angina increases the patient's risk of myocardial infarction perioperatively, and the presence of heart failure increases mortality.

The tests shown in Table 4.1 are of use in diagnosing and assessing the severity of heart disease. Their preoperative use is controversial. However, cardiopulmonary exercise testing has been used in evaluating perioperative risk, and in particular a low anaerobic threshold has been found to be a poor prognostic indicator in major surgery. Interpretation of cardiopulmonary exercise testing is often difficult and poor patient effort may produce misleading results.

Arrhythmias

Optimization of angina

This should be done in close liaison with the patient's cardiologist or general practitioner. If the patient's angina is stable and the patient is on appropriate medical treatment, surgery is presently not in itself an indication for revascularization. The use of coronary stents prior to non-cardiac surgery necessitates a period of antiplatelet therapy with aspirin and clopidogrel, which in itself may increase the morbidity and mortality of surgery.

Valvular heart disease

Valvular heart disease can influence greatly the fitness of a patient for surgery. Of particular note are stenotic valves, which will greatly limit the ability of the body to increase its cardiac output. The most common of these is aortic stenosis. As mentioned before, anaesthesia causes marked vasodilation, leading to a reduction in peripheral vascular resistance. Normally, this would be compensated for by an increase in cardiac output, but with a stenotic valve in place this is not possible. Therefore, there will be an exaggerated and sometimes catastrophic reduction in the blood pressure.

Aortic stenosis

Aortic stenosis is:

- often asymptomatic, but may present with syncope or angina
- identified by an ejection systolic murmur, associated slow rising pulse and heaving apex beat; there is narrow pulse pressure
- characterized by left ventricular hypertrophy on ECG
- diagnosed by echocardiogram.

Mitral stenosis

Mitral stenosis:

- presents with atrial fibrillation (AF), syncope, general malaise
- has a subtle diastolic murmur, which is often missed
- shows a large p wave (p mitrale) on ECG – if the patient is in sinus rhythm
- diagnosed by echocardiogram.

Arrhythmias

Atrial fibrillation

The most common arrhythmia in the general surgical population, AF is present in approximately 1% of the UK population, increasing to 10% in those over 75 years old. The atria contribute approximately 15% of the total cardiac output, and atrial fibrillation increases the likelihood of blood stagnating in the atrium, clot formation and distal embolization. A patient in AF is therefore at increased risk perioperatively of both low cardiac output states and distal ischaemia owing to embolism. Paroxysmal AF may be difficult to diagnose as ECG evidence may not be available, but has a similar risk of embolism. Most patients who have been diagnosed with AF are anticoagulated (http://www.bcshguidelines.com/documents/warfarin_4th_ed.pdf) and so present an additional challenge in the perioperative period.

Risk factors for perioperative atrial fibrillation

These include:

- major surgery
- electrolyte abnormalities:
  - hypokalaemia
  - hypomagnesaemia
- infection (especially pneumonia)
- central venous catheters (if inserted too far)
- advanced age
- previous atrial fibrillation episode

- thyrotoxicosis
- Wolff–Parkinson–White and other disorders of conduction.

Prevention and treatment of perioperative atrial fibrillation
This includes:

- keeping the serum potassium concentration above 4.5 mmol/L
- treating hypomagnesaemia early
- ensuring correct placement of central venous catheters
- treating sepsis early
- considering antiarrhythmics in liaison with a physician or anaesthetist
- considering DC cardioversion.

Narrow complex tachycardia
Syndromes such as Wolff–Parkinson–White may lead to perioperative re-entry tachycardia (supraventricular tachycardia). A history of fast palpitations and previous cardioversions may point to this diagnosis. A cardiology review and continuing antiarrhythmics is important in these patients.

Heart failure

Heart failure is defined as the inability of the heart to deliver sufficient oxygen to the body to satisfy its metabolic demands. At rest, it may be asymptomatic, or manifest itself only in non-specific symptoms such as fatigue. Heart failure poses a significant risk for major and minor surgery as the body is not able to respond to an increase in the metabolic demands and haemodynamic changes that occur during surgery and anaesthesia.

Diagnosis
History and examination are vital in the diagnosis of latent heart failure, and the severity of heart failure is graded according to the New York Heart Association classification (Figure 4.1). Echocardiography and cardiopulmonary exercise testing are useful in the investigation and risk classification of heart failure.

Hypertension

Hypertension is persistent raised blood pressure above 140/90 mmHg. It is extremely common in the surgical population. Hypertension is a risk factor for ischaemic heart disease, cerebrovascular disease and renal disease.

'White coat hypertension' is the presence of elevated blood pressure at clinic/hospital visits only, with normal blood pressure when not agitated. It may be necessary to perform ambulatory blood pressure monitoring to distinguish this from genuine hypertension.

Mildly elevated blood pressures have not been shown to present a significantly increased risk for surgery in trials.

Patients with severe hypertension should have their elective surgery deferred for treatment of their blood pressure. First-line therapy of thiazide diuretics may not be appropriate for this as it frequently takes up to 6 weeks to see an improvement in the blood pressure.

Patients on antihypertensive therapy should continue this in the perioperative period – particularly beta-blockade. Being 'nil-by-mouth' does not preclude patients taking their tablets with a little water. Angiotensin-converting enzyme blockers may increase haemodynamic instability during surgery, and some anaesthetists recommend withholding these on the day of surgery.

Anticoagulation in the perioperative period

Anticoagulant and antiplatelet therapy is commonly encountered in patients undergoing surgery and presents a significant challenge to the surgeon and anaesthetist. Careful balancing of the risk of pausing anticoagulant or antiplatelet therapy with the risk of bleeding must be undertaken and a decision made whether to start the patient on short-term anticoagulation, or simply to stop long-term treatment and restart once the likelihood of bleeding is low.

Common indications for anticoagulation

These include:

- atrial fibrillation (permanent and paroxysmal)
- valvular heart disease
- previous venous thromboembolism
- thrombophilia
- bypass grafts and other foreign materials.

NYHA Class	Symptoms
I	Cardiac disease, but no symptoms and no limitation in ordinary physical activity, e.g. shortness of breath when walking, climing stairs etc.
II	Mild symptoms (mild shortness of breath and/or angina) and sliht limitation during ordinary activity.
III	Marked limitation in activity due to symptoms, even during less-than-ordinary activity, e.g. walking short distances (20-100m). Comfortable only at rest.
IV	Severe limitations. Experiences symptoms even while *at rest*. Mostly bedbound patients.

Figure 4.1 New York Heart Association classification of heart failure.

Common indications for antiplatelet therapy

These include:

- ischaemic heart disease
- previous myocardial infarction
- angioplasty and coronary stents (particularly drug-eluting stents).

Management of warfarin

Warfarin treatment is common in the surgical population. It acts by inhibition of synthesis of vitamin K-dependent clotting factors in the liver. It has a slow onset of action and requires a loading dose. It takes around 3–4 days for a warfarinized patient's clotting to return to normal after it has been stopped. The management of warfarinization perioperatively should be altered in relation to the risk of thromboembolism during that period. Other forms of anticoagulation (such as low-molecular-weight heparin) may have greater risks than warfarin, and it may not be in the patient's best interest to continue full anticoagulation before surgery. This is a guide to management:

- Low risk of thromboembolism (e.g. lone atrial fibrillation): simply withhold warfarin 4 days before operation (or according to local protocol) and restart once the risk of bleeding is low postoperatively.
- Intermediate risk (e.g. recurrent thromboembolism): stop warfarin as above, but cover with a treatment dose of low-molecular-weight heparin starting the day after warfarin has been stopped, the last dose being given on the morning of the day before surgery.
- High risk (e.g. prosthetic heart valves): as above but admit the patient the day before surgery and commence an unfractionated heparin infusion. Stop 2 hours preoperatively, measure the activated partial thromboplastin time, and restart as soon as the risk of bleeding is low.

It should be stressed that oral non-warfarin anticoagulants such as dabigatran are becoming more common, and may supersede injectable heparins in time (see Chapter 7).

Diabetes mellitus

The perioperative care of patients with diabetes mellitus causes much confusion and often leads to worsening of diabetic control at the time of surgery. In addition, the stress response to surgery and many of the drugs used during surgery and anaesthesia increase insulin resistance, worsening diabetic control.

Patients with type 1 diabetes often present to surgery for treatment of complications of their disease. These complications are more likely when control has been poor or the condition has been present for a long time.

Complications of diabetes mellitus

These are:

- ischaemic heart disease
- hypertension
- renal disease
- retinopathy
- cerebrovascular disease
- peripheral vascular disease
- peripheral and autonomic neuropathy
- hyper- and hypoglycaemia
- gastric stasis.

Principles of management of the diabetic patient in the perioperative period

These are as follows:

- minimize starvation time
- ensure good diabetic control before elective surgery [haemoglobin A_{1C} (HbA_{1C}) between 6% and 8%]
- ideally, the patient should be first on the list
- keep the patient on his or her normal regimen for as long as possible
- those with type 1 diabetes should have an insulin infusion for long operations.

CASE STUDY 1

A 46-year-old woman with type 1 diabetes is scheduled for a laparoscopic cholecystectomy. She is on a long-acting insulin, which she takes in the evening, and injects herself with short-acting insulin before every meal, monitoring her glucose after her meal, supplementing insulin when necessary. Her control is excellent and she is very familiar with her insulin regimen.

Traditionally, she would be admitted the night before and started on a sliding scale of insulin. However, in this case she is admitted on the day, advised to take her long-acting insulin as normal and can drink clear fluids until 06.30 in the morning. She is first on the operating list, her blood glucose is monitored intraoperatively and she is allowed to eat and drink afterwards, having her lunch on the ward at midday with her normal short-acting insulin. There is minimal disruption to her insulin regimen and she can be discharged once the normal criteria have been met.

CASE STUDY 2

A 58-year-old man is scheduled for a right hemicolectomy. He has type 1 diabetes with nephropathy and previous retinal surgery. He is on twice-daily injections of a long/short-acting insulin mix, and is envisaged to have a period of not eating for around 2 days after the operation. He is admitted the night before surgery and started on an insulin infusion sliding scale, and intravenous fluids to avoid dehydration. He could be admitted on the morning of surgery if he omits his morning insulin (having taken the previous night's dose), and started on insulin after induction of anaesthesia. Care must be taken to account for his normal insulin dose in the regimen he gets written up for rather than just to opt for a standard sliding scale if he is on an unusually high or low dose of the mixed insulin. Consultation with a diabetologist will be useful in this instance.

CASE STUDY 3

A 65-year-old man presents for a hernia repair. He has type 2 diabetes treated with metformin and gliclazide. He is obese with a body mass index of 33, and smokes occasionally. His creatinine is 145 mmol/L and he had a coronary stent inserted 2 years ago. He is presently on aspirin.

During his initial appointment he is encouraged to prepare for his operation and minimize his anaesthetic risk. This includes referral to a smoking cessation programme and advice on weight reduction and exercise. After a risk–benefit discussion between the surgeon and cardiologist the decision is made to continue aspirin perioperatively, and his oral hypoglycaemics are omitted on the day of operation. He is scheduled first on the operating list.

Because of his high creatinine level he does not have a non-steroidal anti-inflammatory drug prescribed, and he has his gliclazide with lunch. The metformin is withheld until the following morning because of the small risk of lactic acidosis.

Type 1 diabetes mellitus

Type 1 diabetes mellitus is an autoimmune-mediated disease characterized by the destruction of the cells of the pancreas, leading to the inability to produce endogenous insulin. The consequences of insulin deprivation are severe, starting with a metabolic ketoacidosis and osmotic diuresis.

Preoperative management: principles

Withholding insulin from patients with type 1 diabetes leads to acidosis and may prove fatal. It is therefore vital that in the perioperative period insulin administration is not stopped for any significant length of time.

Type 2 diabetes

Unlike type 1 diabetes, in which there is a lack of insulin, type 2 diabetes is characterized by resistance to insulin. Therefore, a lack of insulin does not lead to ketoacidosis, and the absence of insulin during periods of 'nil by mouth' are not as dangerous as in type 1 diabetes.

The key points are:

- optimize control of diabetes and aim for HbA_{1c} of 8% or below
- screen for end-organ damage such as renal impairment and ischaemic heart disease
- advise lifestyle modification (smoking cessation, exercise and weight loss)
- minimize starvation time
- withhold oral hypoglycaemic agents on the day of operation.

Respiratory disease

Assessment of respiratory disease

History and examination still form the mainstay of respiratory assessment, with exercise tolerance providing vital and valuable information on the patient's physical reserve. The ability to climb one flight of stairs without stopping is used by many anaesthetists to predict a trouble-free anaesthetic, but difficulties may arise when there are other disabilities making movement difficult, principally arthritis. Peak flow and pulmonary function tests provide further information but are again difficult to interpret when the patient has poor technique or limited understanding on how to perform these tests:

- peak flow: useful to screen for bronchospasm and reduced respiratory muscle power
- pulse oximetry: detects hypoxia
- spirometry: distinguishes between restrictive and obstructive disease
- full pulmonary function tests: also detect interstitial lung disease if transfer factor is included
- chest radiograph: of limited use as a preoperative screening test.

Chronic obstructive pulmonary disease

Chronic obstructive pulmonary disease (COPD) is the presence of chronic airflow limitation, excessive secretions and destruction of lung tissue, usually as a result of smoking. Patients with COPD have around three times higher risk of pulmonary complications after surgery. This rises to 4.7 times for thoracic and abdominal surgery. The decision on proceeding to surgery should be made by the consultant anaesthetist and surgeon looking after the patient, taking into account the severity of the disease and the risks and benefits of the operation (National Institute for Health and Clinincal Excellence 2010).

Asthma

Asthma is common in the surgical population, and characterized by reversible bronchoconstriction caused by smooth muscle activation in the bronchi. The spectrum of disease varies from very mild exercise-induced asthma with no impact on the day-to-day activity of the individual, to constantly life-threatening asthma with frequent admissions to hospital and intensive care units. The mild forms of the disease have little impact on the patient's perioperative risk, whereas the severe form increases the risk of operation and anaesthetic considerably.

Features suggesting severe asthma

These include:

- exercise tolerance limited by shortness of breath
- previous hospital admissions with asthma exacerbations
- high doses of inhaled steroids
- frequent courses of oral steroids
- second- and third-line asthma drugs
- fluctuations in peak flow.

Preparation for surgery: asthma and chronic obstructive pulmonary disease

Preparations include:

- history and examination
- considering pulmonary rehabilitation and optimization by a respiratory physician

- smoking cessation
- evaluation of the severity of COPD (spirometry, pulmonary function tests, exercise tolerance test)
- careful evaluation of the risks and benefits of surgery in the case of severe disease
- continuing respiratory medication perioperatively
- considering a nebulized bronchodilator immediately prior to surgery.

Obstructive sleep apnoea

During sleep, a person's airway muscle tone decreases and obstruction can develop (e.g. snoring). Obstructive sleep apnoea is a condition in which there are frequent pauses of 20–40 seconds during sleep when the patient does not take a breath. Hypoxia ensues and carbon dioxide builds up in the body. Symptoms may be subtle and commonly include daytime somnolence, tiredness and restless sleep. In severe cases, pulmonary hypertension and cor pulmonale may develop, leading to right heart failure and peripheral oedema.

The prevalence of obstructive sleep apnoea is increasing and is often undiagnosed in a patient attending for surgery.

Risk factors for obstructive sleep apnoea

These include:

- obesity
- anatomical features causing narrowing of the airway
- craniofacial syndromes
- weak airway muscle tone
- previous brain injury.

Obstructive sleep apnoea presents a particular challenge during the perioperative period. The anatomical features that lead to obstructive sleep apnoea can frequently lead to difficulties in airway management. In addition, during airway management, any difficulties may lead to trauma and swelling of an already narrowed airway. This in turn can lead to difficulties in breathing in the immediate postoperative period when the patient may already be drowsy from anaesthetic agents and analgesics. These patients are at higher risk postoperatively from upper airway obstruction and hypoventilation.

Gastrointestinal considerations

Anaesthesia obtunds the reflexes protecting the airway from foreign materials, including stomach contents. Anaesthesia reduces the tone of the gastro-oesophageal sphincter, and many anaesthetic agents cause nausea and vomiting. Stomach contents are very acidic and cause a chemical pneumonitis when aspirated into the respiratory tract.

Factors delaying gastric emptying

These are:

- large solid fatty meal
- distress and pain (particularly in children)
- labour
- position (supine)
- obstruction (e.g. gastric outflow obstruction)
- abdominal sepsis (e.g. appendicitis)
- drugs: opioids, anticholinergics, dopamine
- autonomic disorders (e.g. diabetes-induced gastroparesis).

Preventing aspiration of gastric contents

Strategies employed by anaesthetists to prevent aspiration pneumonia involve identifying patients at risk, premedication, modification of anaesthetic techniques and postoperative care aimed at minimizing drowsiness, nausea and vomiting (see Rapid sequence induction).

Central nervous system disorders

Cerebrovascular disease

Patients with previous strokes frequently present for anaesthesia for unrelated conditions. The perioperative period presents a high risk of further strokes and it is important to weigh carefully the benefit of the operation with the risk to the patient. This should be done during a careful preassessment and discussion between the surgeon and anaesthetist, with the patient and relatives closely involved.

Perioperative strategies for prevention of further stroke

These measures are:

- when possible continue antiplatelet therapy
- reinstate antiplatelet therapy (when stopped) as soon as is deemed safe
- ensure antihypertensives are continued perioperatively
- avoid hypotension and keep the patient's blood pressure within 20% of their preoperative blood pressure.

Disorders causing muscle weakness

Disorders such as motor neurone disease and myasthenia gravis lead to a reduction in skeletal muscle power. This may have severe implications for recovery from anaesthesia. The presence of respiratory muscle weakness increases the risk of postoperative hypoventilation; pneumonia, weak cough and weak upper airway reflexes increase the risk of aspiration of gastric contents:

- continue therapeutic medication (e.g. pyridostigmine) on the day of operation to maximize power postoperatively
- minimize medication that increases drowsiness, and use regional techniques when possible
- ensure there is minimal residual neuromuscular blockade remaining postoperatively
- the patient may require a high-dependency or intensive care unit bed postoperatively to monitor for hypoventilation and signs of sepsis
- the decision whether to operate or not should be taken by the surgeon and anaesthetist in discussion with the patient and should take into account the risks and the benefits of the surgery.

Intraoperative care

Principles of anaesthesia

Anaesthesia is a pharmacologically induced and reversible lack of awareness. This can be total lack of awareness, as in general anaesthesia, or partial, as in sedation.

General anaesthesia

This includes the triad of hypnosis, analgesia and muscle relaxation that is started in the period of *induction of anaesthesia* and further continued during *maintenance* until the end of the procedure, when *emergence* from anaesthesia begins.

Induction of anaesthesia

This is usually achieved by the use of *intravenous* anaesthetic agents, but the *inhalational* route using volatile anaesthetics may also be used.

Intravenous agents include propofol, thiopentone, etomidate, ketamine:

- advantages: rapid onset, titratable dose
- disadvantages: hypotension and apnoea common (except ketamine).

For inhalational induction, volatile agents are used, including sevoflurane, halothane and nitrous oxide:

- advantages: no need for initial cannulation (paediatrics), respiration maintained
- disadvantages: slower onset (especially in adults), unpleasant and irritable.

Rapid sequence induction

When a patient is judged to be at risk of aspiration of gastric contents a rapid sequence induction is used. The principles of the rapid sequence induction are to minimize the time between the loss of laryngeal reflexes and the securing of the airway. It is used to achieve optimal intubating conditions in around 30 seconds.

It involves:

- preoxygenation: 3–5 minutes, leading to replacement of nitrogen for oxygen in the functional residual capacity and increase oxygen stores to maximize the time available before the patient desaturates
- cricoid pressure: aims to prevent passive regurgitation of gastric contents
- availability of suction and tilting trolley: to minimize aspiration if regurgitation occurs
- fast administration of thiopentone and suxamethonium or rocuronium: fast induction and paralysis
- avoidance of bag–mask ventilation, which may lead to air entering the stomach and increasing gastric pressure.

Maintenance

Both the intravenous and inhalational route may be used.

Inhalational routes use volatile agents (sevoflurane, desflurane, isoflurane) in combination with carrier gases (oxygen, air, nitrous oxide):

- advantages: monitoring of end-tidal levels and so capillary (blood) levels; familiarity, convenience, minimal additional equipment needed
- disadvantages: emetogenic, greenhouse pollutant.

Intravenous routes can be infusion only (total intravenous anaesthesia) or boluses. Propofol is the only anaesthetic agent currently used for maintenance:

- advantages: reduced postoperative nausea and vomiting
- disadvantages: dedicated intravenous line, so it is not possible to monitor blood levels (risk of awareness).

Emergence

This is simply achieved by stopping the anaesthetic agent and administering high-flow oxygen. The inhalational agents are then expired, leading to eventual drop in blood concentration levels and subsequent emergence. Propofol has a very large volume of distribution and on cessation of the infusion will redistribute and lead to emergence.

Muscle relaxation

Anaesthetic agents provide a certain degree of muscle relaxation, but paralysis is achieved by giving neuromuscular blockers. This is to aid intubation and provide paralysis for easier surgical access (e.g. relaxation of abdominal muscles for laparotomy and laparoscopy).

They are classified into:

- Depolarizing neuromuscular blockers: suxamethonium:
  - advantages: fast paralysis (intubation in 30 seconds), short acting
  - disadvantages: numerous side effects, including myalgia, hyperkalaemia, bradycardia, increased intracranial and intraocular pressure.
- Non-depolarizing neuromuscular blockers: atracurium, vecuronium, rocuronium
  - advantages: safer side effect profile
  - disadvantages: long onset time, may accumulate with renal and hepatic failure.

Other agents

Analgesics (opioids, α_2-agonists) and other hypnotics (benzodiazepines, α_2-agonists) are added to reduce the anaesthetic agent requirements as well as provide analgesia.

Ketamine

This drug is gaining in popularity, especially in emergency and field anaesthesia. It acts as an *N*-methyl-ᴅ-aspartic acid antagonist and can cause profound analgesia, anaesthesia and amnesia. Its routine use is limited because of its potential side effects, including emergence delirium, dysphoria and hallucinations, tachycardia, hypertension and increased intracranial pressure.

Airway

During anaesthesia it is important to maintain an open airway owing to loss of normal tone causing the tongue and soft tissues to obstruct the airway.

Different types of airway include:

- Oropharyngeal/nasopharyngeal: least likely to stimulate airway reflexes but more prone to failure and stomach inflation with ventilation.
- Laryngeal mask: easy to insert requiring little training.
- Endotracheal tube (oral/nasal): definitive airway allowing efficient ventilation and protecting against airway soiling.

- Tracheostomy: a hole made in the trachea allowing bypass of the upper airway altogether. This is frequently used as a part of a weaning protocol on the intensive care unit. Also it is rarely performed as an emergency for a failed attempt at intubation (in this case usually through the cricothyroid membrane).

Patient may ventilate *spontaneously* but *artificial* ventilation is carried out during periods of apnoea or if paralysis is used.

The methods of ventilation include:

- bag and mask
- hand ventilation using anaesthetic circuits
- mechanical ventilation.

Monitoring during anaesthesia

There are standards of basic monitoring that must be carried out during the conduct of all anaesthetics. These have been recommended by the AAGBI and are strictly adhered to by all anaesthetists.

These apply to all procedures including local/regional and sedative techniques and should start before the induction of anaesthesia and continue until the patient has fully recovered.

The AAGBI guidelines on minimal standard monitoring include:

- the presence of anaesthetists throughout the procedure
- pulse oximetry
- non-invasive blood pressure (NIBP) monitoring
- ECG
- capnography and monitoring of gases: O_2, CO_2, vapours
- airway pressures.

With the availability of the following:

- means of measuring temperature
- nerve stimulator.

During the recovery phase, pulse oximetry and NIBP must be present and all others must be available.

The aims of standard monitoring during anaesthesia include:

- monitoring of vital signs to ensure adequate tissue perfusion and oxygenation
- monitoring depth of anaesthesia
- early warning of adverse events and errors.

Additional monitoring

Other forms of monitoring are also used in individual patients and during certain procedures. These include:

- urine output: indicator of cardiac output, volume status, kidney function
- invasive blood pressure monitoring: allow beat-to-beat assessment of blood pressure and sampling line for arterial blood gas measurements
- central venous monitoring: indication of patient volume status, effect of fluid challenge and venous blood sampling
- other modes of cardiac output measurement: Doppler probe, pulmonary artery flotation catheter, PICCO (pulse contour analysis) (see Chapter 6)
- depth of anaesthesia: electroencephalogram, modified EEG, bispectral analysis, evoked potentials.

World Health Organization surgical safety checklist

This is a worldwide initiative to reduce the number of surgical errors and complications. It has been endorsed by the Department of Health, National Patient Safety Agency and all the Royal Colleges and, after an initial trial, has now been implemented nationwide.

The WHO's 10 essential objectives include:

1. The team will operate on the correct patient at the correct site.
2. The team will use methods known to prevent harm from anaesthesia, while protecting the patient from pain.
3. The team will recognize and effectively prepare for life-threatening loss of airway or respiratory function.
4. The team will recognize and effectively prepare for risk of high blood loss.
5. The team will avoid inducing any allergic or adverse drug reaction known to be of significant risk.
6. The team will consistently use methods known to minimize risk of surgical site infection.
7. The team will prevent inadvertent retention of instruments or swabs in surgical wounds.
8. The team will secure and accurately identify all surgical specimens.
9. The team will effectively communicate and exchange critical patient information for the safe conduct of the operation.
10. Hospitals and public health systems will establish routine surveillance of surgical capacity, volume and results.

The checklist has been modified for its use in the UK taking into account the local healthcare system and practices and is now an essential tool in all surgical and radiological procedures.

Three separate checks are carried out:

1 *Sign in: before conduct of anaesthesia*

- Confirmation with patient of identity, site, procedure and consent.
- Confirmation of site marking.
- Anaesthetic machine and drugs checked.
- Allergies.
- Difficult airway and aspiration risk.
- Risk of >500 mL blood loss (7 mL/kg in paediatrics).

2 *Time out: prior to start of surgery*

- Introduction of team by name and role.
- Surgeon, anaesthetist and registered practitioner verbally confirm patient, site and procedure.
- Anticipated critical events.
- Surgeons review: any issues, blood loss, special requirements and investigations.
- Anaesthetic review: any concerns.
- Nurse/operating department practicioner review: any equipment and instrument issues.
- Surgical site infection bundle: antibiotic prophylaxis, warming, glycaemic control, hair removal.

3 *Sign out: before any member of the team leaves the operating room*

- Verbally confirm the name of the procedure recorded.
- Instruments, sharps and swab counts correct.

- Correct labelling of specimens.
- Equipment problems identified.
- Surgeon, anaesthetist and registered practitioner review key concerns for recovery and management.

The WHO also recommends briefing and debriefing at the beginning and end of the list to improve communication, situational awareness and team work.

Regional anaesthesia

This is anaesthesia that affects a part of the body. It is achieved by the use of local anaesthetics and other agents to remove the sensation of pain from a specific area. This can be as a single injection, by placement of a catheter for continuous infusion or by intermittent administration of the drug.

The indications include:

- sole anaesthetic technique for surgery in an awake or sedated patient
- in combination with general anaesthesia for intra- and postoperative pain relief
- for pain relief only, e.g. epidural analgesia during labour, chronic pain injections.

It can be broadly divided into:

- central/neuroaxial techniques: spinal, epidural, combined spinal epidural and caudal
- peripheral techniques, which are further subdivided into:
  - plexus blocks: brachial plexus, lumbar plexus blocks
  - individual nerve blocks: femoral, sciatic, median, ulnar nerves
- intravenous regional technique: Biers block (now rarely used)
- local techniques: wound infiltration, topical to mucous membranes, teeth.

Central/neuroaxial blocks

Spinal anaesthesia is achieved by injecting local anaesthetic in the intrathecal space (Figure 4.2). It is normally done at the L3–4 level (spinal cord terminates at L1–2 in adults) as a single injection but catheter techniques are also available. All lower abdominal, pelvic and lower limb surgery can be performed under a spinal block.

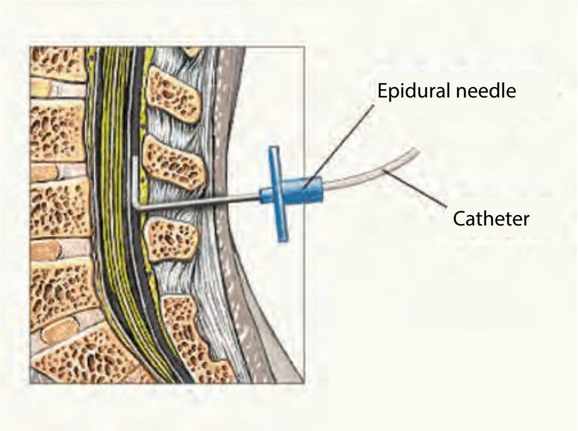

Figure 4.2 Sagittal view of the vertebrae and spinal cord, Tuohy needle in place ending in the epidural space and a thin spinal needle ending in the cerebrospinal fluid

Epidural anaesthesia is achieved by placement of a catheter in the extradural space. Normally its placement corresponds to the midpoint of the surgical scar, but it can be anywhere along the thoracic and lumbar spine. The block is normally not as dense as a spinal, but can cover higher dermatomes and so makes it ideal for pain relief in upper abdominal surgery.

Caudal anaesthesia involves insertion of a needle or cannula into the caudal space via the sacrococcygeal membrane and injection of approximately 20 mL of local anaesthetic. A catheter may also be passed. It is indicated for anaesthesia and pain relief for perineal and inguinal surgery.

The common complications of neuroaxial blocks include:

- failure: either immediate (e.g. catheter not in epidural space) or delayed (catheter migration)
- hypotension: intraoperatively or postoperatively owing to sympathetic block (common cause of hypotension in recovery).

Rare complications include:

- damage to structures: spinal cord, nerves, ligaments, blood vessels
- local anaesthetic toxicity owing to intravascular injection or peripheral absorption: agitation, fitting, loss of consciousness, severe arrhythmias, cardiac arrest
- high block: hypotension, bradycardia, difficulty in breathing/apnoea, reduced/loss of consciousness
- postdural puncture headache: due to cerebrospinal fluid leak through a tear in the dura mater (occurs in approximately 1:200 epidurals, rarer for spinals)
- epidural haematoma or abscess: needs urgent imaging and neurosurgical involvement.

The drugs used are:

- local anaesthetics: commonly bupivacaine, lidocaine, ropivocaine
- opioids: fentanyl, diamorphine, morphine
- other adjuncts: ketamine, clonidine, epinephrine (adrenaline), bicarbonate.

Peripheral nerve block techniques

Peripheral nerves and plexuses may be blocked by local anaesthetic injection guided by landmarks, nerve stimulator or ultrasound imaging. In general surgery, the most commonly used blocks are ilioinguinal nerve blocks, transversus abdominis plane blocks, paravertebral blocks and intercostal nerve blocks.

Transversus abdominis plane block

Local anaesthetic is injected in the space between the fascia of internal oblique and transverse abdominis muscles to block the anterior rami of the lower six (T7–L1) thoracic nerves. This provides good postoperative pain relief for a variety of procedures involving the lower abdomen down to the pubic region. It is commonly performed with ultrasound guidance for needle placement, and a catheter may be sited. This is particularly useful for unilateral abdominal surgery such as reversal of Hartmann's procedures, but may be performed bilaterally to cover lower abdominal laparotomy scars.

CASE STUDY 4

A 67-year-old man undergoes a total colectomy with an incision from the xiphisternum to pubic symphysis (dermatomes T6–12). An epidural catheter is inserted 5 cm into the epidural space and an infusion of 'low-dose mix' (bupivacaine 0.1% with 2 µg/mL fentanyl) is commenced at 10 mL/h. Block to cold sensation of T4–L1 is achieved and the patient is pain free, but still able to move and has no numbness. He is able to cough effectively and co-operate with physiotherapy.

Epidural catheters in general abdominal surgery

In recent years it has become commonplace to site an epidural to provide analgesia for abdominal procedures. When successful, this technique results in excellent pain relief with most patients reporting no pain at all. However, the postoperative management of epidural catheters can be difficult and should be done by the pain team and/or anaesthetist in charge of the patient.

Infusions used

Most commonly a combination of a dilute concentration of local anaesthetic (such as bupivacaine) is combined with an opiate (such as fentanyl) to provide a preferential block of unmyelinated C nerve fibres while sparing the other myelinated fibres. Consequently, a preferential block of pain is achieved while preserving touch and motor function. The infusion may be continuous, or a continuous background infusion with patient-controlled boluses (patient-controlled epidural analgesia).

Common problems

These include:

- Epidural never effective: usually due to the epidural catheter not being in the right place.
- Pain in the top of the wound: the epidural catheter may be placed too low (e.g. a lumbar epidural for an abdominal procedure) or the infusion rate may be inadequate.
- Pain in the bottom of the wound: the epidural catheter may be placed too high or the infusion rate may be inadequate.
- Epidural requiring repeated 'boluses' to achieve pain relief, with little or no block to cold sensation: the epidural catheter may have migrated, usually so that it is only partially in the epidural space, or not at all. Epidural boluses may result in temporary relief of pain even when the catheter is subcutaneous as systemic absorption of fentanyl is significant.
- Interruption in epidural infusion leads to breakthrough pain after 30 minutes to 1 hour.

Rare serious problems

These require prompt action:

- severe headache, worse on standing, accompanied by auras and nausea may indicate postdural puncture headache
- a dense block with paralysis during an infusion of dilute local anaesthetic may indicate an epidural haematoma or abscess and needs immediate imaging and intervention
- a rise in inflammatory markers in the absence of other signs of infection may indicate an epidural abscess; this is very rare.

Analgesia in the perioperative period

Principles of relief of pain

The WHO defines pain as 'an unpleasant sensory or emotional experience associated with actual or potential tissue damage, or described in terms of such damage'. It is important to note that pain is a subjective concept and patients' experience of pain after a similar procedure varies considerably.

World Health Organization pain ladder

The WHO pain ladder (http://www.who.int/cancer/palliative/painladder/en/) was originally described for cancer pain, but is now used as a basis for the treatment of many other types of pain, including postoperative pain. It consists of three steps:

1. mild pain: treated with non-opioids and adjuvant agents
2. moderate pain: treated with mild opioids in addition to the above
3. severe pain: treated with strong opioids, non-opioids and adjuvants.

Types of analgesic

These are categorized into (1) non-opioids, (2) mild opioids and (3) strong opioids:

- Non-opioid:
  - paracetamol (acetaminophen)
  - NSAIDs.
- Mild opioids:
  - codeine
  - tramadol.
- Strong opioids:
  - morphine
  - diamorphine
  - fentanyl
  - oxycodone.

Adjuvant agents may also be given, including:

- local anaesthetic infiltration
- regional analgesia
- gabapentin/pregabalin
- ketamine
- anxiolytics
- anti-inflammatory drugs (e.g. steroids).

The treatment of surgical pain should consist of a combination of agents appropriate for the expected level of pain. Regular administration of analgesics should be the mainstay of pain management with 'as required' agents available if necessary. The aim should be for the patient not to need to ask for pain relief, but for the drugs to be given regularly enough to relieve the pain.

Paracetamol (acetaminophen)

Paracetamol is a commonly used analgesic useful for mild to moderate pain. It can be given orally, rectally and by intravenous infusion. Its mechanism of action is still unclear despite much study, but it seems to be a highly selective cyclo-oxygenase (COX) 2 inhibitor, and may inhibit COX-3 in the brain. In addition, it may affect the brain cannabinoid system, producing pain relief. It has few side effects and few contraindications. Although it causes liver failure in overdose, it has been used in patients with liver impairment without adverse effects.

Non-steroidal anti-inflammatory drugs

These work by COX-1 and COX-2 inhibition, and have both analgesic and anti-inflammatory properties (unlike paracetamol, which has only analgesic properties). Because of their COX-1 inhibition they have a more significant side effect profile and contraindications. They work well, particularly for incision pain and bone pain.

The side effects of NSAIDs include:

- gastrointestinal ulceration
- exacerbation of asthma (most asthmatics are not affected by NSAID use)
- renal impairment
- platelet inhibition (especially aspirin).

Opioid analgesia

Opioids are strong analgesic drugs that act on opioid receptors – most on μ receptors in the brain and the spinal cord. They cause profound analgesia and are the mainstay of postoperative pain relief for moderate to severe pain.

Commonly used opioid analgesics include morphine, diamorphine, fentanyl and pethidine. Fentanyl may be given via any route, and morphine can be given orally or parenterally. Oral absorption of morphine is affected by first-pass metabolism and the bioavailability is under 50%.

The common side effects of opioid analgesia include:

- sedation
- respiratory depression
- nausea
- vomiting
- constipation
- urinary retention.

Patient-controlled analgesia

The principle behind patient-controlled analgesia is the ready supply of pain relief controlled by the patient themselves with some important safety features to prevent abuse and overdose. The details are as follows:

- the patient is attached to a pump containing the analgesic (usually morphine) via a dedicated intravenous cannula
- the pump delivers a dose of the drug (e.g. 1 mg morphine) every time the button is pressed
- there is a lockout period following each activation (e.g. 5 minutes) to prevent repeated dose delivery causing overdose
- the pump should only be activated by the patient themselves (or trained nurse in children, for example) – never by relatives
- a background infusion may be used to reduce the number of times a patient has to activate the pump.

Patient-controlled analgesia works best when prescribed with coanalgesics such as paracetamol and NSAIDs.

CHAPTER 5

Patient-reported outcomes to evaluate surgery

JANE M. BLAZEBY

Introduction

Evaluation of surgery can be defined as a rigorous assessment of the advantages and disadvantages of interventions both in the short and long term and this process is important for surgeons, patients and health service providers. Evaluation may involve audit or research methods, and both can improve the quality of care for patients because capturing data about outcomes, and making information available to key stakeholders means that action and collective responsibility can be taken for the results. Whatever the type of study design used to evaluate surgery it will be necessary to choose, measure and report outcomes which are defined as endpoints that gauge the effectiveness of an intervention. Both the design of the study *and* the selection and measurement of the particular outcomes are, therefore, of critical importance to inform practice.

Traditionally outcomes used to evaluate surgical interventions have been those selected by surgeons regarding complications, and these have predominantly been morbidities occurring within the same hospital stay as the procedure itself. Outcomes of utmost concern for surgeons usually relate to perceived measures of technical performance, such as rates of anastomotic leakage following bowel resection, rates of arterial occlusion in peripheral vascular surgery or rates of bleeding after cardiac surgery. There has also been a focus on reporting longer term surgical outcomes, including how surgery may affect functions (e.g. bowel function following subtotal colectomy) or how successful surgery has been in removing the original problem, e.g. 5 year survival rates after surgery for cancer or recurrence of reflux problems following fundoplication. Although measuring and understanding short- and long-term complications will always be of paramount importance to surgeons, the assessment of outcomes of interest to other stakeholders will provide a more comprehensive evaluation of interventions to inform decision-making. Over the past three decades there has been a growing interest in measuring patient-reported outcomes (PROs) to provide data to use in shared decision-making consultations between surgeons and patients.

PROs assess any aspect of health that is reported by patients themselves and that is not interpreted by an observer, and patient-reported outcome measures (PROMs) are the instruments designed to assess a PRO. Understanding how PROs may be used to evaluate surgery is the focus of this chapter, which will define PROs, PROMs and the glossary of terms used in this field. The chapter will provide an explanation of the importance of PROs to surgical practice and a summary of the different types of PROMs, and it will outline how to design a robust study to measure PROs to evaluate surgery. It will illustrate these issues with surgical case studies. Areas for future research in this field will also be considered.

What are patient-reported outcomes?

A PRO is an outcome that assesses any aspect of a patient's health that comes directly from the patient, without the interpretation of the patient's responses by a physician or anyone else. Historically, few scientific evaluations of surgery made an attempt to measure patients' views, and only doctors' or nurses' assessment of patients' symptoms, functional health status or overall quality of life (QOL) were sometimes reported. One of the first instruments that did this, thereby at least broadening outcome measurement beyond clinical measurement of complications, was the Karnofsky Performance Scale proposed for use in 1947. This scale, and several other measures of performance that were (and are still) widely used, asked the clinician to rate from 0 to 100 how the patient's general performance appeared to them. Zero indicated dead and 100 was normal health. The World Health Organization's measure of performance is nowadays used in clinical practice, particularly in oncology. In surgical studies, formal measures of performance have been less widely used, although it is standard for surgeons to make judgements about general health when deciding if a patient is sufficiently fit for a procedure. In the one multicentre audit examining outcomes of gastric cancer surgery, surgeons' judgements of patients' general fitness were used to select patients, and analyses showed that these were prognostic. Using an observer assessment of general health, however, without a definition means that it is not easily reproducible and may be criticized as being invalid. The problem with measures of patients' health made by anyone other than the patient themselves is that they may be incorrect or biased, being an over- or underestimate of the patient's true functional ability. Another study compared several aspects of QOL, including dysphagia scores reported by patients, by carers or by a clinician. Both over- and underestimates were observed and there was only poor to moderate agreement about most aspects of health. Observers may misjudge symptoms, functional aspects of health and make inaccurate global assessments. It is therefore necessary that every effort is made to obtain the information from patients themselves so that an evaluation of the impact of surgery of PROs can be made.

A PRO may refer to a single dimension of health, a global health assessment or it may include a multidimensional assessment of several different aspects of health. A single dimension of health means a report of a single symptom or function, such as a self-reported pain score or a self-reported measure of mobility. A global health assessment means that the patient responds to a question that asks them to rate 'overall health' or 'overall quality of life', and a multidimensional PRO measures more than one aspect of health (e.g. pain *and* mobility). Box 5.1 provides a glossary of definitions of terms commonly used in PRO studies. Other commonly used words include 'health status', 'quality of life' and 'health-related quality of life' (HRQL/HRQoL). Each of these is a PRO only if the assessment is performed by the patients themselves. For example, a doctor may describe and report a patient's QOL, but this is an observer assessment of QOL and not a PRO. However, it is possible for patients to self-report their overall QOL and this would be classified as a PRO.

BOX 5.1 Definitions of terms commonly used in patient-reported outcome studies

- **Patient-reported outcome (PRO)** is an outcome that assesses any aspect of a patient's health that comes directly from the patient, without the interpretation of the patient's responses by a physician or anyone else
- **Patient-reported outcome measure (PROM)** is an instrument that is used to assess any PRO
- **Quality of life (QOL)** is an ill-defined term that may have components of happiness or satisfaction
- **Health-related quality of life (HRQL, HRQoL)** is also ill defined, but it is generally agreed that it can include several aspects of health, such as physical, emotional and social functioning and symptoms
- **An item** is a single question that may assess any aspect (domain) of QOL/HRQL or any PRO
- **A scale** is two or more items in a questionnaire that assess the same health domain
- **A domain** is an aspect of health (e.g. pain, physical wellbeing); it may be assessed by a single item or a scale
- **A global assessment of QOL or HRQL/HRQoL** is an item or scale that assesses generic health or global QOL issues (e.g. how is your overall quality of life?)
- **Patient-reported experience** is a measure of the process of care received by the patients, such as levels of satisfaction with information provision, satisfaction with access to car-parking facilities and experiences waiting in the hospital
- **Patient-reported experience measure (PREM)** is an instrument that is used to assess any PRE

There are no strict internationally agreed definitions of QOL and HRQL, and in layman's terms both mean abstract notions of happiness or satisfaction that may be related to current or past events and individual values. Within a health services research context, however, both QOL and HRQL are terms that are interchangeable and refer to the patient's perception of health, including single and multidimensional components. Because of the potential for confusion with this terminology, it is recommended that, in any evaluation of surgery with PROs, a definition of the health domains of interest is provided in the protocol and report so that readers are aware exactly which aspects of health are being assessed. It is also recommended that clear descriptions of who made the assessment are provided and whether it is truly a PRO or an observer assessment of the patient's health.

It is important to distinguish between a PRO and a patient-reported experience (PRE). A PRE has been referred to as a measure of the process of care received by the patients, such as levels of satisfaction with information provision, satisfaction with access to car-parking facilities and experiences waiting in the hospital. The role of assessing PREs is different from measuring PROs and they will be considered separately.

Patient-reported outcome measures

PROMs or patient-reported experience measures (PREMs) are the instruments used to assess PROs and PREs, respectively. These are most frequently paper-based questionnaires, although it is likely that future methods for capturing PRO data will include electronic means. Whether paper-based questionnaires or electronic methods are used to measure PROs it is critical to use tools that are tested for reliability and validity. There are several types of PROMs. Some of the instruments that are more widely used are described with an outline of their scoring procedures and any constructed scales.

Generic instruments

Some questionnaires are designed for use in any patient population to capture the generic aspects of health. They commonly include scales assessing physical, social, role and emotional function. Some of the more widely used tools have also been updated to include short-form versions to allow a swift assessment of the important generic aspects of health. Table 5.1 summarizes key aspects of commonly used questionnaires including the SF-36 and the EQ-5D. These are available in a range of languages and have been widely used in

Table 5.1 Commonly used generic and disease-specific patient-reported outcome measures

Name of instrument	Number of items and scales	Health domains	Time frame	Scoring system
Medical Outcomes Study Short Form 36 (SF-36)	36 questions 8 health domains	Physical function Role physical Bodily pain General health Vitality Social function Role emotional Mental health	The past 4 weeks Some refer to 'now'	8 scales can be scored or two summary measures, physical and mental health, can be created
EuroQoL (EQ-5D)	5 questions	Mobility Self-care Usual activities Pain/discomfort Anxiety/depression	Today	A single overall index is created
European Organization for Research and Treatment of Cancer Quality of Life Questionnaire (EORTC QLQ-C30)	30 questions 9 scales 6 single items	Physical function Role function Cognitive function Social function Emotional function Global health scale Financial impact (9 symptoms, including pain, fatigue, nausea and vomiting, dyspnoea, anorexia, insomnia, constipation, diarrhoea)	The past week	Each scale and item is scored individually
Functional Assessment of Chronic Illness Therapy (FACIT)	27 questions 4 health domains	Physical wellbeing Social wellbeing Emotional wellbeing Functional wellbeing	The past 7 days	4 scales and an overall summary score
Multidimensional Fatigue Index (MFI)	20 questions 5 domains	General fatigue Physical fatigue Mental fatigue Reduced motivation Reduced activity	'Been feeling lately'	5 scales and an overall summary score
Barthel Index of disability (BI)	10 questions 1 domain	Functional dependency	Not specified	One overall score
Katz Activity of Daily Living scale (Katz ADL)	6 questions 1 domain	Independence	Not specified	One overall score

clinical trials. Generic instruments have the benefit of covering core aspects of health and they allow for cross-study and cross-population comparisons to be made. Disadvantages are that they may not be sufficiently sensitive to capture symptoms or problems peculiar to a given operation or disease. The SEIQoL and the Patient Generated Index are examples of generic health measures that allow the participants to nominate areas of health that are important individually to them, and the instruments examine the current level of functioning within the selected areas. Although these seem appealing, they are less easy to use and score, and making comparisons between study groups is less intuitive because of the knowledge that different components of health make up for the summary scores that are produced.

Disease-specific patient-reported outcome measures

Disease-specific measures have been developed to detect the issues of relevance to patients with particular conditions. Examples of measures developed for cancer are given below, including the EORTC QLQ-C30 and the FACIT questionnaires. Each one assessed issues that are relevant to a wide range of patients with cancer. Both may be supplemented by disease- or treatment-specific modules that will address aspects of treatment or the disease relevant to a patient population. Both questionnaires relate to the past week, and they are extensively tested for reliability and validity in many different populations of patients with cancer. Both have many different modules available to use for specific diagnoses or treatments and studies have demonstrated the value of these tools after cancer surgery.

Instruments for specific patient-reported outcomes

The above instruments all measure PROs of several aspects of health/QOL and some include questions that ask patients to make global assessments. There are situations when a very specific aspect of health is the main outcome and then instruments may be designed to explore issues in much greater depth. Since such instruments measure just one aspect of health/QOL, they are often combined with a generic measure to ensure that the assessment is multidimensional. Two example questionnaires are described in Table 5.1, the Multidimensional Fatigue Index (MFI) and indices to measure activities of daily living (ADLs), the Barthel Index of Disability (BI) and the Katz ADL. The MFI measures fatigue including physical and mental aspects and the BI is an ADL index that measures functional dependency before and after treatment. The Katz ADL measures independence. Measurement of self-reported fatigue and activity may be particularly valuable to use in surgical trials when a PRO assessment of postoperative recovery is required.

Features to consider when selecting a patient-reported outcome measure

In addition to selecting the type of PROM (generic, disease or domain specific) it is necessary to examine the practical aspects of questionnaires and details of their measurement properties. Tips are summarized in Table 5.2. Initial selection will depend upon the type and content of the questionnaire and examination of the scales and questions in the instrument in detail. One method that is useful to look at content, practicality and appropriateness of the questionnaires is to ask a patient to complete the questionnaire while you observe them and their understanding of each item. During this exercise the time taken to complete the questionnaire can be checked, as ensuring that the questionnaires are completed within 20 minutes will optimize response rates and data completeness. Many questionnaires have been formally translated, and if the patient population is multicultural this will be essential to get results that are generalizable. Developers of questionnaires may require a formal licence and a user agreement, sometimes with a fee for the questionnaire to be used. The details are available on the questionnaire websites usually, and may be study or user specific.

A detailed examination of the measurement (psychometric properties) of the questionnaire is important unless a very widely validated and used measure is selected for which you can be confident that these are correct. Ensuring that internal consistency, construct and criterion validity, and test–retest properties are published and of acceptable standards means that the PROM will assess what it is reported to and that it will produce repeatable results. In addition, information about the sensitivity of the questionnaire to changes in health status over time is relevant to longitudinal studies or clinical trials. Traditional psychometric methods include summated scales and factor analysis techniques and it is also possible to examine measurement properties using item response theory models. Both require appropriate expertise.

Table 5.2 Points to consider when selecting a patient-reported outcome measure (PROM)

Questions to ask	How to find out the answer
Is it a PROM?	Check that it is completed by the patient
The content of the questionnaire	
What does the questionnaire measure?	Read the questions
What scales and items are included?	Look at the scoring for the scales/items
Is it relevant to the targeted patients?	Observe a patient completing the questionnaire
Practical issues	
How long does it take to complete?	Complete it and time yourself, examine evidence
Is it available in other languages?	Look at published evidence
Is there a user's agreement?	Contact the developers/check publications
Is there a cost for using the PROM?	Check the developer's details
How is the questionnaire scored?	Look at publications and get the scoring manual
Where are copies of the PROM obtained?	Check questionnaire instructions/read questions
Content validity	
What informed the content of the PROM?	Check the developmental publications
Were patient interviews performed?	Were qualitative patient interviews performed?
Was the literature searched?	Was a systematic review of PROs performed?
Were health professionals views included?	Were professional interviews undertaken?
Reliability	
How were the PROM scales formed?	Examine the factor analyses or multitrait scaling
Are the Cronbach α scores satisfactory?	Scores above 0.7 are good
Has it be tested for reproducibility over time?	A stable instrument has high correlations
Construct and criterion validity	
What domains/clinical outcomes has it been compared with?	Check for comparisons with validated PROMs
Are there correlations with health domains?	Examine publications
How were the scales developed?	Examine validity data in publications
	Examine factor analyses and multitrait scaling
Sensitivity to changes in health status	
Does it cover the relevant time?	Read the questionnaire introduction and the response categories carefully
Does it capture extreme responses? (e.g. severe pain as well as absence of pain)	

PRO, patient-reported outcome.

Core outcome sets for the evaluation of surgery

One of the problems with PRO assessment is the myriad available questionnaires and scales (PROMs) to use. This means that studies often report up to 25 different PROs and that data are difficult to synthesize (because different measures are used). It means that studies may suffer from outcome reporting bias, in which data are presented and published because of statistically significant findings (omitting non-significant results) rather than publishing the results of prespecified hypotheses. These methodological problems are also common in clinical studies, because of the multiple, ill-defined methods used to assess recovery and outcomes of surgery. A potential solution to the problem of outcome reporting is to define core outcome sets for each surgical condition or procedure. A core outcome set is an agreed set of outcomes (usually about 7–10) that are reported in all studies, as a minimum, evaluating a particular condition or intervention. The systematic use of core outcome sets will improve direct and indirect comparisons of trials, data synthesis in meta-analyses, audit of hospitals or surgeons' performance and also reduce outcome reporting bias.

The OMERACT (Outcomes Measures in Rheumatoid Arthritis Clinical Trials) initiative has pioneered this approach, initially developing a core outcome set for rheumatoid arthritis but more recently expanding this to condition- and disease-specific measures. Core outcome sets are developed using an iterative data-driven scientific approach that includes surveying views of key stakeholders to reduce an initial long list of all potential outcomes to a core list that is agreed by reaching consensus. OMERACT initially developed a core clinical outcome set, with seven items selected that were predominantly chosen by rheumatologists. This was subsequently expanded after work with patient groups further identified core 'PRO' sets, and one of the PRO outcomes, fatigue, was subsequently included in the core clinical outcome set. This approach is very likely to improve outcome measurement and reporting in trials and clinical audit and the development of core outcome sets for surgical procedures, including PROs, is strongly recommended. The COMET (Core Outcomes in Effectiveness Trials) (http://www.comet-initiative.org/) initiative brings together researchers interested in the development and application of agreed standardized sets of outcomes. The current sets of outcomes available are collated on the website, and the initiative aims to collate and stimulate relevant resources, both applied and methodological, as well as facilitating exchange of ideas and information, and fostering methodological research in this area.

Summary

Currently, there are a wide range of PROMs available, although as the science in this area develops and the clinical application of PROs is better understood it is likely that these will be reduced. Key aspects of PROMs are to ensure that they are designed to be completed by patients themselves, that they measure the dimensions of interest to the study and that they cover the time frame of interest with response categories that are appropriate. Methods to score each instrument and present clinically meaningful results are developed and available for validated tools. The interpretation of the PRO data alongside clinical outcomes is especially important for results to be used in practice and be meaningful to patients and clinicians. The potential development and identification of core outcomes sets for particular diseases and interventions that include PROs is a practical method for ensuring that outcomes can be synthesized and compared between studies, and it may reduce the problem of outcome reporting bias.

Why measuring patient-reported outcomes is important in the evaluation of surgery

Using patient-reported outcomes in clinical practice

The main roles for measuring PROs in addition to clinical outcomes to evaluate surgery is to use the data from well-designed studies to (1) meet patients' information needs, (2) inform disclosure for consent for surgery and (3) inform clinical and health policy decision-making. These overlapping areas, which all involve the surgeon knowing and understanding PROs from well-designed studies evaluating surgical procedures, are considered in detail below. The PRO data may come from studies examining a single surgical intervention (by describing how the operation impacts on short-term and longer term PROs), or data may come from randomized or non-randomized comparative studies.

Patient-reported outcome data to meet patients' information needs

The information needs of patients scheduled for surgery differ among patients and change over time. Evidence shows, however, that most patients report that they want to know as much information as possible, although in some situations they may be overwhelmed by the sheer amount of information provided by clinicians, the mass media and the internet. In addition to patients wanting information, the family may also be requesting data, and dealing with these issues can be difficult. The type of information that patients want to know includes clinical details about risks and chances of surgery being successful, and patients and families want information about psychosocial and emotional issues and how the patient will feel after the operation. Accurate provision of such information by surgeons during consultations with patients requires that well-designed studies with clinical outcomes and PROs have been performed, that surgeons are aware of these outcome data and that they are able to communicate it effectively.

Communication of risks and benefits of surgical procedures is recommended before consent can be obtained for surgery, and, in the UK, guidance from the General Medical Council also recommends that information provision includes data about how surgery will affect lifestyle and factors that are important to the patients themselves. It is these latter details that require studies to be performed with reliable and valid PROMs, otherwise surgeons will not be aware of how surgery affects psychosocial wellbeing for example, or patients' ability to function.

Some types of surgery have used PROMs in well-designed studies and produced useful data that can be used in consultations and in written information sheets to provide patients and families with relevant details to meet information needs. At present, methods to communicate PRO data are not standardized in practice, although patients may have high levels of understanding of bar charts or pictographs to communicate multidimensional PROs. Explaining risks and rates of clinical outcomes alongside PRO data may be challenging, however, especially if surgery is major. Decision aids have been developed to help clinicians to communicate complex information to patients and data within these tools is usually derived from well-designed studies. Decision aids may be in the form of booklets, prompt sheets, video recordings and interactive web-based formats, which can help patients understand data and lead to a more active role in decision-making. There is evidence that decision aids increase patients' knowledge about options, lower decisional conflict and reduce the proportion of patients remaining undecided about treatment.

Standards for information disclosure in informed consent for surgery

It has already been stated that information needs of patients vary and change over time and, although many patients want as much information as possible, some patients prefer to leave the decisions to the surgeons – taking a passive role in the consultation. Surgeons, therefore, need to make efforts to elicit the information that patients may wish to have and to provide data about clinical outcomes and PROs and information about the process of care to meet each patient's needs. In situations in which patients do not want to have information, there is also the requirement for surgeons to provide at least sufficient information for patients to understand what they are agreeing to undergo and provide 'effective' consent. If patients are unaware of any of the consequences of surgery, they may not realize what they really did want to know in more detail. This highlights the differences between societies' rules governing 'effective consent' and genuine autonomous consent from a patient who truly understands what they are signing up for. Legal consent, for example, may focus on doctors' responsibilities to disclose information, rather than ensuring that patients understand and that they have received information of importance to their values.

There are three theories of informed consent that are relevant to surgeons informing patients of the outcomes of surgery: the professional practice standard (also called the prudent or reasonable doctor standard), the reasonable person standard (or prudent/reasonable patient standard) and the subjective standard. From a professional viewpoint it is theorized that only doctors have the necessary expertise and experience to decide what information patients need to undergo surgery. It is considered that doctors are acting in the best interests of patients (beneficence). Provided that a responsible body of medical opinion agrees on what information needs to be communicated as part of consent, then that is the minimum information required to avoid being negligent. This theory may be criticized, however, and it only views information disclosure from a medical viewpoint, meaning that outcomes of importance to the patients may not be disclosed, overriding principles of autonomy. The reasonable person standard has therefore gained acceptance in over half the US states and in the UK. In this standard, information is deemed important according to what a hypothetical 'reasonable person' might expect. Typically, this information includes the nature and purpose of the treatment, risks, potential benefits and available alternatives. The reasonable person standard confers some considerable ethical advantages: it shifts the determination of what information is important away from the doctor and moves towards ideas of 'autonomous authorization'. It does, however, risk being too patient focused and not allowing patients to gain sufficient understanding of the medical outcomes of an intervention, although it may be argued that there is no moral distinction between reasons why information is important. According to this theory, information that influences individuals' decision-making may be equally important as that which does not. There is therefore another standard that needs consideration when considering information disclosure. In this standard, the information that needs to be disclosed for legal consent is taken on a case-by-case basis. This is because of the subjective personal values that patients use in defining what is 'important'. This standard is not used in the UK. Problems centre on the legal credibility of patients' retrospective opinions, particularly when patients perceive they have been wronged. In addition, it has been considered unreasonable for a doctor to carry out an exhaustive character analysis to determine each patient's relevant needs. The subjective standard may be seen as the preferable moral standard, but, because of the subjectivity, it has been described as insufficient for law.

Patient-reported outcome data to inform decision-making

Between patients and surgeons

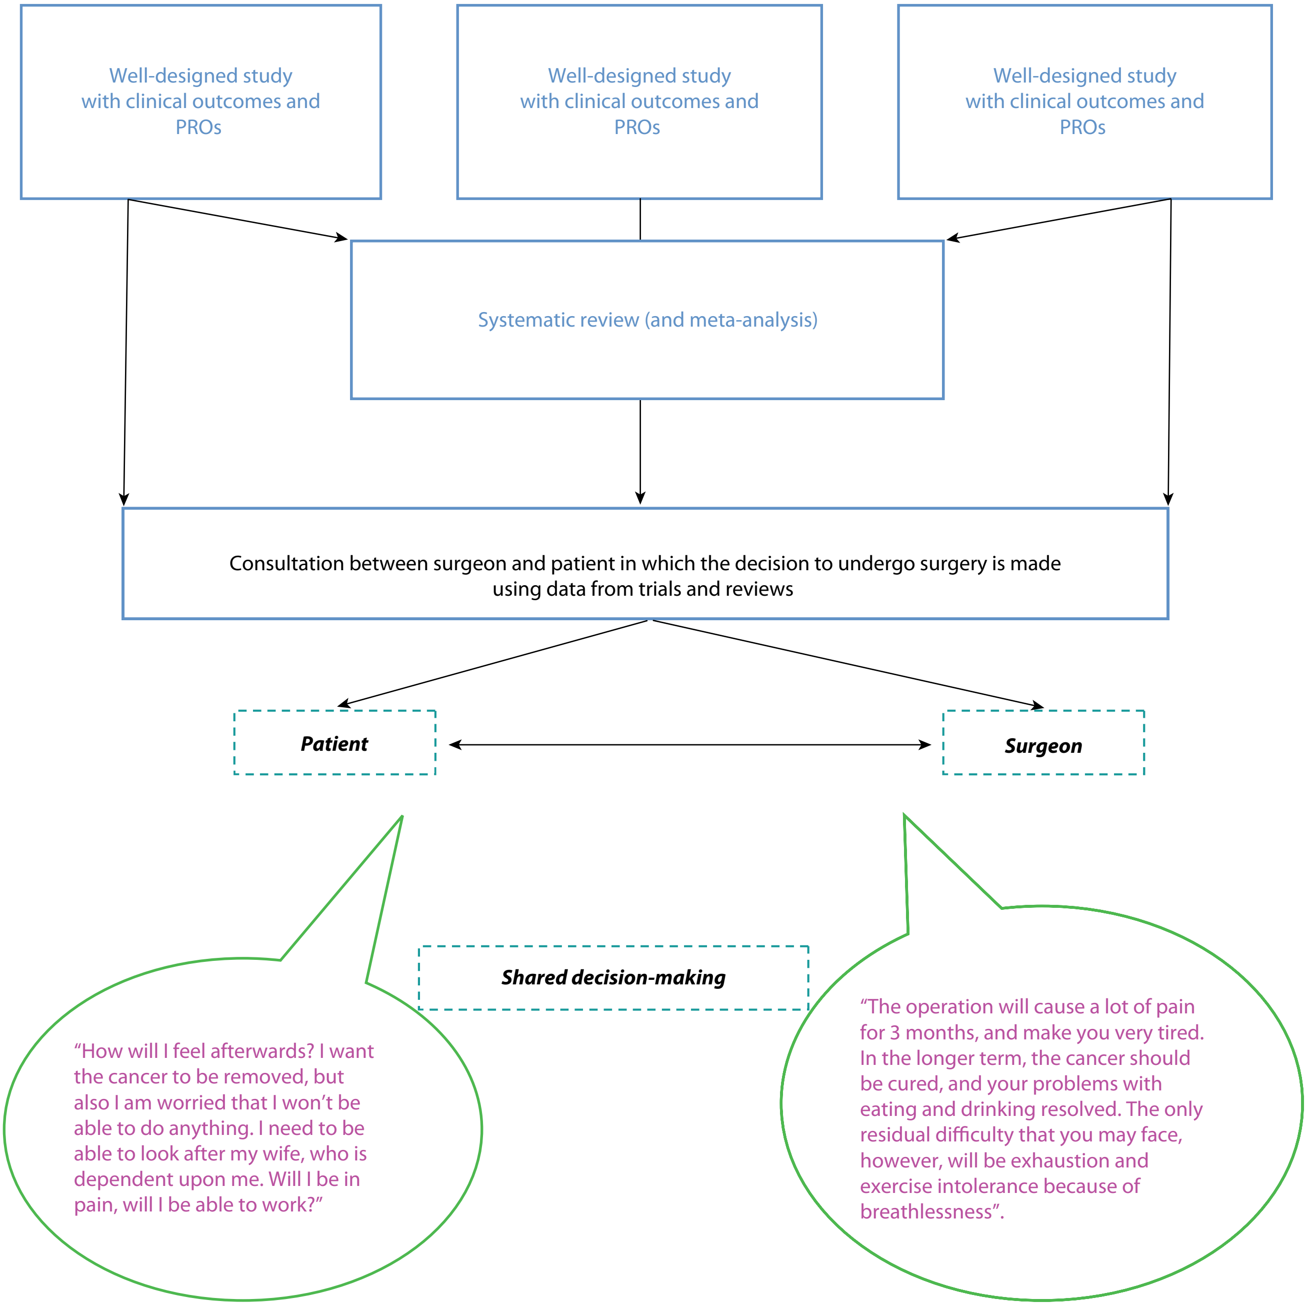
Information exchanged during consultations between surgeons and patients in which decisions to undergo surgery are made is necessary to allow patients to reach an informed decision. Surgeons are ethically and legally required to provide patients with *sufficient* information to ensure that competent and autonomous patients have *substantial* understanding. Information regarding the disease, its natural history, how it may be treated (including surgical and non-surgical alternative treatments) and short- and long-term clinical outcomes and PROs may be communicated. The framework in which information is exchanged is recommended to be one of mutuality, 'shared decision-making', in which both the patient and the surgeon engage in the conversation and there is joint negotiation of values and information that is considered to be important to both parties. Typically, surgeons know the clinical consequences of surgery and rates of these happening, and they can make sensible estimates of these occurring individually based upon risk assessments of the patient's general health, comorbidities and nature of the disease severity. Surgeons, however, are not often aware of how most procedures may affect PROs and they may not be aware of the patient's individual values about different sorts of outcomes. For decision-making, therefore, to be 'shared', it is necessary for a surgeon to be aware of the PROs of each procedure and to elicit the patient's values during the consultation. These principles are supported by most surgical organizations, and in the Royal College of Surgeons of England publication *Good Surgical Practice* (which is endorsed by 12 other organizations) it is stated that:

> A surgeon must listen to and respect the views of patients and their supporters; recognise and respect the varying needs of patients for information and explanation; insist that time is available for a detailed explanation of the clinical problem and the treatment options and encourage patients to discuss the problem.

Therefore, during consultations in which decisions are made to undergo surgery, it is necessary to provide information of relevance to the patient as well as clinical data. Figure 5.1 illustrates how this may work in practice.

Between health policy-makers

PRO data can also be used to inform health policy-makers during decisions in which resource allocation is agreed. This process varies between countries, and the UK model will be described here. In the UK, the National Institute for Health and Clinical Excellence (NICE) provides guidance, sets quality standards and manages a national database to improve people's health and prevent and treat ill health. It makes recommendations to the National Health Service,



Well-designed study with clinical outcomes and PROs
Well-designed study with clinical outcomes and PROs
Well-designed study with clinical outcomes and PROs
Systematic review (and meta-analysis)
Consultation between surgeon and patient in which the decision to undergo surgery is made using data from trials and reviews
Patient
Surgeon
Shared decision-making
"How will I feel afterwards? I want the cancer to be removed, but also I am worried that I won't be able to do anything. I need to be able to look after my wife, who is dependent upon me. Will I be in pain, will I be able to work?"
"The operation will cause a lot of pain for 3 months, and make you very tired. In the longer term, the cancer should be cured, and your problems with eating and drinking resolved. The only residual difficulty that you may face, however, will be exhaustion and exercise intolerance because of breathlessness".

Figure 5.1 How the data from studies with patient-reported outcomes may be used to inform practice.

to local authorities and to other organizations about new and existing surgical procedures and it aims to improve peoples' health as well as keeping costs to a minimum. One of the key indicators used by NICE is a PROM combined with a quantitative outcome, the quality-adjusted life year (QALY). This allows decisions on cost-effectiveness, usually measured in terms of incremental cost per QALY gained, to be made. A QALY places a weight on time lived by patients in different health states. A year of perfect health is worth 1, and a year of less than perfect health is worth less than 1. Death is considered to be equivalent to zero; however, some health states may be considered worse than death and have negative scores. Using QALYs provides a common currency to assess the extent of the benefits gained from a variety of interventions. When combined with the costs of providing the interventions, cost–utility ratios result; these indicate the additional costs required to generate a year of perfect health (1 QALY). Comparisons can also be made between interventions, and priorities can be established based on those interventions that are relatively inexpensive (low cost per QALY) and those that are relatively expensive (high cost per QALY).

The most commonly used PROM for the measurement and QOL when calculating QALYs is the EQ-5D. The EQ-5D is widely used and has been validated in many different patient populations. It has been designed so that people can describe the extent to which they have a problem in each of the five dimensions of health: mobility, ability to self-care, ability to undertake usual activities, pain and discomfort, and anxiety and depression. The responses to the EQ-5D allow 245 health states to be represented. The valuation of the different health states was calculated by a random sample of 3000 people in the UK examining these states and this allows the PRO data to be mapped to utility scores and used to form a QALY. Although the EQ-5D is the most widely used instrument for this purpose, some of the other validated measures of QOL have more recently been mapped into QALYs.

In surgical settings, gaining high-quality data about QALYs is unusual, however, as few trials and prospective studies are performed using this measure, and even fewer have made efforts to systematically capture and report PROs. The next section describes how to design studies with PROs that produce valid data to inform practice.

Using patient-reported outcomes in research

Within a research context there are other roles of PROs that may be relevant to clinical practice in the future. These include using PROs in outpatient consultations to collect detailed information about the range of problems that a patient may face and to use this in real time to facilitate communication in the clinic. PROs may be used as prognostic markers to predict survival after surgery for cancer and it is possible that PROs may be used to monitor patients after surgery for cancer and replace standard clinical follow-up, provided there are good systems in place to respond to PRO data. Although these areas are of interest, a lot more research and development is still required to be certain of the validity of PROs in these situations.

Using patient-reported outcome measures in clinical practice

There is a growing interest in routinely collecting PROs as part of care for individual cancer patients. The purpose of this is to capture patients' perspectives on the impact of their disease and treatment on their own health, including their symptoms, self-reported functions and their assessment of overall health. Feedback of PRO data in real time to clinicians responsible for their care has the potential to help detect unmet needs or problems, theoretically leading to better control and monitoring of the relevant issues. This may also prompt health professionals to discuss issues that may not have been raised by the patients in the clinic and facilitate better communication and care. There is some evidence to show the positive effects of this approach to processes of care (e.g. doctor–patient communication), but less evidence to show that this improves patients' outcomes *per se*. Reviews have summarized these issues and shown how this intervention is highly complex and dependent upon clinician and patient behaviour as well as the nature of the PROMs themselves. They also show how organizational changes are required to facilitate this process and electronic data collection and systems for feedback of the data to clinicians are needed. More recent work shows that doctors may receive PRO data about symptoms more readily than data about functions. Such work has predominantly been carried out in cancer patients and with oncologists. Further work evaluating the use of PRO data in real time in surgical settings is still needed.

The prognostic value of patient-reported outcomes

The predictive value of PROs has been examined in several situations and summarized in reviews. Many of the papers have not rigorously adjusted the multivariable models for known biological or clinical indicators, but those that have also show how some domains of HRQL are independently predictive of survival in many settings in surgical oncology. The underlying reasons for these observations remain unknown, whether patients with clinically unrecognized conditions feel more ill and report this in terms of PROs before the disease is diagnosed or its severity known is one possible explanation, or it may be that better PROs are associated with a healthier lifestyle and longevity. This is an area where further research is required.

Using patient-reported outcomes to monitor and follow-up patients

The use of PROs to monitor and follow-up patients is very plausible because it may reduce the need for outcome consultations, where a simple questionnaire can suffice to detect persistent or new issues. This has been examined in several non-surgical settings and results show that this is an expensive process with little impact on clinical practice. Whether following surgical interventions this may have better results and whether the use of electronic devices (e.g. by mobile phone) will make this cheaper and more readily usable in the health services is unknown and warrants further research.

Designing studies with patient-reported outcomes

The design of a PRO study that will yield data to inform practice is essential to ensure that outcomes are valid, that the results are believed and that they can be implemented. In addition to careful study design, the reporting of the study is critical and these two concepts are linked. A well-designed study should lead to a high-quality report, although even a weakly designed study can be well reported, allowing the reader to judge the validity of the study findings. A summary of the key things to consider during study design and reporting is given in Table 5.3. Several papers have recommended methods to ensure that PRO studies yield valid data in randomized clinical trials and the key issues relevant to trials and other studies are described below.

Selecting the time points to measure patient-reported outcomes before and after treatment

Selection of the relevant time to assess PROs will depend upon the study objectives and whether PROs are primary or secondary endpoints. This can be achieved when the study rationale is considered, and the PRO domain(s) or interest selected. It is recommended that the specific nature of the anticipated effects of the intervention and the expected time for them to be exerted be considered in detail, because this will influence which PRO is selected to be measured, which tool is used to measure it and the timing and frequency of its administration. For example, in a trial of minimal access gastrointestinal surgery versus an open procedure, a PRO measure assessing pain or physical function may be important to distinguish differences between the two interventions. This, however, will need to be assessed within a few days or weeks of surgery, or the differences between the two procedures may be less apparent if an assessment is performed 4 or 6 weeks after surgery.

In addition to giving consideration to the timing of the postoperative PRO assessment it is recommended that a pre-treatment assessment of PROs is performed to provide baseline data. The boundaries of the time windows around the baseline assessment need specification (e.g. within 4 weeks before surgery or within 4 weeks before randomization). Capturing PRO before treatment can be difficult but it is essential because it is extremely difficult for patients who have undergone surgery to look back to reflect about their symptoms and functional ability before the operation.

Ensuring that the right domain of health is measured in a study, with the best instrument, will require discussion within a multidisciplinary team and inclusion of a patient (user representative) in addition to surgeons and methodologists with experience and knowledge of PROMs.

Choice of patient-reported outcome measure

The choice of instrument will depend upon what PROs require measurement and features of the study population, including clinical and sociodemographic details, such as the type of intervention being evaluated, level of education, gender, culture, general health, diagnosis, native language and age range. Assessment of the measurement properties of the PROM is critical and the instrument should be considered for reliability, validity and responsiveness to change. The citation for the instrument development and psychometric testing should be checked with advice from an expert, and the actual questionnaire scrutinized by the study team (details above). Consideration can be given to how long it takes for the questionnaire to be completed, the time frame of each question (asking about problems in the past week or past month for example) and the domains of health

Table 5.3 Issues to consider when designing patient-reported outcome (PRO) studies

Study population	Consider clinical (e.g. prognosis) features Consider demographic features (e.g. language, literacy, age)
Length and content of questionnaire	Check content and length for study population
Optimizing response rates to questionnaire	Select a few assessment points Ensure that all staff are familiar with the protocol Use central questionnaire administration Chase missing responses regularly Provide feedback to units
Dealing with missing data	Establish clear practice to follow in the event of missing assessments Establish clear practice to follow in the event of missing items/pages Document reasons for missing data
Analysing missing data	Document the amount and reasons for missing data and consider causes for bias Impute missing items according to developer's instructions
PRO data analyses	Document missing data Follow scoring instructions of the questionnaire Initially examine descriptive data from scales Be aware of values that are considered to be minimally important clinical changes in PROs Be aware of multiple testing

covered. Table 5.1 shows some of the most widely used validated measures available to assess PROs in surgery.

Determining the health-related quality of life sample size

In randomized clinical trials in which the PRO is a primary endpoint, it will be necessary to consider the effect size of each intervention to determine the number of participants and the expected differences in effect size between each arm of the trial, as well as the required power for the trial. It is also necessary to consider the number of PRO assessments and the proposed analyses and the available information on the underlying assumptions of expected benefit. In general, PROs are secondary endpoints in trials and therefore they do not influence the sample size calculation. Where they are primary endpoints, consideration for non-response and loss to follow-up is also necessary. Although trials measuring PROs often include numerous patient reported outcomes measures (PROMs), it is recommended that a maximum of four or five outcomes *a priori* be included in formal analyses, taking into account the effect of multiple significance testing.

Missing data

Difficulties with obtaining good questionnaire compliance are commonplace in many studies and this can invalidate the results. The most frequent reason for missing questionnaire data is administrative failure and patients are simply not approached and asked to complete assessments. Missing data may also occur because patients are too ill (more common in cancer studies), and about 5% of data are missing because patients refuse to participate. Ensuring high questionnaire compliance is very important, and levels of over 80% should be aimed for to avoid response bias. A number of strategies can be enlisted to minimize missing PRO data. High-quality study design with clear and minimal PRO assessments that are straightforward to complete is one of the most important issues. Likewise, a well-designed study will be appropriately funded and ensuring that staff are familiar with the protocol and understand how to access patients is essential. Utilizing postal administration of questionnaires from a central trials team (after the patient has been recruited locally) is an efficient means of ensuring that questionnaires are administered on time and that missing responses are chased up appropriately.

For surgical trials, it is recommended that an in-built pilot study or a stand-alone feasibility trial be carried out to examine the best methods to collect PRO data and to allow improved organization and preparation for unforeseen difficulties in data collection. Patient-based sources of missing data may be tackled by choosing an appropriate instrument and by paying attention to participants' motivation by providing a clear explanation of the reasons of why, when and how PRO assessments will be made, whom they may contact for help and what will happen to the data they provide (an information sheet that details confidentiality and data dissemination is typically required by most ethics committees). Proxy completion by a carer, clinician or significant other may be considered in the event of missing data as a result of participants' inability to complete the questionnaire. This should be considered prior to the start of the trial if it is anticipated that this might be a common problem. It should be noted, however, that there is evidence to suggest differing levels of concordance between patients and proxies according to the dimension being assessed, which may introduce an element of bias into the PRO assessments.

Missing data may take two main forms: (1) item non-response, in which data are missing for one or more individual items, or (2) unit non-response, in which the whole questionnaire is missing for a participant, because of missing forms, the participant dropping out of the study or entering it late. Although it is possible to prevent much missing data, a certain amount should be expected within any study. The protocol should contain clear instructions on what procedures to follow in the event of a missing questionnaire or missing data for individual items, such as whether the participant should be contacted. In all cases, it is good practice to maintain a record of the reasons for missing data, in order to ascertain the extent to which this was related to the patient's PRO and to inform the analyses and interpretation of the data. The relative amount of missing data, the assumed cause, the sample size and the type of intended analyses will determine the degree to which missing data is a problem, and it will critically inform the interpretation of the results of the study.

Dealing with missing data

Poor compliance resulting in missing data can have a significant detrimental impact on the analyses and interpretation of data. First, fewer observations may result in the power of the study to detect an effect being compromised. Second, missing data may introduce selection bias into a trial and thereby compromise its validity, particularly if low compliance is associated with less well patients who have poor outcomes. It is therefore important that the impact of missing data is carefully addressed, and that the potential cause of the missing data is understood, as the most appropriate method for dealing with it will depend largely on the assumed mechanism by which it is missing: if the reasons for missing data are completely unrelated to the respondent's health, it is classified missing completely at random. If the likelihood of missing data depends only on previous scores but not current or future scores, it is considered missing at random. Data are only considered not missing at random if the 'missingness' is actually related to the value of the missing observation. The relevant approach for dealing with each type of missing data varies depending on whether potential bias due to data not missing at random needs to be addressed. Methods are available to test the assumption of whether or not data are missing at random. Having a record of the reasons for missing data in a trial is particularly important here.

Missing values for individual items may be imputed (filled in) to complete the data in order that a full analysis may be undertaken. Most commonly, the mean of answered questions is imputed, provided that at least half the items are completed, although this may not be suitable for scales whose items are ordered hierarchically according to difficulty. Other less common approaches include imputation based on the responses of other respondents or regression of missing items based on other scale items. Some instruments are provided with instructions on how to score the question when items are missing. Methods for dealing with missing whole questionnaires/assessments in longitudinal (repeated measures) studies when missing data are assumed to be ignorable include complete case analysis, which involves removing patients with incomplete data, and available case analysis, which uses all available cases on a specific variable and is subsequently more desirable. Alternatively, data can be filled in using imputation-based methods such as last observation carried forward, single mean imputation, predicted value imputation or hot-deck imputation. Statistical techniques such as likelihood-based methods have been developed for non-ignorable missing data, but they are complex and controversial and should therefore be applied with caution. More sophisticated models have been developed specifically for non-ignorable missing data, which are likely to arise in trials, but they are limited by their complexity and lack of availability and interpretability. They are often accompanied by sensitivity analyses, which are used to compare the appropriateness of employing a given strategy.

Analysing patient-reported outcomes and integrating results with clinical outcome data

The analyses of PRO data require appropriate methodological expertise, and collaboration with a statistician is recommended. If the research question and study design are clearly stated in the protocol and the PRO hypotheses established, then analysis of data should be possible and overexploring and overinterpreting data avoided. Using descriptive statistics to illustrate the impact of surgery on PROs is the initial first step and data may be presented as means with confidence intervals or in proportions (of patients with good or poor PRO scores). At present, there is still a lack of general understanding about the impact of most surgical treatments on PROs, and therefore using graphical methods to illustrate these simple descriptive changes will aid patients and surgeons.

One of the areas that further work is needed for surgeons to understand PROs within a clinical context is the meaning of changes in PRO scores over time. Because of unfamiliarity with questionnaires and scoring systems it can be difficult to use the data in practice. It is recommended that the use of validated tools and understanding the data themselves is more widespread to aid interpretation of the information and what changes in scores constitute a clinically significant difference.

It is also recommended that clinical outcomes are considered alongside PROs. For example, in a study reporting HRQL scores for cancer surgery, it is inappropriate to report that scores were very good a year after the operation without considering the survival of the group undergoing surgery. In studies of oesophagectomy for cancer, in which 2 year survival rates are approximately 50%, if those who survive have good HRQL then information to be imparted to patients before surgery needs to contain both accurate PRO and survival data for informed treatment choices to be made.

Conclusions

The use of PROs to evaluate surgery has only just begun to be established in healthcare and it is expected that over the next two decades the real value and place of this type of outcome measure will be better understood. In the meantime, it is recommended that more well-designed studies evaluating PROs of surgery are performed, analysed and reported, and that data are used routinely alongside clinical outcomes to inform clinical decision-making. Surgeons require training in the use of communicating PROs, and decision aids for each surgical procedure need developing to assist these processes. Accurate PRO data in the consultations will complement communication of short- and long-term clinical outcomes. The development of core outcome sets for surgical procedures including core PROs is one means of evaluating surgery in ways that will allow cross-centre, -surgeon and -study comparisons and data synthesis to occur. Future research into the prognostic value of PROs and their role in improving individual patient care and follow-up is still needed. It is anticipated, however, that better understanding of PROs will improve surgical practice and allow treatment decisions to be more patient centred and thus lead to better adherence to treatment and surgeon and patient satisfaction with this key part of surgical practice.

CHAPTER 6

Intensive and high-dependency care

ARUP CHAKRABORTY, NICOLAS PRICE AND MARTIN STOTZ

> *Salus aegroti suprema lex.*
>
> (Hippocrates c. 460 BC to c. 370 BC)

What is intensive care?

Intensive care medicine (ICM) is the science and art of identifying and managing critically ill patients while preventing further deterioration.

Intensive care demands a dedicated area in which all monitoring and therapeutic devices are immediately available to the appropriately trained professionals and a holistic approach of all professionals involved to diagnose, evaluate and integrate the patients' needs. This will help to develop objectives of care for the patients' best short-, medium- and long-term outcomes.

This chapter focuses on ICM and shall shed light on different aspects of this specialty. We will discuss advanced haemodynamic monitoring, vasopressor and inotropic therapy, sepsis, mechanical ventilation and, finally, death, which are all integral and important parts of modern ICM. It will not allow enough knowledge to make the careful reader a high-dependency or ICM specialist, but will allow an insight into some topics specifically related to the surgical patient. The aim of this chapter is to provide a fundamental understanding of underlying pathophysiology to facilitate a timely initiation of appropriate therapy by non-intensive care practitioners.

Evolution of a new specialty

Historically, Florence Nightingale was probably the founder of ICM. Nightingale had developed an outstanding dedication to patient care during the Crimean war (1853–6). She was named 'the lady with the lamp' as she was making rounds at night for the injured soldiers. As Florence recognized that some patients needed more frequent and careful monitoring than others, she started to group these patients closer to the nursing station. An area for high-dependency patients was born.

However, it was only in the last century, during the 1952 poliomyelitis epidemic, hospitals in Copenhagen, Denmark, started to create the spaces dedicated to perform mechanical ventilation for the treatment of multiple patients with respiratory failure. This new science, and the medical developments for specialized organ support that followed, needed the creation of designated areas in hospitals: the *Intensive Care Unit* (ICU). In parallel to these advances in technology, generations of physicians and nurses acquired new knowledge and skills over the years to form an integrated package of care, known today as *Intensive Care Medicine*.

Definition of intensive care

Intensive care can be broadly defined as a service for patients who have potentially recoverable conditions and who can benefit from more detailed observation and invasive treatment than that provided safely in an ordinary ward. It is usually reserved for patients who are at risk of, or indeed have, established organ failure. This can arise either as a result or complication of an acute illness or trauma, or as a predictable phase after major surgery.

The borders of intensive care and high-dependency care are fluid and not clearly defined. The progression of a disease over time will define the patient's need for more or less intense therapy. Areas in hospitals are usually classified by the level of care provided within, or more specifically by a nurse to patient ratio, which matches the level of care that can be provided (Table 6.1). The high-dependency unit (HDU) usually consists

Table 6.1 Example of levels of care

Levels of care	Nurse to patient ratio	Patient status
Level 1	4:1	At risk of deterioration Relocation from higher levels of care
Level 2	2–2.5:1	More detailed observation or intervention necessary, including support of a single organ system 'Step down' from higher levels of care
Level 3	1:1	Advanced monitoring and support of >2 organ systems Advanced respiratory support

of level 2 care, whereas level 3 care is reserved for the ICU. This concept has been well tested and is an approved model of meeting medical demands.

It is the concentration of the skills, expertise and resources coming together in one designated area that makes an ICU. However, HDU and ICU care should never be seen as isolated specialties and co-operation with other specialists is mandatory to achieve the best possible patient outcomes.

'Open' and 'closed' Intensive Care Unit models

Today, different models of ICUs exist across the world. Full-time, fully trained intensive care physicians run most ICUs in Europe and Australasia. The intensivist is leading a multidisciplinary team of experts who are able to provide cover for specialized ICU care for 24 hours per day, 7 days per week; this is also known as a *closed* ICU model. This model has evolved since the 1960s, taking into account the development and definition of this unique specialty. The model of care in the USA, however, is different, with a significant number of ICUs still using the *open* model. This means that the decisions about care and therapy of patients remains with the primary physician, who is not necessarily a member of the ICU permanent staff but who leads the patient's management from hospital admission to discharge. The primary physician will, in turn, look after patients on the ICU, with the input of an intensive care professional only if needed.

As the closed model has been shown to decrease both ICU and hospital mortality and length of stay for patients, it seems favourable compared with the open model. Designated staff and around-the-clock availability can best provide continuity of care on the ICU/HDU. It also underlines the fact that ICM has evolved into a separate specialty that requires appropriate training to achieve best outcomes. Hence, ICM has become a specialty in its own right and is best provided by specifically trained professionals.

Criteria for admission to the intensive care unit

Nowadays, ICU professionals seem to become more involved in the care of unstable patients outside the ICU, a movement called 'critical care without walls'. ICM is expensive and labour intensive, thus resources in hospitals may be limited. A significant responsibility is on the intensivist together with the primary team to appropriately identify and triage those patients for ICU and HDU admission who are most likely to benefit from ICM and to restrict admission of others. ICU admission criteria must be able to cope not only with the critically ill emergency patient but also with planned elective admissions after major surgery.

The development of admission criteria is a complex issue and generally depends on multiple factors:

- the medical status of the patient at referral
- any underlying medical conditions, including dependency of the individual before admission
- ethical and religious implications for the patient (including the wishes of the patient, if known) and sometimes needs of the wider society (e.g. epidemic outbrakes such as H1N1)
- availability of level 2/3 care; if this is not available on site, the availability of a transfer team must be considered.

Attempts have been made to define admission (and discharge) policies based on scientific grounds, and were first published by the Society of Intensive Care Medicine in the USA. In Europe, several regional and national guidelines exist, but a conclusive pan-European consensus is missing to date. Most intensivists will usually base the decision whether to admit patients on a combination of prioritizing criteria, such as those outlined in Table 6.2.

Identifying critical illness

Care of the acutely ill patient in hospital may require input from critical care. The ageing population and increasing complexity of medical and surgical care mean that patients in hospital are at increasing risk of becoming acutely ill and may require admission to ICU areas. However, recognition of acute deterioration of the unwell can be delayed or even missed, as outlined in several reports.

The minimum standard should record the following physiological observations:

- heart rate (HR)
- respiratory rate
- systolic blood pressure
- level of consciousness
- oxygen saturation
- temperature.

Table 6.2 Priorities for admission to an intensive care unit

Priority	Patient	Intervention needed	Limitations of treatment	Special considerations
1	Critically ill Unstable physiology Emergency or planned admission	Advanced monitoring Intensive care most likely	None	Brain death confirmed or expected (consider organ donation)
2	Critically ill Moderately unstable Emergency or planned admission	Advanced monitoring Possibly intensive care	None	
3	Critically ill Instability of various degrees	Advanced monitoring Possibly intensive care	Perhaps	Underlying disease Reduced likelihood of recovery
4	Instability of various degrees		Yes or no	'Too well to benefit' 'Too sick to benefit' Refusal by patient

Physiological track-and-trigger systems are useful to monitor all patients in acute hospital settings. Staff should have competencies in monitoring, interpretation and response to the acute deterioration. If abnormal physiology is detected, a graded response should be triggered. This should be agreed and delivered locally. If admission to a critical care area is indicated, the decision to admit the patient should involve both a senior decision-maker of the primary team caring for the patient on the ward and the ICU.

Patients can be classified into three groups and should trigger responses as follows:

- Low score group:
  - increased frequency of observations and informing the senior nurse.
- Medium score group:
  - urgent call to the primary medical team
  - simultaneous call to personnel with competencies in acute illness.
- High score group:
  - emergency call to the team with critical care competencies. These competencies should include assessment of the critically ill patient, advanced airway management and resuscitation skills.

Several physiological track-and-trigger systems are in use. Single parameter systems are simple to use and are easy to reproduce. Multiple parameter systems are more complex but allow for better monitoring of clinical progress and for a graded response strategy, but may lack reproducibility.

Whatever track-and-trigger system is used locally, escalation policies should be agreed as well as follow-up of the recognized deterioration. To support this, some institutions use specialized response teams or critical care outreach that can be contacted if a patient deteriorates.

Haemodynamic monitoring

Although clinical examination can assist guiding fluid and inotrope therapy, it is not always accurate. Advanced haemodynamic monitoring has established itself as an invaluable tool to guide therapy in the critically ill patient. It encompasses examination and measurement of the arterial pressure waveform, the central venous pressure (CVP) and cardiac output (CO). And, indeed, haemodynamic monitoring has been shown to improve outcome in a variety of settings. This section will discuss some elements of advanced haemodynamic monitoring and the underlying cardiovascular physiology.

Physiology

To a certain extent, CO and organ perfusion can be assessed clinically with a combination of the following:

- feeling the temperature of the extremities
- assessing the capillary refill time
- assessing the conscious level
- measuring the urine output
- blood pressure measurement.

In addition, blood lactate and base deficit can also give an indirect indication of global organ perfusion. However, clinical assessment of CO has a great interobserver variation and different observers may give widely differing opinions of the CO and filling status of the same patient. One reason for the use of more scientific methodology to quantify CO is to attain a degree of standardization and reproducibility.

Cardiac physiology

CO is the product of heart rate (HR) and stroke volume (SV), i.e. CO = HR × SV, whereas SV is determined by the cardiac preload, afterload, and contractility.

The cardiac index (CI) is obtained by dividing the CO by the patient's body surface area {BSA; BSA (m^2) = $\sqrt{[\text{height (cm)} \times \text{weight (kg)}]/3600}$} allowing comparison of individuals by adjusting for height and weight:

$$\mathrm{CI} = \mathrm{CO}/\mathrm{BSA}$$

Blood pressure = CO × vascular resistance; therefore systemic vascular resistance (SVR) and pulmonary vascular resistance (PVR) are:

$$\mathrm{SVR} = [(\mathrm{MAP} - \mathrm{CVP}) \times 80]/\mathrm{CO}$$

$$\mathrm{PVR} = [(\mathrm{PAP} - \mathrm{PAWP}) \times 80]/\mathrm{CO}$$

where MAP is the mean arterial pressure, CVP is the central venous pressure, PAP is the pulmonary arterial pressure and PAWP is the pulmonary arterial wedge pressure (see Fig. 6.4). The factor of 80 in the above equations serves for unit conversion (dynes s/cm^5).

Physiology of oxygen

Blood oxygen content (CaO_2) is the sum of the oxygen bound to haemoglobin (Hb-O_2) and the oxygen dissolved in plasma: 1 g of haemoglobin is able to bind a maximum of 1.34 mL of oxygen, whereas 1 g of plasma binds 0.003 mL of oxygen:

$$CaO_2 = (\mathrm{Hb\text{-}O_2}) + (PO_2 \times 0.003)$$

$$\mathrm{CaO_2} = ((\text{Hb oxygen saturation}/100) \times \mathrm{Hb} \times 1.34) + (PO_2 \times 0.003)$$

Delivery of oxygen (DO_2) is the product of CaO_2 and CO:

$$DO_2 = CaO_2 \times \mathrm{CO}$$

$$DO_2 = ((\text{arterial oxygen saturation} \times \mathrm{Hb} \times 1.34) + (PO_2 \times 0.003)) \times \mathrm{CO}$$

Perhaps the most important goal in the management of the critically ill patient is the maintenance of adequate DO_2. The amount of oxygen dissolved in plasma is so small that, for most purposes, it can be almost ignored. O_2 consumption (VO_2) is obtained by multiplying the CO by the difference in arterial and mixed venous oxygen content:

$$VO_2 = \mathrm{Hb} \times 1.34 \times ((\text{arterial saturations}/100) - (\text{mixed venous saturations}/100)) \times \mathrm{CO}$$

Table 6.3 Summary of equations with normal ranges

Variable	Calculation	Normal range
CI	CO/BSA	2.5–4.2 L/min/m^2
SI	SV/BSA	40–60 mL/m^2
SVR	((MAP – RAP) × 80)/CO	960–1400 dyn.s/cm^3
PVR	((PAP – PAWP) × 80)/CO	25–125 dyn.s/cm^3
DO_2	CO × ((saturations/100) × Hb × 1.34)	950–1300 mL/min
VO_2	CO × Hb × 1.34 × ((arterial saturations/100) – (mixed venous saturations/100))	180–320 mL/min

BSA, body surface area; CI, cardiac index; CO, cardiac output; DO_2, oxygen delivery; MAP, mean arterial pressure; PAP, pulmonary arterial pressure; PAWP, pulmonary arterial wedge pressure; PVR, pulmonary vascular resistance; RAP, right atrial pressure; SI, stroke index; SV, stroke volume; SVR, systemic vascular resistance; VO_2, O_2 consumption.

Some of the equations with normal ranges are summarized in Table 6.3.

Following this concept, Shoemaker and peers aimed to improve survival in critically ill patients through therapeutically driving DO_2 and VO_2 to supranormal levels by early aggressive fluid therapy and by using vasopressors and inotropes in the early 1990s. After initial promising results, other authors were not able to confirm this hypothesis and the concept has been abandoned these days. Moreover, evidence has emerged recently that, rather than a decrease in overall oxygen delivery, microcirculatory abnormalities and an inability to extract oxygen (dysoxia) seem to prevail in critical illness.

Arterial pressure

Non-invasive measurement of blood pressure is intermittent. Continuous invasive arterial pressure monitoring is often employed in ICUs as real-time measurement of blood pressure and is mandatory for patients treated with vasoactive medication. In addition, frequent arterial blood gas analyses are often necessary in critically ill patients who receive mechanical ventilation.

The radial, femoral and brachial arteries are the most commonly used sites for insertion. The arterial pressure is transduced via a short extension of rigid manometer tubing. The transducer is zeroed to atmospheric pressure and should be positioned at the level of the patient's heart (or axilla).

A marked respiratory swing of the arterial wave can signify hypovolaemia, especially in a ventilated patient. Hypovolaemia can also lead to a low dicrotic notch (Figure 6.1). The SV can be derived from the arterial waveform by analysis of the area under the systolic portion (see section "Measuring cardiac output").

Central venous pressure

The CVP is most frequently measured using the internal jugular and subclavian veins. While the femoral vein can be used as well, it is noteworthy that values of femoral CVP are less accurate than those of the internal jugular and subclavian veins. The central venous catheter is connected to a transducer system that is identical to that of arterial catheters.

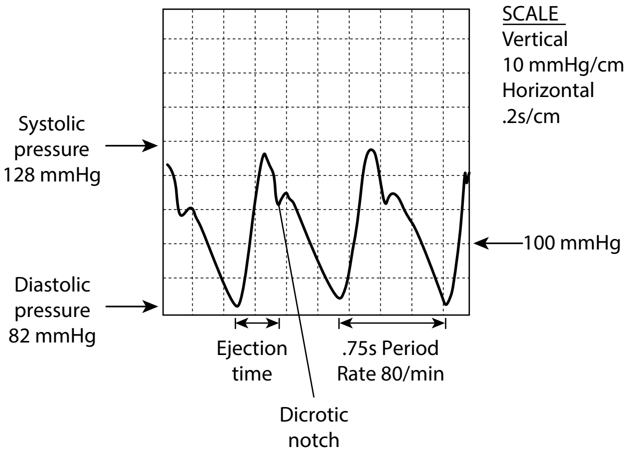

Figure 6.1 A typical arterial wave. Note that the dicrotic notch in a peripheral arterial wave is thought to be the pressure wave reflected peripherally rather than the closure of the aortic valve. Scale: vertical, 10 mmHg/cm; horizontal, 2 s/cm.

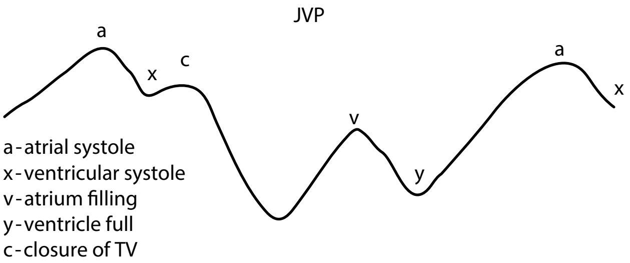

Figure 6.2 Components of central venous pressure (CVP). a, atrial systole; x, ventricular systole; v, atrium filling; y, ventricle full; c, closure of tricuspid valve.

In spontaneously breathing patients the CVP should be measured at end-expiration as it decreases during spontaneous inspiration (by a suction effect of the lungs), whereas in patients undergoing positive-pressure ventilation measurements should be taken at end-inspiration. A typical CVP waveform is displayed in Figure 6.2.

Determinants of CVP are:

- blood volume
- venous tone
- right heart compliance
- intrapleural pressure
- patient position.

See also section "Fluid responsiveness".

Central and mixed venous oxygen saturation

Central venous oxygen saturation can be measured from blood taken from the superior vena cava. In turn, the mixed venous oxygen saturation is acquired by taking blood from the pulmonary artery. In theory, central and mixed venous oxygen saturation differ only in the addition of the venous return of the heart muscle to the latter, but in practice values do not always correlate (Table 6.4). Targeting the central venous oxygen saturation is an important part of early goal-directed therapy in sepsis (see section "Sepsis").

Table 6.4 Mixed venous and central venous oxygen saturation explained

Low venous oxygen saturation (high peripheral oxygen extraction)	**High venous oxygen saturation (low peripheral oxygen extraction)**
Increased O_2 consumption or metabolic rate, e.g. sepsis (early stage)	Decreased O_2 consumption, e.g. hypothermia
Low cardiac output, e.g. cardiogenic shock	Increased cardiac output, e.g. pregnancy, vasodilatation
Hypoxaemia	Left-to-right shunt
Anaemia	Sepsis (after adequate resuscitation)

Measuring cardiac output

We know invasive and non-invasive methods of measuring the CO, as described below.

Invasive

These include:

- the Fick method
- dye dilution
- thermodilution
- pulse contour analysis.

Non-invasive

These include:

- doppler
- thoracic bioimpedance
- echocardiography.

Fick method

The Fick method utilizes the principle that the amount of oxygen consumed is equal to the difference in oxygen concentration between the mixed venous and arterial systems multiplied by the CO. VO_2 is measured in breath samples from a reservoir bag using a spirometer. A pulmonary artery catheter is used to obtain mixed venous blood whereas an arterial line is used to determine the other variable in the Fick equation:

$$CO = VO_2/(\text{arterial} - \text{mixed venous } O_2 \text{ content difference})$$

This method is rarely used in clinical practice.

Dye dilution

The dilution of a defined volume of dye or indicator into an unknown volume of fluid and measurement of its concentration over time can indirectly measure the CO. Indocynanine green can be used but a substance much more commonly used in clinical practice is lithium (LiDCO system). Dye can be injected into either a peripheral or a central vein and sampled from a normal arterial catheter and CO can be derived. To maintain accuracy intermittent calibration with injection of small, non-toxic doses of lithium is suggested. LiDCO is becoming increasingly popular as it is less invasive than pulmonary artery catheterization and interobserver variation is not a problem as with other techniques for advanced haemodynamic monitoring such as oesophageal Doppler.

Thermodilution

This technique is utilized by both the pulmonary artery catheter (PAC) and the PiCCO system to measure CO. The PAC (Figure 6.3) has an inflatable balloon at the tip that allows floating of the PAC with the bloodstream into the pulmonary artery. This is guided by the pressure waveforms at different points (right atrium, right ventricle, pulmonary artery and wedge position).

The proximal lumen, 30 cm from the tip, lies in the right atrium and measures CVP. The thermistor lumen is situated 4 cm from the tip of the catheter and measures temperature. The distal lumen is at the tip of the catheter, lies in a branch of the pulmonary artery, and is connected to a pressure transducer. The balloon lumen permits introduction of 1.5 mL of air into the balloon at the distal tip.

The pressure waveforms at different anatomical points are illustrated in Figure 6.4. These are used to determine the position of the pulmonary catheter. As the PAC is floated, it passes from the right atrium to the right ventricle, the systolic pressure increases and the diastolic pressure stays the same.

When advanced further, the PAC passes from the right ventricle to the pulmonary artery, typically indicated by an increase in diastolic pressure. As the PAC passes from the pulmonary artery into the occlusion (or wedge) position, the pressures decrease (to less than the pulmonary artery diastolic pressure).

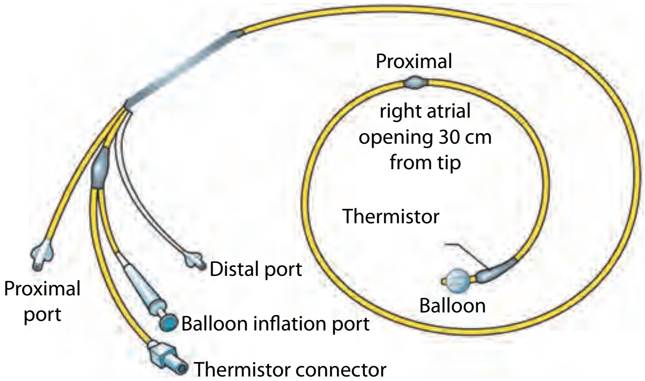

Figure 6.3 Pulmonary artery catheter.

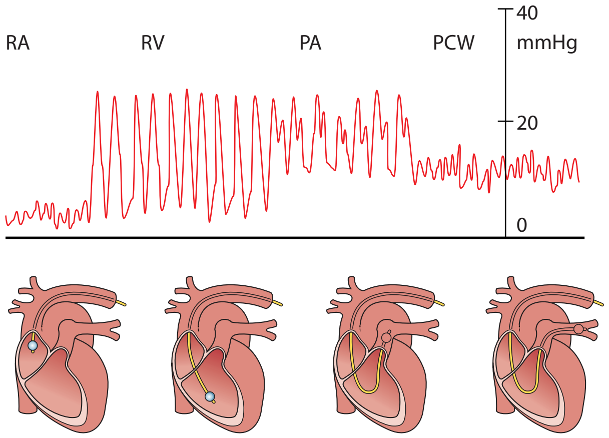

Figure 6.4 Change of pressure wave form (top) according to the location (bottom) of the tip of the Swann–Ganz catheter. PA, pulmonary artery; PCW, pulmonary capillary wedge pressure; RA, right atrium; RV, right ventricle.

The PAC can be used to directly measure or derive the following:

- the CO: a 10 mL bolus of cold fluid is injected through the proximal lumen into the central circulation (right atrium) and the temperature change of the circulating blood is detected by the distal thermistor near the catheter tip. CO is calculated using the drop of temperature over time as volume and temperature of the injected solution are known.
- RAP: measured directly.
- right ventricular pressure: measured directly.
- pulmonary artery pressure: measured directly.
- left atrial pressure: this correlates with the occlusion pressure. This is the pressure measured by occluding ('wedging') a pulmonary catheter with an inflated balloon. The tip distal to the balloon measures the pressure in a continuous column of blood that extends from the catheter tip, through the pulmonary capillaries and veins, and into the left atrium. The pulmonary artery occlusion pressure ('wedge') pressure can give an indication of the filling status of the left ventricle.
- mixed venous oxygen saturation: this is obtained by taking blood from the distal lumen.

Indications for pulmonary arterial catheterization
These include:

- left and right heart pressures do not correlate:
  - right heart failure
  - left heart failure
  - pulmonary hypertension
  - valvular heart disease.
- fluid status difficult to assess:
  - heart failure
  - renal failure.
- left ventricular ejection fraction unknown/echocardiography unavailable.
- guide use of vasoactive drugs, fluids and diuretics.

Contraindications of pulmonary arterial catheterization
These include:

- coagulopathy
- tricuspid valve pathology
- pulmonary valve pathology.

Insertion of a PAC is not without complications. Beside the well-known risks of central venous cannulation these specifically include arrhythmias, pulmonary artery rupture and lung infarction, as well as damage to the heart valves and catheter knotting.

As with CVP readings, wedge pressure readings should be taken at end-expiration (the highest part of the wedge waveform), whereas for ventilated patients pressures should be taken at end-inspiration.

Several studies have put the use of the PAC for management of critically ill patients in question. A prospective cohort study from 1996 has suggested increased mortality of patients managed with PAC, whereas other studies including *PACman* in 2005 and *ARDSnet* in 2006 failed to show an overall benefit of the use of PAC. Not surprisingly, use of the PAC on ICUs has declined significantly in recent years as other less invasive and less complex methods of advanced haemodynamic monitoring have become available to the medical practitioners. However, PAC is still the technique of choice for measurement of pulmonary artery pressures.

Pulse contour analysis

SV can be derived from the area under the systolic portion of the arterial waveform. To increase accuracy, waveform analysis to calculate CO can be calibrated against a standard curve generated with either dye dilution (LiDCO) or thermodilution (PiCCO). Unlike LiDCO, a special arterial catheter with a thermistor and a central venous catheter are required for the PiCCO system. Both systems automatically calibrate to derive CO and other parameters from continuous pulse contour analysis. Besides CO, these devices also claim to be able to determine other parameters that are thought to be helpful in patients' management such as stroke volume variation (SVV), pulse pressure variation (PPV) and extravascular lung water as well as providing an estimate for cardiac contractility. SVV and PPV are considered measures of preload and fluid responsiveness, respectively, which will be described later.

Other devices use algorithms, unique to each manufacturer, and claim to derive CO from waveform analysis without calibration. Examples of pure pulse contour analysis devices are Vigileo and LiDCOrapid.

Oesophageal Doppler

The Doppler effect is a change in the observed frequency of a sound wave occurring when the source and observer are in motion relative to each other, with the frequency increasing when the source and observer approach each other and decreasing when they move apart. Oesophageal Doppler monitoring (ODM) is perhaps the most common form of CO monitoring in use in UK ICUs and operating theatres today. A probe is placed in the oesophagus via the oral or nasal route. The probe generates a low-frequency ultrasound signal, which is reflected by red blood cells moving down the descending aorta. By applying the Doppler principle, the reflected signal is proportionate to the flow velocity. A normogram is used to account for the patient's weight, age and sex as the area of flow for measurement is equally important. SV and CO can be derived from blood flow time; peak velocity is an indicator for myocardial contractility. Fluid management is guided by the use of ODM by observing changes in SV following a fluid challenge. This approach can correct functional hypovolaemia and optimize intravascular volume. This approach has shown promising results to the extent that the National Institute for Health and Clinical Excellence (NICE) in the UK has recently recommended the use of ODM in patients undergoing major or high-risk surgery.

Thoracic bioimpedance

Bioimpedance is defined as the electrical resistance of tissue to the flow of current. When small electrical signals are transmitted through the thorax, the current travels along the blood-filled aorta, which is the most conductive area. Changes in bioimpedance, measured at each beat of the heart, are inversely related to pulsatile changes in volume and velocity of blood in the aorta. CO thus can be calculated from bioimpedance.

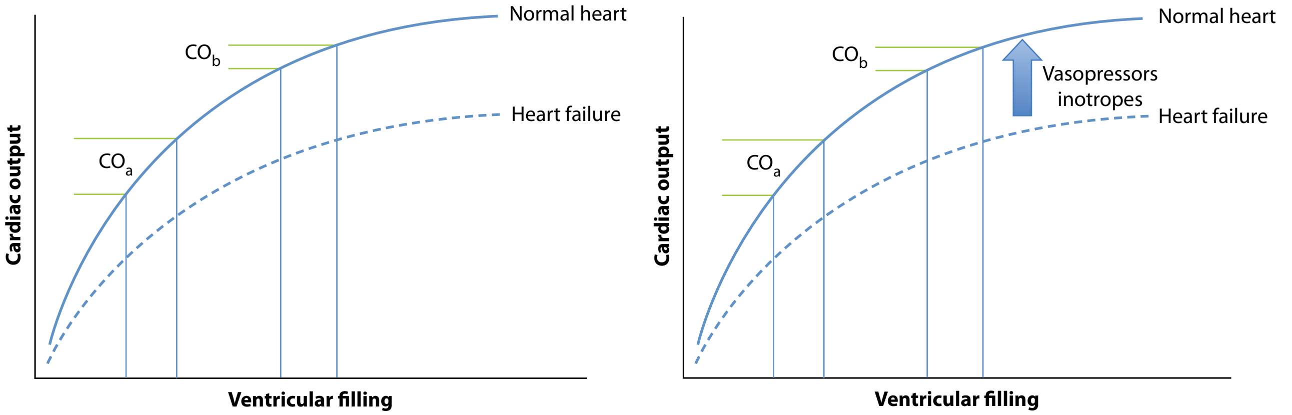

Figure 6.5 The Frank–Starling relationship shows the dependency of cardiac output (CO) on left ventricular filling. A defined change of left ventricular filling leads to a higher increase in CO on the steep slope of the curve (ΔCO_a) than on the flat part of the curve (ΔCO_b). Heart failure changes this relationship (dashed line); changes in ventricular filling need to be carried out more carefully to avoid ventricular overload.

Echocardiography

The use of echocardiography is increasing in operating theatres, emergency medicine and ICUs. Echocardiography is non-invasive and can be used at the bedside at all times. In addition, it gives results in real time and can be repeated for perioperative monitoring and in critically ill patients. The main disadvantages are that it needs an operator trained in its use and that the method is highly operator dependent. Furthermore, obtaining images in intubated patients can be technically challenging.

Transoesophageal echocardiography (TOE) uses higher ultrasound frequencies than transthoracic echocardiography (TTE) to produce better resolution images. TOE is less available than TTE but might be more useful in the ICU setting.

Goal-directed therapy

Optimizing central venous oxygen saturation, SV or CO has been shown to improve outcome. Improved outcome has been shown for the following:

- severe sepsis
- pre- and perioperatively for colon surgery, hip fractures and other major or high-risk surgery
- postoperatively, including cardiac surgery and major or high-risk surgery.

Typically, fluid management is guided by observing changes in SV following fluid challenges to achieve optimal CO. The aim of this approach is to correct functional hypovolaemia and optimize intravascular volume according to the Frank–Starling relationship (Figure 6.5).

The evidence shows that optimization of cardiac performance reduces complications after surgery and length of hospital stay, and decreases the use of central venous catheters, therefore improving systems' performance and reducing healthcare costs. Although the evidence for use of goal-directed fluid therapy in the ICU settings is not as clear, there is still widespread use.

Sepsis

Sepsis, severe sepsis and septic shock represent increasingly grave stages of the systemic inflammatory response to severe infection (Figure 6.6). Reported mortality rates of severe sepsis and septic shock still remain at 40–60% today and have not changed significantly in the past 20 years. Despite intense research and recent advances in treatment, patients with sepsis suffer considerable long-term morbidity. This section tries to elucidate the underlying cellular mechanisms of sepsis. The progression from a simple infection to septic shock and multiorgan failure is discussed and current treatment strategies explained.

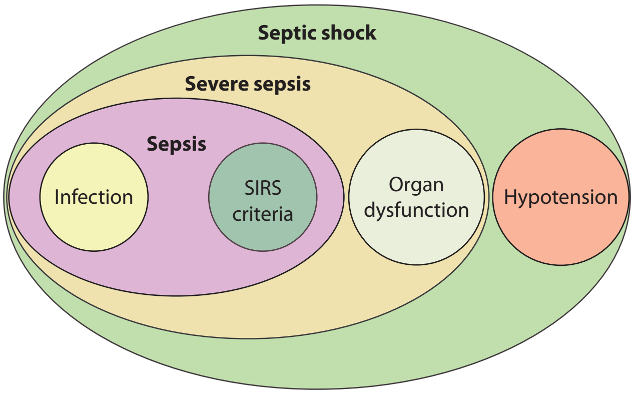

Figure 6.6 The different severities of sepsis may be a continuum. SIRS, Systemic inflammatory response syndrome.

Infection and immunity

A considerable number of bacteria exist on our internal and external surfaces. Mucosa of skin and gut is the first barrier and line of defence to prevent bacterial invasion of the human host. However, when this barrier fails or is disrupted (i.e. by surgical wounds, indwelling catheters, burns), the host becomes susceptible to pathogen invasion. The second-line defence is the immune system that recognizes, fights and destroys invading germs. Sepsis represents systemic response of the immune system to infection. Both pathogen virulence and host resistance regulate the severity of the inflammatory response. The resistance and immune competence of the host are determined by multiple factors such as age, sex, genetic predisposition, nutritional status and underlying health conditions. The inborn or innate immune system consists of cellular and humoral components, both orchestrating the host immune response.

The cellular and humoral components of the innate immune system

The cellular component of the innate immune system includes circulating monocytes, tissue macrophages, neutrophils and lymphocytes. Tissue macrophages are capable of engulfing and digesting microbes and will recruit and attract other phagocytes by secreting cytokines. Macrophages present particles of dispatched microbes as antigens to lymphocytes and hence interact closely with the adaptive immune system. Neutrophils are important phagocytes, but can also destroy invading pathogens by secreting toxic substances such as reactive oxygen species (ROS). Neutrophils attracted by chemokines migrate and translocate into the infected tissue to fight pathogens. More neutrophils and immature forms are liberated from the stimulated bone marrow, leading to a final increased number in blood (neutrophilia and leftward shift of the neutrophils). Eosinophil and basophil granulocytes are responsible for secreting inflammatory mediators and creating an inflammatory environment. These lead to dilation of tight junctions of the adjacent vessels, facilitating the migration of more inflammatory cells into the infected tissue and leading to efflux of plasma. As a consequence of these processes, signs of local inflammation (rubor, calor, dolor) occur. Of note, cells of the innate immune system can fight invading pathogens directly without involvement of the adaptive immune system.

Cytokines are the humoral components of the innate immune system and act either directly on pathogens or as mediators between cells and organs. ROS in high concentrations have a toxic effect on bacteria by damaging their cell walls. ROS in lower concentrations seem to act as important regulatory mediators. Interleukins (IL) and tumour necrosis factor (TNF) are other mediators that have the ability to promote inflammation from a localized to a systemic process. Some of these cytokines are stored in myeloid cells and can be secreted rapidly after contact with pathogens.

Pathogen recognition and activation of the inflammatory cascade

Cells of the innate immune system can detect typical molecular patterns of most microbes, including viruses, bacteria, fungi and protozoa. Examples of such patterns are lipopolysaccharides (endotoxin) from the cell wall of Gram-negative bacteria; lipoteichoic acid and peptidoglycan from Gram-positive bacteria; unmethylated bacterial DNA; or double-stranded RNA from viruses. These molecules are recognized by three families of specific pattern recognition receptors: toll-like receptors (TLRs), intracellular nucleotide-binding proteins, and peptidoglycan recognition proteins. To date, 10 different types of TLRs have been identified in humans. Most act in conjunction with other molecules such as CD14, or with other TLRs expressed on the cell surface. Binding of a microbial molecule to its specific TLR results in signal transmission by the toll/IL-1 receptor homologous region adaptor proteins to a complex intracellular cascade of enzymes. These enzymes consist of kinases – enzymes that phosphorylate and thus activate proteins necessary for nuclear gene transcription and production of cytokines. Although the most well-known, nuclear factor κB (NF-κB) is only one example of many transcription factors activated during sepsis. One of the genes expressed via NF-κB codes for TNF, which further amplifies local NF-κB activation (Figure 6.7). TNF is then released in the systemic circulation to reach effector sites. On a systemic level, TNF and IL-6 induce the production of acute phase proteins in the liver, e.g. C-reactive protein, procalcitonin and fibrinogen. TNF also plays an important role in the activation of programmed cell death or apoptosis.

Another activated enzyme of interest is inducible nitric oxide synthase (iNOS). In sepsis, iNOS is upregulated and generates high levels of nitric oxide (NO), a fundamental proinflammatory molecule. NO activates other enzymes such as guanylyl cyclase, which leads to the production of cyclic guanosine monophosphate (cGMP). cGMP and NO are responsible for local and systemic vasodilatation, which can lead to hypotension and shock. Newer data seem to suggest that NO may have beneficial effects that are determinants in patients' survival.

Anti-inflammatory activity during sepsis

To prevent an overwhelming and possibly deleterious proinflammatory response anti-inflammatory mechanisms are activated simultaneously during infection. These include secretion of specific cytokines such as IL-10 and the soluble TNF receptor leading to a decrease in lymphocyte cell count. The overall balance is presumed to be proinflammatory in the early phase of sepsis and anti-inflammatory later. The advantage of this systemic anti-inflammatory response may be the attenuation of deleterious

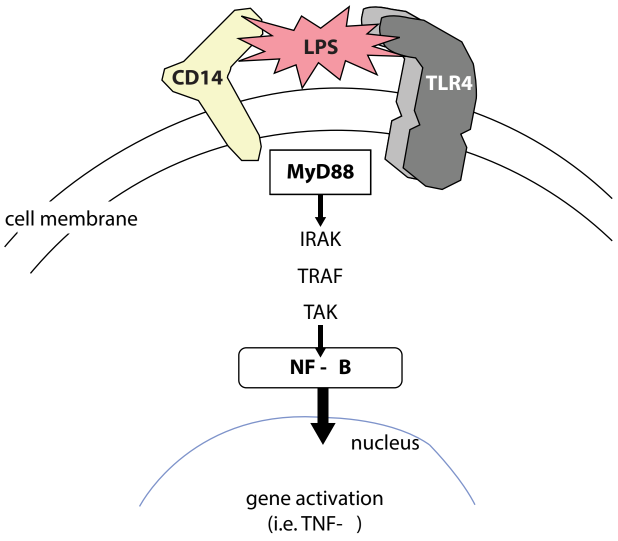

Figure 6.7 Activation of a CD14+ T-helper cell by a fragment of Gram-negative bacteria. IRAK, interleukin-1 receptor-associated kinase; LPS, lipopolysaccharide (endotoxin); NF-kB, nuclear factor kB; TAK, TRAF-associated kinase; TLR, toll-like receptor; TNF, tumour necrosis factor; TRAF, tumour necrosis factor receptor-associated factor. LPS from the Gram-negative bacterial wall binds to TLR4 and CD14, activating the toll/IL-1 receptor homologous region domain called myeloid differentiation protein 88 (MyD88). This activates the IRAK, which stimulates the TRAF and, consequently, the TAK. As a result, the nuclear transcription factor NF-kB is liberated from its inhibitor and is able to dislocate into the cell nucleus to bind to DNA, activating hundreds of specific genes coding for proteins. (With permission of EMH Swiss Medical Publishers Ltd; www.smw.ch.)

systemic proinflammatory effects and the concentration of the inflammatory response at the site of infection. However, when anti-inflammatory mechanisms dominate, the immune system is depressed (immunoparesis), thus increasing the body's susceptibility to nosocomial infections and to dormant pathogens such as cytomegalovirus. Whether patients with severe sepsis might benefit from immune system stimulation is the topic of current investigations.

Microcirculation and mitochondrial dysfunction

Early sepsis is characterized by vasodilatation and intravascular volume depletion (from increased capillary leak and external losses), leading to a low CO. This is made worse by myocardial depression and microvascular distribution alterations and causes an oxygen supply–demand imbalance in various organ beds. Fluid administration during early sepsis increases oxygen delivery to the organs and is known to improve outcome (see below). Within the cells, mitochondria require oxygen to produce ATP by oxidative phosphorylation. ATP is the predominant source of intracellular energy and is needed for all energy-dependent cellular functions. Mitochondria will suffer structural and functional damage by the inflammatory insult following infection by three separate mechanisms: (1) direct inhibition of the respiratory enzyme complexes by increased concentrations of nitric oxide and its metabolite peroxynitrite, (2) increased production of ROS and (3) genetic downregulation of new mitochondrial protein formation. This damage is facilitated by overwhelmed mitochondrial defence mechanisms (reduced glutathione, superoxide dismutase). Loss of mitochondrial function is associated with electron microscopic structural changes such as membrane thickening, swelling and vacuolization of mitochondria and finally loss of mitochondrial integrity and death.

Mitochondrial biogenesis

Failure on a mitochondrial level of energetic status in patients with sepsis-induced multiorgan failure has been shown recently. However, repair mechanisms exist and mitochondria may be repaired or regenerated by mitochondrial biogenesis. Mitochondrial biogenesis is triggered by increased expression of transcription factors in the nucleus. This will result in restoration of the energetic status and ATP production over time and promote survival of critical illness. This may prove to be a useful therapeutic target for accelerating organ recovery, and stimulation of mitochondrial biogenesis (such as with NO) may play an important role in the future.

Hibernation

Macro- and microcirculatory failure will cause tissue hypoxia by insufficient oxygen supply, whereas impaired oxygen utilization owing to mitochondrial dysfunction will lead to tissue dysoxia. Both mechanisms decrease intracellular ATP production. This not only may impair organ-specific cell function but may also result in a loss of energy-dependent cell integrity. Hence, lack of ATP will lead to cellular dysfunction and, eventually, cell death. However, postmortem studies of septic patients failed to reveal micro- and macroscopic evidence of cell death.

This lack of necrosis has led to the hypothesis that organ dysfunction may represent a functional rather than a structural phenomenon and thus may be potentially reversible. Therefore, cells may shift the use of ATP only to processes essential for cell survival. By shutting down energy-dependent organ-specific functions the cell can decrease its total ATP expenditure, allowing the net ATP balance to remain positive despite a decrease in ATP production. This 'suspended animation' is analogous to aestivation and hibernation. Although this is a new concept for multiorgan dysfunction in sepsis, it is a well-established protective strategy in a variety of animals as an adaptive response to heat, cold or drought. Hence, organ dysfunction during sepsis can be seen as an adaptive and even protective process that will help to prevent cell death. Once infection is overcome and the organism returns back to 'normal', mitochondrial function is restored. ATP production then increases and the cell can regain its normal metabolism and organ-specific function.

Definitions and diagnosis of sepsis

Despite being a frequent reason for admission to the ICU, infections and sepsis can be difficult to diagnose. The definitions in Table 6.5 may be helpful and provide the clinician with the appropriate nomenclature for the diagnosis and management of infections. Of note, systemic inflammatory response syndrome (SIRS), sepsis, severe sepsis and septic shock are thought to represent increasing severity of disease (Figure 6.7).

Different stresses can stimulate the human body to liberate cytokines, which can clinically present as a SIRS. Therefore, SIRS may be seen not only following infection but also after major surgery and severe trauma, making the diagnosis of sepsis potentially difficult. However, the search for the origin of the SIRS is of the utmost importance, as this time delay may prove significant for the patient.

A few features of the definitions of sepsis, however, warrant a closer look. First, the definition of sepsis needs only SIRS and the suspicion of infection (positive cultures are *not* essential for the diagnosis of sepsis). This warrants a thorough review of the patient at the bedside by an experienced clinician. Second,

Table 6.5 Nomenclature for the diagnosis and management of infections

Bacteraemia	**Positive blood cultures**
Infection	Invasion of the body by organisms
SIRS	Two or more of the following: Temperature >38°C or <36°C Heart rate >90/min Respiratory rate >20/min or minute volume >10 L/min in ventilated patients or $PaCO_2$ <4.3 kPa White cell count >12 000/mL or >10% immature forms or wcc < 4 × 10^2/L
Sepsis (former sepsis syndrome)	SIRS *plus* the clinical suspicion of infection
Severe sepsis	Sepsis *plus* evidence of organ dysfunction
Septic shock	Sepsis *plus* hypotension refractory to volume resuscitation
Multiorgan failure	Failure of >2 organ systems

SIRS, systemic inflammatory response syndrome.

the diagnosis of septic shock includes a therapeutic intervention such as fluid resuscitation. This is an important feature as the failure to respond to fluid resuscitation is the discriminating factor between severe sepsis and septic shock.

But, rather than seeing sepsis as an isolated disease, it is now the belief that sepsis represents a disease *complex* with potential involvement of several organ systems (multiorgan failure). As described above, sepsis often presents clinically with hypoperfusion of organs.

The clinical signs of decreased organ perfusion include:

- low blood pressure and hypotension
- oliguria
- confusion/drowsiness
- angina or signs of myocardial ischaemia on 12-lead ECG
- metabolic (usually lactic) acidosis.

Most common locations of the septic focus are:

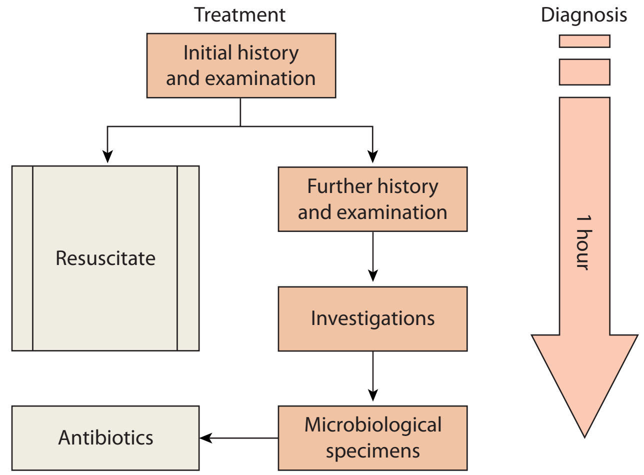
- lungs
- abdomen
- genitourinary tract
- skin
- indwelling catheters
- central nervous system.

Therapeutic principles: the 'golden hour' of sepsis

The principles of sepsis treatment include early goal-directed therapy, source identification and control, early antibiotics, steroids, activated protein C and tight glycaemic control (Figure 6.8).

Early goal-directed therapy

Early adequate fluid resuscitation and source control of the infectious focus are still the cornerstones of therapy for sepsis. To minimize delay in treatment, ideally diagnosis and therapy should be rolled out simultaneously. In trauma care, the 'golden hour' after the insult is a widely recognized concept that should be equally applied to the treatment of sepsis.



Treatment
Initial history and examination
Diagnosis
Resuscitate
Further history and examination
1 hour
Investigations
Antibiotics
Microbiological specimens

Figure 6.8 The 'golden hour' of sepsis. Diagnosis and treatment need to be performed simultaneously to minimize time delay.

The goal of fluid resuscitation is to achieve and maintain adequate end-organ perfusion (early goal-directed therapy). This will minimize mitochondrial damage and finally organ failure. Rivers and co-workers were able to show a significant decrease in hospital mortality due to sepsis from 46.5% in the standard group to 30.5% in the early goal-directed therapy group by introducing an early (within 6 hours of admission) and aggressive therapeutic approach. Whether crystalloids or colloids are the optimal choice for resuscitation is still under debate (see Shock). Fluid challenges according to the patient's needs and to optimize CO are more appropriate than the blind administration of maintenance fluids.

In an initial phase, 250 mL of colloid or 500 mL of crystalloid should be administered rapidly (i.e. 10–15 minutes) to the septic patient and titrated against clinical response and reversal of clinical signs of hypoperfusion (restoration of skin perfusion, blood pressure, urine output, metabolic acidosis). The insertion of a central venous line, urinary catheter and arterial line may help facilitate diagnosis and treatment in severe cases. It is of special importance not to pass the threshold of tolerance of the cardiovascular system and induce congestion. Rivers and his peers advocated fluid administration for a CVP of 8–12 mmHg. If blood pressure is not restored with adequate fluid challenges alone, vasopressors such as norepinephrine (noradrenaline) or vasopressin might be considered to target a MAP of >65 mmHg (see Vasopressors and inotropes). Dopamine is still used widely as a vasopressor in sepsis, but has less favourable 28 day mortality than norepinephrine. A MAP target of >65 mmHg has never been tested in RCTs and is only founded on expert opinion, but to target a higher MAP and expose patients to higher doses and prolonged treatment with vasopressors seems to have less favourable outcomes.

The next goal of early goal-directed therapy is to restore adequate CO. Having achieved restoration of fluid status and blood pressure, aiming for a central venous saturation ($ScvO_2$) of >70% has been advocated. $ScvO_2$ is a used as a surrogate for peripheral oxygen extraction assuming that peripheral oxygen extraction is inversely related to CO (see Haemodynamic monitoring). To achieve $ScvO_2$ >70%, first a haematocrit above 30% (haemoglobin >10 g/L) should be targeted using allogenic blood transfusion if necessary. If this is achieved, inotropes such as dobutamine or epinephrine (adrenaline) may be used to increase CO. The use of a combination of norepinephrine and dobutamine for septic shock has comparable outcomes to the use of epinephrine alone.

Source identification and control

Simultaneously to the initiation of treatment of sepsis, identification and eradication of the source of infection is crucial. If time allows, appropriate samples for microbiology should be taken and additional imaging should be considered before initiation of antibiotic therapy. Sampling for microbiology processing should include blood cultures taken from all indwelling catheters and simultaneously taken peripheral stabs, respiratory samples as well as sample fluids from all drains (urinary catheter, wound drains, spinal or ventricular drains). Sputum is preferred in the non-intubated patient, whereas directed or non-directed bronchial lavage provides more accurate results in patients with artificial airways. Gram staining may help to facilitate the choice of treatment in this 'urgent choice' antibiotic strategy, but has its pitfalls.

If additional imaging reveals a septic focus (e.g. intra-abdominal abscess, obstructive cholecystitis), image-guided percutaneous drainage may be considered at the same time. This offers diagnostic as well as therapeutic options, which may avoid the patient having to undergo more surgery.

Early antibiotics

In contrast to clinical situations in which the start of antibiotics can be delayed, patients with severe sepsis and septic shock must receive appropriate antibiotics within the first hour of diagnosis. Each hour of delay in antibiotic administration for the initial 6 hours is associated with a decrease in survival.

The choice of antibiotic is dependent on several factors, such as the patient's underlying disease, whether the infection is community or hospital acquired and the local antimicrobial resistance. Immunocompromised or neutropenic patients, including those after splenectomy, are likely to have acquired different infections from immunocompetent patients, and the choice of antimicrobial treatment must account for this special situation. In contrast to community-acquired infections, hospital-acquired infections tend to involve more resistant pathogens, or at least pathogens with a different antimicrobial spectrum, which, again, needs to be considered.

It is beyond the remit of this chapter to give specific recommendations for antibiotic treatment, but the principle of treatment for severe sepsis and septic shock should always entail early *broad-spectrum* antimicrobial cover, following the previous considerations, and narrowing of antimicrobial spectrum after receiving microbiology results. Guidelines for antimicrobial treatment are especially helpful for the use of antibiotics by the less experienced and have been shown to be beneficial for patients' outcome. Guidelines should also consider the duration of treatment for common clinical situations as prolonged antibiotic treatment can promote microbial resistance. To avoid increasing local antibiotic resistance, regular input from microbiologists and infection control teams should be sought. ICUs are areas where antibiotic consumption and resistance rates are highest. This gives the intensivist the special responsibility in antibiotic stewardship to avoid spiralling antimicrobial resistance.

Steroids in sepsis

For decades the use of corticosteroids in sepsis has been and is still controversially discussed. Besides the common and well-known effects of corticosteroids, advantageous specific effects in sepsis include inhibition of cytokines and iNOS (see above) and potential to reverse septic shock. Disadvantages include hyperglycaemia, risk of superinfections and an increased incidence of critical illness polyneuromyopathy.

Since the late 1980s several trials have failed to show survival benefit from the use of pharmacological doses of corticosteroids in sepsis (i.e. hydrocortisone 100 mg t.d.s.). In addition, timing of treatment (early versus late) did not show beneficial effects on outcome. However, this research also revealed that sepsis has the potential to increase adrenal dysfunction and tissue resistance to corticosteroids. This new insight has allowed a follow-up on the concept of steroid treament. Finally, Annane and co-workers were able to demonstrate beneficial effects of low-dose early treatment with corticosteroids (hydrocortisone 50 mg q.d.s. and fludrocortisone 50 μg o.d.) in patients with inadequate adrenal response. Based on this multicentre RCT, many physicians worldwide have started to use steroids for patients in septic shock requiring vasopressors.

Just a few years later, another multicentre RCT of low-dose early corticosteroids failed to confirm these beneficial effects. However, this so-called *Corticus trial* was also able to confirm earlier reversal of shock with the use of hydrocortisone. This has finally led the Surviving Sepsis Campaign to recommend that 'hydrocortisone should be considered in the management strategy of patients with septic shock after blood pressure is poorly responsive to fluid resuscitation and vasopressor therapy'.

Tight glycaemic control

Stress-induced hyperglycaemia is the elevation of blood glucose in the presence of acute illness. Stress hormones, endogenous and exogenous, such as epinephrine and cortisol as well as cytokines, are contributing factors, all potentially inhibiting insulin release and action, therefore enhancing gluconeogenesis and inhibiting glycogen formation. In turn, administration of intravenous glucose, parenteral nutrition and a series of other medications can also contribute to hyperglycaemia. On one hand, hyperglycaemia can reflect the severity of disease; on the other, hyperglycaemia can be linked with worse outcomes in non-diabetic patients admitted to the ICU as duration of exposure to higher glucose concentrations is inversely associated with survival.

Only since the turn of the century has evidence for glucose control on the ICU emerged and tight glycaemic control (TGC) been advocated for the treatment of critically ill patients. Van der Berghe and co-workers were able to demonstrate more favourable outcomes in a large single-centre trial if blood glucose was kept in a tight range (4.4–6.1 mmol/L) than with a more conventional approach (target 10–11 mmol/L). Patients on TGC had decreased mortality, fewer days of ventilation and shorter length of stay on the ICU than controls; however, significantly more episodes of hypoglycaemia were reported in the treatment group. As this trial was carried out in a selected group of patients, mostly after cardiac surgery, a subsequent trial including general medical patients failed to show the same beneficial effect. In contrast, it has also become evident that hypoglycaemia is associated independently with increased mortality in the critically ill. Therefore, it is the recent recommendation to target a blood glucose range of 6–10 mmol/L in non-diabetic critically ill patients. This is achieved best by administering short-acting insulin by continuous intravenous infusion according to local protocols; measures to minimize and treat hypoglycaemia are important. Evidence for the perioperative period is less conclusive.

Vasopressors and inotropes

Shock

Shock is a state of impaired tissue perfusion insufficient to meet the metabolic demands of tissues. Clinical signs of impaired perfusion can still be subtle, but, owing to tissue hypoperfusion, increased lactate production from a switch to anaerobic metabolism at the cellular level may already be present. Global tissue perfusion depends upon blood flow, and MAP (product of CO and SVR) is often used as a clinical surrogate. It is important to note that, although a low blood pressure is synonymous with shock, it does not strictly speaking form part of this definition. This is because during shock a compensatory tachycardia and/or vasoconstriction can result in preservation of a relatively normal blood pressure. Shock can be categorized by the underlying pathophysiological mechanism:

- hypovolaemic
- cardiogenic
- obstructive
- distributive.

Hypovolaemic shock can result from dehydration, haemorrhage or burns and is usually associated with a compensatory vasoconstriction and increase in SVR to maintain vital organ perfusion. Cardiogenic shock is most often a result of myocardial ischaemia but can be seen in association with arrhythmias, valvular heart disease or after cardiac surgery. It can be biventricular or affect predominantly either the left or right side of the heart. In cardiogenic shock, the CI is <2.2 L/min/m^2 (Table 6.3) despite an adequate ventricular preload. Cardiogenic shock due to critical myocardial ischaemia has a high mortality of approximately 50%, which can be significantly reduced with urgent revascularization. Obstructive shock is caused by mechanical obstruction of blood flow, e.g. by cardiac tamponade or massive pulmonary embolism. Management should be directed at the cause of the obstruction, such as pericardiocentesis for cardiac tamponade. Distributive shock is manifest by a markedly reduced vascular tone, mostly from the release of vasodilatory inflammatory mediators. There is often a compensatory increase in the CO. This is the commonest type of shock found in sepsis, but is also seen with high spinal cord injuries with peripheral vasodilatation from loss of sympathetic tone and anaphylactic reactions.

In clinical practice, these distinctions are often arbitrary, and more than one form of shock can coexist. Septic patients are usually (relatively) hypovolaemic, may have evidence of left ventricular hypokinesia and have distributive shock (see section "Sepsis").

Fluid therapy

First-line management for all types of shock involves the administration of intravenous fluids as well as treating the underlying cause. In cardiogenic shock, fluid resuscitation needs to be applied with caution to avoid left ventricular failure resulting in pulmonary oedema. Often, the preload can be optimized by administering fluid boluses carefully, particularly when right ventricular impairment is present (e.g. with an inferior myocardial infarct). The relationship between left ventricular end-diastolic volume (a surrogate for preload) and CO was described by Frank and Starling (Figure 6.5); the therapeutic process aims to shift the CO to the peak of the curve, but note that, for the failing myocardium, the slope of the initial part of the curve is more gradual. However, assessing the optimal fluid administration is far from easy and a more useful concept of fluid responsiveness has been described.

Fluid responsiveness

Accurate clinical assessment of fluid status is notoriously difficult, but thorough clinical examination is essential to look for signs of hypovolaemia such as dry mucous membranes and reduced capillary refill. Measurement of CVP is often helpful, especially the haemodynamic response to a fluid challenge/higher CVP. However, it is important to note that the pressure measured depends upon the compliance of the vena cava, which is in turn dependent upon vasomotor tone. There is poor correlation between the CVP and left ventricular end-diastolic volume, and hence the ability of the CVP to accurately inform the clinician of the likely improvement in CO with fluids is unreliable. A high CVP can, however, be helpful as it suggests adequate preload and hence a low likelihood of a successful response to a fluid bolus. A suitable challenge is 250 mL of fluid given over a short period of time (e.g. 15 minutes) with a comparison of physiological variables such as CO or MAP before and after the challenge. CO monitoring can be very helpful for this purpose. Up to 50% of patients with septic shock will show no improvement in CO when given fluid loading. Once patients no longer respond to fluid resuscitation, therapeutic considerations should include using inotropes and vasopressors.

Inotropes/vasopressors

Inotropes act primarily by increasing the intracellular calcium concentration (via increased cyclic AMP) available for excitation–contraction coupling in the cardiac myocyte, and hence increasing myocardial contractility and finally improving CO. Vasopressors, on the other hand, increase vascular tone by activation of sympathetic-mediated vasoconstriction (Table 6.6), which is mostly receptor mediated. Most commonly used agents have mixed actions and work on more than one receptor (Table 6.7). Most vasopressors have short half-lives and need to be given by continuous intravenous infusion; potent vasoconstrictors must be given by a central venous line to avoid peripheral complications.

Table 6.6 Classification of cardiovascular adrenergic receptors

Receptor type	Site	Action
α_1	Vascular smooth muscle	Vasoconstriction
β_1	Heart	Increase in heart rate and contractility
β_2	Vascular smooth muscle	Relaxation

Table 6.7 Commonly used vasopressors and inotropes

Drug	Dose range	Receptors				Notes
		a	β_1	β_2	Dopaminergic	
Epinephrine	0.01–0.1 µg/kg/min	+++++	++++	+++		Can cause raised serum lactate, hyperglycaemia, metabolic acidosis and arrhythmias
Norepinephrine	0.01–3 µg/kg/min	+++++	+++	++		Can cause decreased cardiac output if used in hypovolaemic patients Probably the commonest vasopressor used in the ICU
Dopamine	0–5 µg/kg/min				++	Effects vary according to infusion rate
	5–10 µg/kg/min	+	+	+	++	Low-dose dopamine does not reduce the incidence of renal failure
	10–20 µg/kg/min		+	+	++	
Dobutamine	2–20 µg/kg/min	+	+++++	+++		Adverse effects include tachycardia, arrhythmias, hypotension (from β_2-mediated vasodilatation)
Vasopressin	0.01–0.1 U/min					Acts on V_1, V_2 and V_3 receptors State of relative vasopressin deficiency can develop in prolonged shock
Milrinone	Bolus 50 µg/kg over 10–30 minutes Infusion 0.375–0.75 µg/kg/min					PDEIII inhibitor. Used for severe congestive cardiac failure Contraindicated with left ventricular outflow tract obstruction (e.g. HOCM, aortic stenosis)
Levosimendan	Loading dose 12–24 µg/kg over 10 minutes Infusion 0.05–0.2 µg/kg/min					Binds to troponin C, causing positive inotropy, and opens ATP-sensitive K^+ channels, causing vasodilatation Used to improve left or right ventricular function after cardiac surgery and short-term haemodynamic improvement in acute heart failure

HOCM, hypertrophic obstructive cardiomyopathy; ICU, intensive care unit; PDEIII, phosphodiesterase III.

It is crucial to ensure adequate fluid resuscitation before considering inotropes or vasopressors. Shock and subsequent activation of the sympathetic nervous system may cause selective perfusion of vital organs and may exert changes in regional blood flow. This will happen at the expense of perfusion of the gut and skin, resulting in relative ischaemia, release of endotoxins and, hence, worsening of the inflammatory cascade. This mechanism can be exacerbated by vasopressors. If inotropes are used in hypovolaemic patients, this has the potential to increase the (already elevated) myocardial oxygen consumption, which, if unmatched by oxygen supply, will cause myocardial ischaemia.

Norepinephrine (noradrenaline)

Norepinephrine is an endogenous catecholamine (it is the primary neurotransmitter at postganglionic sympathetic neurones) with a predominantly α_1 agonist activity and minor β_1 agonist activity (especially at low doses). It causes arteriolar and venous vasoconstriction and hence increases peripheral resistance with little change in CO.

Epinephrine (adrenaline)

This naturally occurring catecholamine acts as a potent agonist at α and β receptors. Its effects also vary according to the dose; at low doses, β effects predominate, but with higher doses α-mediated vasoconstriction becomes more apparent. It is most commonly used in patients with a low CO unresponsive to other inotropes. Epinephrine often causes a tachycardia and can reduce splanchnic blood supply as well as increase serum lactate, which is not necessarily related to organ hypoperfusion. It is used most often for anaphylaxis, cardiac arrest and in patients with severe bronchospasm.

Dopamine

Dopamine is the natural precursor to norepinephrine and epinephrine. It acts on dopamine receptors as well as α and β receptors. Its effects vary according to the infusion rate:

- 0–5 µg/kg/min: renal and splanchnic vasodilatation (via dopamine receptors)
- 5–10 µg/kg/min: increase in HR and contractility (β_1 effect)
- 10–20 µg/kg/min: vasoconstriction (α_1 effect).

Although it does increase urine output, low-dose dopamine does not reduce the risk of renal failure in the critically ill. Dopamine is more arrhythmogenic and increases HR and SV more than norepinephrine.

Dobutamine

This synthetic catecholamine is primarily a β_1 agonist, but also has mild β_2 and weak α_1 activity. It causes an increase in HR and SV, thereby increasing CO. It is often given in combination with norepinephrine to counteract the β_2 effects of vasodilatation. It will increase HR and myocardial oxygen consumption, which may be deleterious if coronary blood flow is impaired.

Vasopressin

Vasopressin is an endogenous peptide released from the posterior pituitary in response to hypotension/hypovolaemia or increased serum osmolality. It causes vasoconstriction via stimulation of

V_1 receptors on vascular smooth muscle cells. In septic shock there is often a relative vasopressin deficiency; however, there is little convincing evidence to suggest it should be used as a first-line vasopressor, hence it is normally used in conjunction with norepinephrine or dopamine. Terlipressin, which has a longer half-life, is sometimes used as an alternative.

Other agents

The phosphodiesterase inhibitors *milrinone* and *enoximone* are sometimes used, particularly in patients with heart failure or after cardiac surgery. These agents inhibit cyclic AMP breakdown by inhibition of phosphodiesterase III, thus causing positive inotropy as well as facilitating diastolic relaxation (lusitropy) and cardiac filling. Phosphodiesterase inhibitors are usually administered as an intravenous bolus followed by a continuous infusion. They are both potent vasodilators owing to their β_2 effect, and often patients need treatment with a vasopressor simultaneously to maintain MAP.

Levosimendan

This is an inodilator used for acutely decompensated chronic heart failure. It binds to troponin C, increasing myocardial calcium sensitivity, and has a positive inotropic effect. It is also a potent vasodilator via opening of ATP-sensitive K^+ channels; hence, myocardial contractility is increased without increased myocardial oxygen consumption. As with the phosphodiesterase inhibitors, a vasopressor such as norepinephrine often needs to be infused as well to offset its vasodilatory effect.

Ventilation support

Ventilation support is a cornerstone of ICU and HDU care. HDUs and ICUs should be able to offer ventilation treatment and the medical team are familiar with this technique. As ventilation support does warrant specialized monitoring, it is obvious that this must be provided simultaneously. Some specialized services offer ventilation assist as well (e.g. weaning units, spinal units), but this exceeds the aim of this section.

Respiratory failure

In health pulmonary ventilation matches the demands of the body and will regulate O_2 uptake and CO_2 elimination. Pulmonary gas exchange is a combination of alveolar ventilation and lung perfusion. The normal alveolar ventilation–perfusion relationship (V/Q) in health is approximately 0.8 and any change in either ventilation or perfusion can alter this equilibrium and lead to respiratory failure. Respiratory failure can be acute or chronic. For more details also refer to Chapter 9 "Pulmonary insufficiency".

Two types of respiratory failure can be distinguished: whereas type 1 acute respiratory failure is defined by the inability to meet the patient's oxygen demand resulting in hypoxaemia, type 2 respiratory failure denotes the inability of CO_2 clearance and will typically result in hypercapnia. As the amount of alveolar CO_2 can accumulate to critical levels, severe hypercapnic failure will lead to hypoxia. In contrast, hypoxic failure may lead to respiratory fatigue, and accumulation of CO_2 can finally occur. A combination of both hypoxia and hypercapnia is therefore common. The alveolar–arterial (A–a) oxygen gradient can be of help to diagnose the cause of hypoxia.

Arterial blood gas analysis is the method of choice to diagnose disturbances of pulmonary gas exchange. Peripheral oxygen saturation and end-tidal CO_2 ($etCO_2$) as well as the respiratory rate and respiratory mechanics can point to an impairment of gas exchange but are not able to replace direct arterial blood gas measurement.

The equation for the A–a oxygen gradient is:

$$\text{A–a gradient} = PAO_2 - PaO_2$$

where PAO_2 is the alveolar PO_2 (calculated from the alveolar gas equation) and PaO_2 is the arterial PO_2 (measured in arterial blood).

The alveolar gas equation is (see Table 6.8 for explanation of the abbreviations and sample values):

$$PAO_2 = FIO_2(P_{ATM} - P_{H2O}) - (PaCO_2(1 - FIO_2(1 - RQ)))/RQ$$

Hypoxaemic, or type 1, respiratory failure is a potentially dangerous condition as cellular metabolism is dependent on oxygen. The human body can tolerate hypoxaemia for a certain period of time, especially when conditioned by high altitude or chronic pulmonary disease. The Extreme Everest Project has demonstrated recently that trained healthy volunteers were able to tolerate low blood oxygen tension (mean arterial oxygen partial pressure 3.28 kPa).

If oxygen administration via a nasal cannula or facemask (with rebreathing bag) does not improve the patient's hypoxic condition, breathing assist with continuous positive airway pressure (CPAP) should be considered. Hypercapnia is mainly a result of decreased alveolar ventilation and the lack of CO_2 clearance. Type 2 respiratory failure therefore warrants an increase in alveolar ventilation.

Assisted breathing

The goal of assisted breathing is to maintain continuous positive airway pressure (CPAP). This can only be achieved by the use of a tight fitting facemask. During spontaneous breathing, negative intrathoracic pressures will prevail during a normal breathing cycle. Therefore, assisted breathing and mechanical ventilation

Table 6.8 Explanation of the abbreviations and sample values for the alveolar gas equation

Quantity	Description	Sample value
P_AO_2	Alveolar partial pressure of oxygen (PO_2)	107 mmHg (14.2 kPa)
FIO_2	Fraction of inspired gas that is oxygen (expressed as a decimal)	0.21 (= 21%)
P_{ATM}	Atmospheric pressure	760 mmHg (101 kPa)
P_{H2O}	Saturated vapour pressure of water at body temperature and at atmospheric pressure	47 mmHg (6.25 kPa)
P_aCO_2	Arterial partial pressure of carbon dioxide (PCO_2)	36–45 mmHg (4.79 kPa)
RQ	The respiratory quotient	0.8

should not be mistaken for spontaneous breathing, even if the patient breathes spontaneously!

Positive intrathoracic pressures will impede venous return to the heart and may compromise CO. In susceptible individuals, this effect needs to be counteracted by additional fluid administration and/or haemodynamic support with vasopressors and inotropes. On the other hand, this effect can be used to decrease left ventricular preload in patients with acute heart failure.

During assisted breathing via facemask, inflation of the stomach may occur. A nasogastric tube on continuous drainage may be needed to prevent overinflation and to minimize the risk of pulmonary aspiration of gastric content. Enteral feeding while on continuous or intermittent assisted breathing therapy warrants careful consideration. Both breathing assist and the underlying pathology can cause distress to the patient, resulting in agitation and a lack of co-operation. If sedation and analgesia are considered, this must be carefully titrated to the desired effect to avoid respiratory and haemodynamic compromise.

PEEP, NIV or what? The 'babel' of assisted breathing

Several devices and techniques are available for ventilation assist. To complicate matters for the inexperienced, a uniform nomenclature does not exist. Hence, it may be useful to understand the underlying principle of assisted breathing.

For a start, positive end-expiratory pressure (PEEP) and continuous positive airway pressure (CPAP) are synonyms. To increase the alveolar partial pressure and to decrease the A–a gradient, oxygen can be delivered with positive pressure. Many devices will serve that purpose and are available on the market. A valve in the expiratory circuit is used to regulate the end-expiratory pressure (overflow). PEEP levels of 5–10 cmH_2O are usually safe to administer via facemask. If higher levels of PEEP are required to maintain sufficient oxygenation, endotracheal intubation may be considered.

PEEP will not only prevent end-expiratory alveolar collapse but has also the potential to reopen and recruit collapsed alveoli, resulting in an increase in the overall area of pulmonary gas exchange. PEEP, however, does provide only minimal assistance during inspiration and will lead to only a minimal increase in alveolar ventilation. PEEP is therefore predominantly of use in hypoxic failure.

For treatment of hypercapnia, an increase in either tidal volume or respiratory rate is needed to facilitate alveolar CO_2 removal. To achieve an increase in tidal volume, inspiratory volume support will be needed in addition to PEEP. The increase in tidal volume is facilitated by pressure support during inspiration (or flow, which in turn results in increased inspiratory pressures), as pressure and volume are directly correlated. Combined with PEEP, this will lead to a biphasic positive-pressure curve, or bilevel positive airway pressure (BiPAP) (Figure 6.9). Confusingly, BiPAP and non-invasive ventilation (NIV) are often used as synonyms in daily practice. In addition, NIV is used for the description of all ventilation assist that is not delivered through an endotracheal tube. For the purpose of this chapter, NIV is used as a synonym for BiPAP.

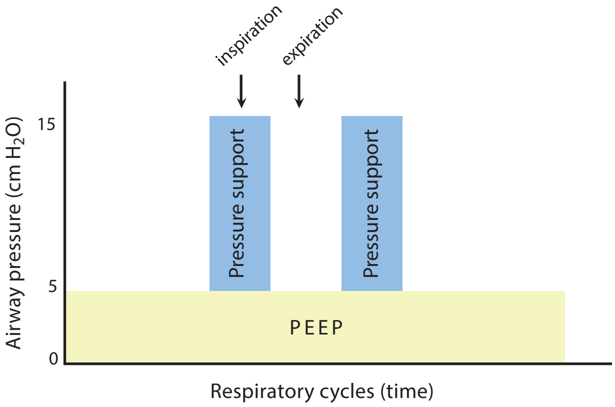


Figure 6.9 Illustration of PEEP and pressure support (NIV) in regard to airway pressures during the respiratory cycle.

NIV will assist to increase alveolar ventilation, resulting in a decreased alveolar CO_2. Many ventilation disorders are associated with additional work of breathing to compensate for the underlying condition. Pressure support and NIV have the potential to significantly reduce the work of breathing, therefore avoiding further patient treatment escalation.

Indeed, in two independent investigations, NIV therapy has been shown to prevent endotracheal intubation in up to 60% of patients with acute respiratory failure and finally to improve outcomes. Moreover, prophylactic use of CPAP and NIV postoperatively after major abdominal and lung resection surgery has been shown to reduce the reintubation rate by almost 40%.

Mechanical ventilation

Mechanical ventilation is usually delivered via an endotracheal tube (ETT). However, most NIV machines are able to deliver full mechanical and mandatory ventilation via facemask. Mechanical ventilation warrants a higher level of support and its use is limited to the ICU and the ICU specialized medical team. Patients on mechanical ventilation usually need more sedation and analgesia than for CPAP/NIV and are at high risk of suffering complications from overdosing and accumulation of analgosedation.

The most common modes of mechanical ventilation are found in Table 6.9. In contrast to short-term ventilation in the perioperative setting, mechanical ventilation on the ICU should allow more interaction of the patient (spontaneous breathing), to prevent and rebuild respiratory muscle loss.

Mechanical ventilation is not without risks, and evidence is accumulating that instrumentation of the upper airway with ETT or tracheostomy can be harmful. Recognized postintubation pulmonary complications can be divided into long term and short term. If excluding the immediate life-threatening complication of intubation, short-term complications consist predominantly of ventilator-associated pneumonia (VAP), whereas long-term complications include:

- airway symptoms (persistent hoarseness, stridor)
- tracheal stenosis
- cosmetic deformities.

Table 6.9 The most common modes in mechanical ventilation

Mode		Spontaneous breathing	Mandatory ventilation
IPPV	Intermittent positive pressure ventilation	–	+
CMV	Continuous mandatory ventilation	+	+
SIMV	Spontaneous intermittent mandatory ventilation	+	+
PCV	Pressure control ventilation	+	+
BiPAP	Bi-level positive airway pressure ventilation	+	+
PSV	Pressure support ventilation	+	–

The debate whether tracheostomy is superior to ETT for ventilation exceeding 5 days is currently ongoing. Also, whether early tracheostomy is more beneficial than late for patients' outcome remains unclear.

Ventilator-associated pneumonia

Postintubation pulmonary complications, and more specifically ventilator-associated pneumonia (VAP), have become well-recognized complications of mechanical ventilation. It is now accepted that long-term ventilation increases patients' morbidity and mortality *per se*. VAP does increase ICU and hospital stay and has significant cost implications, with increased antibiotic use and need for additional ICU resources and for the healthcare system.

VAP is defined as an airway infection after mechanical ventilation for more than 48 hours. VAP is presumed to originate from microaspiration of pharyngeal secretions along the cuff of the airway device (ETT or tracheostomy). The patient's underlying condition and pre-existing pulmonary pathology is a recognized cofactor. VAP is more commonly reported after certain types of surgical procedures, such as thoracic and cardiac surgery as well as complex vascular procedures. It is, however, difficult to prove causality arising from the surgical procedure itself, as many patients undergoing this type of surgery will have pre-existing pulmonary pathologies. Not surprisingly, duration of the operation seems to be as important as the time of postoperative mechanical ventilation.

Several care bundles have been proposed to prevent VAP in mechanically ventilated patients. These include regular mouthwashes for oral decontamination, establishing early enteral feeding and stress ulcer prophylaxis. Whether selective decontamination of the digestive tract, as practised in some ICUs, is able to prevent VAP is still under debate. New airway devices with changed cuff shapes and subglottic aspiration facility have shown promising preliminary results to decrease the incidence of VAP.

In conclusion, mechanical ventilation can cause VAP and cannot be seen as a low-risk procedure as it has an inherent morbidity and mortality.

Acute lung injury/acute respiratory distress syndrome

Severe pulmonary failure is defined by diffusion hypoxia due to a global decreased diffusion capacity of the alveolar membrane. Because of the lower ability of oxygen to cross membranes than CO_2, the increased diffusion distance will affect pulmonary oxygen gas exchange first. Traditionally, acute lung injury (ALI) and acute respiratory distress syndrome (ARDS) have been defined as a continuum of deteriorating gas exchange in the absence of left ventricular heart failure. Primary ALI/ARDS is defined by an underlying pathology directly affecting the lungs (i.e. pneumonia), whereas secondary ALI/ARDS is a consequence of pulmonary reaction to a systemic disease (i.e. massive transfusion). ALI/ARDS is caused by the loss of integrity of the alveolar membrane, which will lead to a thickening of the membrane and finally exudation of plasma into the alveoli as a result of capillary leakage. Histology has shown that ALI/ARDS will not uniformly affect the lung, but healthy and diseased alveoli will coexist in very close proximity. ALI/ARDS is a serious disease complex and has a reported mortality of up to 50% (see Chapter 9 "Pulmonary insufficiency" for more details).

The ratio of the arterial oxygen tension (PaO_2) to the fraction of inspired oxygen (FiO_2) is used to distinguish between ALI and ARDS (P/F ratio):

- ALI = P/F ratio <400 mmHg (53.3 kPa)
- ARDS = P/F ratio <200 mmHg (26.7 kPa).

Treatment of ALI/ARDS should be restricted to the ICU. Prevention of further harm while gaining time to heal is the therapeutic principle of mechanical ventilation for ALI/ARDS. Limiting tidal volumes to 6 mL/kg of ideal body weight and the utilization of high PEEP (up to 20 cmH_2O) has been shown to be beneficial to patients by the *ARDS Network*. Ventilation with low airway pressures is presumed to limit overdistension of the more rigid alveoli while minimizing harm to non-affected lung parenchyma. Intravenous fluid administration should be optimized to the minimum necessary to maximize CO. Changing of the patient's position with rotation beds and mattresses (even proning) will help to alter V/Q gravitational changes and should be considered in ALI/ARDS treatment. The concept of permissive hypercapnia, aiming to induce a left shift of the oxygen dissociation curve to facilitate peripheral oxygen release to tissues, has been found to be a valid concept during ALI/ARDS. In the most severe ARDS cases, extracorporeal membrane oxygenation has been used with success.

Death and organ transplantation

The diagnosis, confirmation and certification of death are core medical skills. This might sound obvious and straightforward, but in times when resuscitation techniques are more successful than ever and the medical benefits of organ transplantation are becoming widely recognized, special challenges for the clinician can arise.

Owing to mechanical ventilation, respiratory death can be prevented and has transformed the course of many terminal neurological disorders. This has led to the understanding that, along with the definition of cardiorespiratory death, a new definition has become necessary. Whereas in cardiorespiratory arrest the cessation of circulation will obviously lead to irreversible loss of brain function, the irreversible loss of brain function *with maintenance of circulation* has proved a novel concept. To date, medical professionals as well as lay people throughout the world have adopted the concept that a person is dead when his/her brain is dead.

This section will outline the principles of the diagnosis of death, with a special emphasis on brain stem testing and the principles of organ donation.

Death after cardiorespiratory arrest

There are currently no standardized criteria in the confirmation of death following irreversible cessation of cardiorespiratory function. As a result, practice still varies worldwide from confirming death as soon as the heart stops or when attempts at cardiopulmonary resuscitation are abandoned to waiting for 10 minutes or longer after the onset of asystole and apnoea. In the primary care setting this practice continues to be appropriate, whereas in hospitals the increasing practice of non-heart-beating organ donation warrants a standardized approach to confirming death. Guidance from the Academy of Medical Royal Colleges in the UK proposes that death can be diagnosed and confirmed after a minimum of 5 minutes of continuous observed asystole. Asystole can be identified by the absence of a central pulse on palpation and absence of heart sounds on auscultation. In the hospital and especially ICU setting, at least one of the following additional monitoring modalities should be used to prove absence of cardiac function: ECG display (also from a defibrillator), intra-arterial pressure monitoring and echocardiography. The time of death is recorded as the time at which these criteria are fulfilled.

Diagnosing brain death

Different protocols have been adopted among countries around the world for brain death testing and the requirements for number of observers, the specialty of the assessing physician, the duration and the use of confirmatory tests may differ. This section cannot account for all these differences. Requirements for special considerations are necessary for diagnosing brain death in children, an area that is reserved for the specialized physician. We will, however, focus on the principles of diagnosing brain death in adults. As a principle, because of conflict of interest, no member of the transplant team can be involved in brainstem testing.

As brain death occurs, reflexes will disappear in a rostral to caudal direction and the medulla oblongata is the last part of the brain to cease function. Several hours may be required for the destruction of the brainstem to be complete. The clinical neurological examination remains the standard for determination of brain death and has been adopted by most countries. This process must be carried out by experienced physicians and with precision. A complete clinical neurological examination includes documentation of coma, the absence of brainstem reflexes and apnoea.

Irreversible coma

First, the cause for persistent coma needs to be established and any reversibility must be excluded. Potential reversible factors are intoxication by drugs and medication, neuromuscular blocking agents, hypothermia and electrolyte imbalance (Table 6.10).

Acute endocrine imbalance associated with brainstem death is not the cause of reversible coma; chronic profound endocrine failures can usually be excluded from the history. Prolonged action and accumulation of hypnotics, tranquilizers and sedatives must be taken into account and sufficient time should be allowed for their clearance. If significant diagnostic uncertainty remains, brainstem testing cannot be undertaken.

Irreversible cessation of brainstem function

A thorough neurological examination must follow the assessment of irreversible coma to assess brainstem function (Table 6.11). To diagnose brainstem death, pupils must be assessed for absent reaction to bright light; a corneal reflex must be absent. No motor response to painful stimuli must be found. As reflexes at a spinal level might still be present, a *peripheral* motor response to *peripheral* stimulation can be observed, which is not a higher

Table 6.10 Potential reversible causes of coma that need to be addressed before testing for brainstem death

Factor	Lower limit	Upper limit	Comment
Temperature	34°C		Impaired consciousness <34°C, brainstem areflexia <28°C
Biochemistry			
Sodium	115 mmol/L	160 mmol/L	Derangements that are clearly the result of brain death (hypernatraemia associated with diabetes insipidus) may not require correction ahead of testing
Potassium	2 mmol/L	–	
Magnesium	0.5 mmol/L	3 mmol/L	
Phosphate	0.5 mmol/L	3 mmol/L	
Glucose	3 mmol/L	20 mmol/L	Blood glucose should be checked immediately before testing
Other parameters:			
pH	7.35	7.45	
$PaCO_2$	2.0 kPa	6.0 kPa	
PaO_2	10 kPa		
Mean arterial pressure	60 mmHg		

Table 6.11 Clinical criteria for brain death

Absence of all of the following:
• pupillary response to light
• corneal reflex
• motor response
• caloric response (oculovestibular reflex)
• gag reflex
• coughing in response to tracheal suctioning
• respiratory drive with hypercapnia

function of the brain. Therefore, application of painful stimuli in the distribution of the cranial nerves is preferred (supraorbital nerve, temporomandibular joint) and a lack of motor response must be observed. To test oculo-vestibular response, a clear view of the tympanic membrane should be established before instilling 50 mL of ice-cold water in each ear with the head tilted 30° to the horizontal plane. No eye movement must be observed following water instillation. Cough reflex to tracheal stimulation with a suction catheter must be absent as well as a gag reflex following stimulation of the posterior pharynx with a spatula. All of these tests must show absence of brainstem function before the apnoea test can be performed.

The apnoea test is the process of testing the respiratory response of the brainstem to hypercarbia and should be performed last. The patient should be in cardiovascular stability and ventilated to normocapnia before beginning the apnoea test. The apnoea test is not valid when direct high cervical injury was sustained (see below). The patient is disconnected from the mechanical ventilator, and observed for spontaneous respiratory efforts for 5 minutes. During the test, oxygen is inflated in the tracheal tube via a suction catheter to minimize hypoxia. Hypercarbia must be documented with blood gas analysis. After documenting the absence of respiratory response to hypercarbia, the patient should be reconnected to the ventilator for normoventilation.

Brainstem death can only be declared if all tests have failed to show any brainstem function. Most countries will acknowledge a patient's death after the first diagnosis of brainstem death. A second, confirmatory, brainstem test is often required before further management of the patient can be initiated.

Additional investigations and special considerations

The accuracy of clinical examination for the diagnosis of death by cessation of brainstem function has proven to be highly accurate and reliable. Therefore, not including results of neurophysiological and imaging investigations as part of these criteria has become widely accepted. However, death cannot be diagnosed on the basis of brainstem testing alone in circumstances when comprehensive neurological examination is not possible (such as extensive maxillofacial trauma, high cervical cord trauma or residual sedation). In such circumstances, confirmatory tests may reduce elements of uncertainty and shorten the period of observation prior to clinical brainstem testing.

Confirmatory tests can be categorized as assessing perfusion and neurophysiology:

- assessment of blood flow in the larger cerebral arteries (four-vessel angiography, transcranial Doppler, magnetic resonance angiogram and spiral CT angiogram)
- assessment of brain tissue perfusion (xenon CT, positron emission tomography, cerebral scintigraphy)
- assessment of neurophysiology (electroencephalogram, evoked potentials).

Not all tests are readily available in every hospital, have the same amount of diagnostic accuracy and reliability, nor are easy to interpret. In addition, haemodynamic instability occurs frequently in the dying patient, and transfer out of the ICU may not be without risk. When appropriate, such cases should be referred for a specialist neurological or neurosurgical opinion.

Differential diagnosis of brainstem death

Besides hypothermia and drug intoxication, differential diagnosis of brainstem death includes locked-in syndrome and Guillain–Barré syndrome.

Locked-in syndrome typically occurs following a destruction of the base of the pons. This is often caused by an acute embolus to the basilar artery. Patients with locked-in syndrome are conscious but cannot move their limbs, grimace or swallow, but voluntary blinking and vertical eye movements persist. Guillain–Barré syndrome is often reversible and can involve peripheral and cranial nerves. It represents an acute inflammatory demyelinating polyneuropathy, a disorder affecting the peripheral nervous system; patients have ascending paralysis, with weakness beginning in the feet and hands and migrating towards the core. Guillain–Barré syndrome is usually triggered by an acute infection and the progression occurs over a period of days. Meticulous history-taking should prevent the misdiagnosis of brain death.

Further management

After the clinical criteria of brainstem death have been met, the physician needs to inform the next of kin, who can be approached about organ donation. This can be done with the involvement of an organ procurement team. If organ donation is declined, withdrawing of ventilatory assistance may be the most appropriate course. However, if organ donation is considered a realistic option by the next of kin and the medical team, suitability of the patient should be confirmed by additional tests. This is usually a time-consuming process during which the patient must be treated appropriately. Normal body homeostasis should be maintained with fluid replacement and vasopressor/inotropic therapy, and ventilation must be continued. Electrolyte imbalances such as hypernatraemia, hypokalaemia and changes in glucose balance are frequent, especially if diabetes insipidus occurs. These should be corrected with the aim of normal ranges, as normalization of electrolytes will positively affect outcome of the transplanted organs. Substitution of hydrocortisone, thyroxine and antidiuretic hormone will help to balance the failure of the endogenous neuroendocrine response.

CHAPTER 7

Anaemia, hypovolaemia and oedema

SIR ALFRED CUSCHIERI

Introduction

This chapter covers the pathophysiology and management of patients who have a reduced haemoglobin (Hb) load (anaemia), or who sustain a sudden reduction in the circulatory blood volume (hypovolaemia) or who accumulate abnormal amounts of fluid in the interstitial space or serous cavities (oedema). Transfusion of blood and blood products is also covered in this chapter. The spectrum of disorders covered is wide and of variable surgical urgency, from the patient with iron-deficiency anaemia requiring elective surgery for a right-sided colon cancer to the emergency management of a patient with profound hypotension from major ongoing blood loss, and patients with generalized oedema due to cardiac, hepatic or renal disease.

Anaemic patients: types, pathophysiology and management

Definition and types of anaemias

Anaemia is defined as a reduced level of circulating Hb. Minor degrees are asymptomatic as the oxygen-carrying capacity of the blood, although reduced, is sufficient to meet the needs for daily activities. Below a certain level of Hb (8.0 g/dL), the oxygen-carrying capacity is sufficiently compromised as to be unable to meet the oxygen needs except at rest and the patient becomes symptomatic (symptomatic anaemia). The primary symptoms are those of oxygen lack (asthenia, lethargy, tiredness, diminished exercise, tolerance, etc.); others follow from the compensatory mechanism that consists essentially of a fast hyperkinetic circulation giving rise to palpitations, buzzing in the ears and angina. Severe anaemia may indeed cause heart failure. The types of anaemia are summarized in Box 7.1.

BOX 7.1 Types of anaemia

- Iron deficiency (hypochromic microcytic)
- Sideroblastic (hypochromic microcytic + ringed sideroblasts in the marrow)
- Anaemia of chronic disease (normocytic normochromic)
- Macrocytic normoblastic
  - Liver disease
  - Alcoholism
  - Reticulocytosis secondary to haemolysis
- Macrocytic megaloblastic
- Congenital haemolytic (various morphological types, splenomegaly)
  - Red cell membrane defects: hereditary spherocytosis, hereditary elliptocytosis
  - Red cell enzyme defects: glucose-6-phosphate deficiency, pyruvate kinase deficiency
  - Haemoglobinopathies (abnormal haemglobins): sickle cell disease, thalassaemia
- Acquired haemolytic
  - Idiopathic warm autoimmune haemolysis [active at 37°C, immunoglobulin (Ig) G antibodies]
  - Idiopathic cold autoimmune haemolysis (active at lower temperatures, IgM antibodies)
  - Drug-induced immune haemolysis
  - Haemolytic disease of the newborn (rhesus D incompatibility)
- Aplastic/hypoplastic (bone marrow stem cell failure/depression)

In surgical practice, by far the most common is iron-deficiency (hypochromic microcytic) anaemia due to chronic occult blood loss (low serum ferritin and iron, high serum transferrin with low percentage saturation) exemplified by carcinoma of the right colon or stomach. In right colon cancer, hypochromic microcytic anaemia with positive faecal occult blood is the only early manifestation of the disease.

Megaloblastic anaemia arises from deficiency of vitamin B_{12}, folate or both. In a surgical context, megaloblastic anaemia is important from the preventive aspect, i.e. the need for vitamin B_{12} replacement therapy after gastrectomy and distal ileal resection/disease; it occurs (due to folate deficiency) in patients on chemotherapy for cancer and in those on chronic dialysis prior to renal transplantation. Pernicious anaemia (megaloblastic anaemia + atrophic gastritis with achlorhydria + parietal cell antibodies and impaired absorption of vitamin B_{12} corrected by oral intrinsic factor) assumes surgical importance because of the high risk for gastric cancer in these patients.

Anaemia associated with chronic disorders (normocytic normochromic) is commonly encountered in surgical practice in patients with malignant disease. It often does not respond to haematinics and then requires blood transfusion. Iron-deficiency anaemia and the anaemia of chronic disease may coexist. Patients with marrow failure (leukaemia, high-dose chemotherapy and malignant infiltration) require haematological support with blood transfusion, other component transfusion (platelets, granulocytes, clotting factors) and marrow rescue agents (recombinant colony-stimulating factors).

Anaemia and blood volume

The blood transfusion requirements of the anaemic patient are very different from those of the patient with acute blood loss. The crucial difference between anaemia and hypovolaemia (from acute haemorrhage) concerns the circulating blood volume (CBV), which is maintained or increased in anaemic individuals irrespective of the morphological type and aetiology of the anaemia (even when due to chronic blood loss). The deficit in anaemia thus relates to the Hb load and hence to the oxygen-carrying capacity of the blood. This reduced Hb level in symptomatic anaemia, even when fully saturated (oxygen saturation = 100%), is insufficient to provide normal tissue oxygenation. The compensatory mechanism consists of a hyperkinetic circulation with tachycardia and fast circulation time. In itself, this persistent tachycardia may contribute to anaemic cardiac failure due to deficient oxygenation of the myocardium (reduced diastolic interval).

During transfusion of anaemic patients, therefore, the prime consideration from the therapeutic safety standpoint is the prevention of circulatory overload and congestive cardiac failure. The objective of the transfusion is thus to raise the Hb load in a volume and during a time scale (slow transfusion over a 4 hour period) that can be tolerated by the patient. A transfusion of red cells of 4 mL/kg will raise the circulating Hb concentration by approximately 1.0 g/dL. Thus, each unit of red cells (300 mL) should raise the circulating Hb in a 70 kg adult by this amount. As the reason for transfusion of anaemic patients is to increase the oxygen-carrying capacity of blood, the red cell concentrates should be less than 14 days old as these have near normal levels of 2,3-diphosphoglycerate (2,3-DPG).

Nature, causes and consequences of hypovolaemia

Hypovolaemia is defined as a reduced CBV (= 70 mL/kg in adults; 80 mL/kg in infants) and can be either true or apparent. True hypovolaemia results from contraction of the CBV as a result of losses (blood from haemorrhage, plasma in the burnt patient and dehydration from deficits of water and saline). Apparent hypovolaemia ensues from an increased vascular capacity, usually due to loss of the peripheral resistance in the muscular arterioles (sepsis, adrenal insufficiency, anaphylaxis, neurogenic factors), although in some of these conditions, e.g. sepsis, the situation is more complex as the increased capillary permeability induces intravascular fluid losses into the interstitial space.

Response to hypovolaemia

Ultimately, the adverse effects of hypovolaemia are due to an inadequate (not necessarily reduced) cardiac output (CO) and hence inadequate cellular perfusion. To appreciate the pathophysiological consequences of hypovolaemia, one has to appreciate the normal control of CO. Overall CO is determined by the stroke volume (SV) and heart rate (HR) as follows: CO = SV × HR. In a young, fit adult at rest, each ventricle fills during diastole to reach an end-diastolic volume of 120 mL of blood. With each ventricular contraction (systole), 70 mL is ejected from each ventricle. The actual amount is known as the ejection fraction, and is normally 60% of the volume of blood present in each ventricle at the end of diastole. In accordance with Starling's law (force of cardiac contraction increases with the diastolic stretch of the cardiac muscle fibres), the more the heart fills during diastole, the greater the amount of blood expelled with each beat (SV), but the ejection fraction remains fairly constant. CO is then determined by (1) preload, (2) cardiac contractility, (3) afterload and (4) HR.

Preload

This refers to venous filling, venous return and is determined by the CBV and venous tone. The peripheral veins, especially the venules of the liver and spleen (capacitance vessels), act as a large reservoir and contain 45% of the intravascular volume, whereas the large central veins hold about 18%. Hence, preload is reduced significantly in hypovolaemia. To some extent, the compensatory venous vasoconstriction due to the release of norepinephrine (noradrenaline) from the sympathetic nerve endings in the vein walls may help to maintain an adequate preload up to a certain deficit in the CBV

Two other mechanisms facilitate the venous return: respiratory excursions and skeletal muscle activity. During inspiration, the diaphragm descends, increasing the intra-abdominal pressure that is transmitted to the intra-abdominal veins. At the same time, the intrathoracic pressure falls, lowering the right atrial pressure, the net effect being to accentuate venous return.

This mechanism remains operative in hypovolaemia, unless complicated by chest injuries, which preclude normal ventilation (flail chest, haemopneumothorax and ruptured diaphragm). The contraction of the skeletal muscles within their fascial compartments is the main contributor of venous return in the lower limbs (the muscle pump). The contracting muscle bulk restrained by the overlying fascial sheath directly compresses the deep veins and encourages flow from the superficial to the deep venous systems. The efficiency of the muscle pump is dependent on the integrity of the venous valves. The muscle pump is lost in the prostrated hypovolaemic patient, but, because of the supine or head-down position in which these patients are nursed, the loss of the muscle pump is not an important factor in the reduced preload.

Cardiac contractility

Cardiac contractility is diminished in hypovolaemia as a consequence of the reduced end-diastolic filling/volume of the ventricles (and thus stretch of the cardiac muscle fibres).

Afterload

Afterload equals the peripheral arterial resistance which acts as an impediment to cardiac ejection and thus a reduced afterload (e.g. by vasodilator therapy) tends to favour an increase in the CO, but only in the presence of an adequate CBV. In the hypovolaemic patient, peripheral resistance is initially increased (sympathetic and adrenal response) so that the percentage fall in the blood pressure is always an underestimate of the drop in the CO. Thus, for example, in previously healthy young adults, the acute loss of 20% of the blood volume reduces, on average, the arterial pressure by 15% and the CO by 41%.

Heart rate

Within limits, tachycardia increases the CO but extreme HRs reduce output by diminishing ventricular filling and coronary artery nutrient blood flow to the myocardium.

The response of an individual to blood loss varies considerably. Indeed, some young, healthy individuals, by virtue of the intense vasoconstriction they can mount in response to volume deficits, can lose as much as 25% of the CVB without any significant change in the arterial blood pressure. The response is influenced by age, duration and severity, pre-existing myocardial disease, anaemia and associated trauma. In the accident victim, the additional trauma alters the neuroendocrine and metabolic response. Thus, trauma victims with mild to moderate hypovolaemia may have a normal or even an elevated CO, and they may be normotensive or even hypertensive after the accident. Even the HR response is variable in these patients, with either a tachycardia or bradycardia at the time of resuscitation.

Consequences of hypovolaemia

Diminished tissue perfusion, tissue hypoxia, anaerobic glycolysis and lactic acidosis

The immediate consequence is hypovolaemic shock, defined as a state of inadequate cellular perfusion. The delivery of oxygen (DO_2) to the tissues is reflected by the product of CO × arterial oxygen content (CaO_2) adjusted to the patient's build (indexed):

$$DO_2 \text{ (mL/min/m}^2) = \text{CO} \times CaO_2 \times 10$$

The arterial oxygen content depends on the Hb level and the percentage oxygen saturation. Under normal physiological conditions, DO_2 ranges from 500 to 720 mL/min/m^2 and the oxygen consumption (VO_2) between 100 and 160 mL/min/m^2, representing an oxygen extraction ratio of 22–30%. This level of tissue oxygenation ensures aerobic metabolism of glucose with the production of ATP, CO_2 and H_2O via pyruvate so that the blood lactate is very low (>2.0 mmol/L) unless there is sustained muscular exertion when a certain amount of anaerobic metabolism is incurred with the production of lactate. This tendency to acidosis shifts the oxyhaemoglobin to the right, favouring dissociation, i.e. increased release of oxygen. Thus, any fall in the DO_2 is compensated for by increased extraction of oxygen. Tissue oxygenation is disturbed in all forms of shock.

DO_2 is reduced in hypovolaemic shock and is accompanied by an increased extraction, so that VO_2 is not markedly depressed unless the hypovolaemia is extreme. The severity of the lactic acidosis and the extent of reduction of the mixed venous Hb saturation in the pulmonary artery, SVO_2 (obtained by pulse oximetry of a blood sample or from the distal lumen of a Swan–Ganz catheter), depend on the severity of the hypovolaemia and on adequate early restoration of the blood volume.

Acute renal failure

Every organ incurs hypoxic damage from sustained hypovolaemia. The intense peripheral and splanchnic vasoconstriction that occurs in response to blood volume losses to redistribute the available blood to the brain puts the kidneys at particular risk of ischaemic damage: acute renal failure (ARF). Initially (prerenal or potential ARF), the renal function is simply responding to the prerenal deficits and intense vascular shut down, with low perfusion pressure and reduced oxygen delivery. There is 'physiological' oliguria with the production of small volumes of concentrated urine and low fractional sodium excretion. Renal tubular function is relatively well maintained. Urine osmolality is still greater than serum osmolality (urine/plasma osmolality ratio >1.05). There are no structural changes and recognition of the problem at this stage with adequate correction of the prerenal deficits can prevent the development of established acute tubular necrosis (ATN). ARF (pathologically ATN) is a potentially reversible reduction in the capacity of the kidney to excrete nitrogenous wastes and maintain fluid and electrolyte homoeostasis. ARF is common, complicating 5% of all medical and surgical admissions in a large American study. A UK community-based study reported an overall annual incidence of ARF of 172 cases per million adult population.

Pathogenesis of acute tubular necrosis

Overall the renal blood flow amounts to 25% of CO but most of this supplies the cortex, which contains the glomeruli and convoluted tubules as these require preferential perfusion for filtration and reabsorption, the latter having high energy requirements. In contrast the outer medulla receives blood which is low in oxygen hydrostatic pressure after having traversed the glomerular capillary bed. These features, though essential for maintaining the osmotic gradients within the medulla, render it susceptible to variations in blood flow especially as the medulla contains the ascending limb of the loop of Henle and the S3 segment of the proximal tubule, which have high oxygen requirements. The resulting impaired tubular sodium reabsorption encountered is sustained in hypovolaemia as the reduced perfusion causes constriction of the afferent arterioles, which further reduces the glomerular filtration rate. This tubular–glomerular feedback (designed to protect the downstream nephron) may cause renal injury if the low-flow state is prolonged. The reduced blood flow in the peritubular capillaries produces ischaemic damage in vascular endothelial cells, resulting in cell swelling and leucocyte activation, which in turn produce cytokines and reactive oxygen species that damage endothelial and tubular epithelial cells. Tubular cells swell, lose their brush border and develop cytoskeletal abnormalities with abnormal localization of cell membrane components (Na$^+$/K$^+$-ATPase) and loss of cell–cell and cell–basement membrane attachment. These swollen cells detach and obstruct the tubular lumen. The exfoliation of tubular cells is thought to be due to redistribution of the integrin adhesion molecule receptors from the basolateral to the apical membranes. The exfoliated cells adhere downstream to other tubular cells to form casts. The ATN tubular damage is thus found predominantly in the outer medulla where oxygen delivery is always borderline. Changes in the cortical tubules are less marked, partly because cortical blood flow, and hence transport workload, fall rapidly after the ischaemic insult. The renal impairment results from (1) a fall in the whole kidney glomerular filtration rate, (2) obstruction of tubules by cellular debris/casts and (3) back-leakage of filtrate across the damaged tubules into the interstitium. Histologically in ATN, the tubules are surrounded by flattened, denuded epithelium, and the lumen filled by cell debris, with congested peritubular capillaries, extensive inflammatory cell infiltrate and cell necrosis

A previously healthy patient is able to regain normal structure and function after ATN if renal perfusion and oxygen supply are normalized. The regeneration is from viable cells adherent to the tubular basement membrane, which divides and spreads to cover denuded areas before differentiation to normal tubular epithelium and function. The return of glomerular filtration aids clearance of tubular debris and relief of obstruction. Often there is a period when glomerular filtration has returned to normal before tubular function is restored. This accounts for the polyuric phase of ATN.

Risk, Injury, Failure, Loss and End-stage Kidney (RIFLE) classification

To establish a uniform definition for acute kidney injury, the Acute Dialysis Quality Initiative formulated the Risk, Injury, Failure, Loss, and End-stage Kidney (RIFLE) classification (Table 7.1). RIFLE defines three grades of increasing severity of acute kidney injury – *risk* (class R), *injury* (class I) and *failure* (class F) – and two outcomes: (1) loss (persistent ARF = complete loss of kidney function >4 weeks) and (2) end-stage kidney disease. The RIFLE classification provides three grades of severity for acute kidney injury based on changes in either serum creatinine or urine output from the baseline condition into one of the three RIFLE severity classes: acute kidney risk (R), acute renal injury (I) or ARF (F). Within the general intensive care unit population, acute kidney 'risk, injury, failure', as defined by the RIFLE classification, has been shown to be associated with increased hospital mortality and patients in the RIFLE class R are at high risk of progression to class I or class F. RIFLE class I or class F patients have an increased risk of in-hospital mortality compared with those who do not progress beyond class R irrespective of severity of illness, case mix, sex and age.

Table 7.1 Risk, Injury, Failure, Loss, and End-stage Kidney (RIFLE) classification

Category	GFR criteria	UO criteria	
Risk	Increased creatinine × 1.5 or GFR decrease >25%	UO <0.5 mL/kg/h × 6 hours	High sensitivity
Injury	Increased creatinine × 2 or GFR decrease >50%	UO <0.5 mL/kg/h × 12 hours	
Failure	Increase creatinine × 3 or GFR decrease >75%	UO <0.3 mL/kg/h × 24 hours or anuria × 12 hours	High Specificity
Loss	Persistent ARF = complete loss of kidney function >4 weeks		
ESKD	End-stage kidney disease (>3 months)		

ARF, acute renal failure; ESKD, end-stage kidney disease; GFR, glomerular filtration rate; UO, urine output.

Recovery of acute reversible intrinsic renal failure

Clinically, recovery of sufficient renal function for independent survival after oliguric acute reversible intrinsic renal failure takes 2–4 weeks. Old age, sepsis, jaundice and cardiorespiratory failure are adverse factors that usually prevent recovery of renal function.

Management of acute renal failure

ARF develops in up to 5% of patients at hospital admission and affects up to 20% of patients in intensive care units. The aetiology in the individual patient can be identified in most instances by an appropriate history, physical examination and selected laboratory investigations. Management is aimed in the first instance at correction of life-threatening consequences and providing support of the patient until recovery of renal function. The life-threatening consequences of ATN are (1) hyperkalaemia, (2) pulmonary oedema and (3) severe acidosis and these require immediate attention. Additionally, any causative factors, including nephrotoxic drugs, that may have contributed to ATN must be withdrawn and corrective measures put in place and any urinary tract obstruction must be relieved. Renal replacement therapy (RRT) is used when appropriate.

Hyperkalaemia

Severe hyperkalaemia (plasma potassium >6.5 mmol/L) is a medical emergency because of the risk of cardiac arrhythmias and arrest. Severe hyperkalaemia is accompanied by a typical pattern of ECG changes: peaked/tented T waves, flattening of the P wave and prolongation of the QRS complex, sine waves with higher K levels (8–9 mmol/L) ventricular fibrillation or asystole. Urgent treatment of hyperkalaemia must be initiated when the serum potassium exceeds 6.5 mmol/L, or in the presence of any ECG changes.

The treatment of hyperkalaemia entails:

- Stabilization of cardiac myocytes by calcium as this antagonizes the effects of hyperkalaemia on the myocardium. Calcium should be administered as soon as P wave or QRS changes are noted on the ECG as a slow intravenous bolus of 10–20 mL of 10% calcium gluconate over 2–5 minutes. In patients on digoxin, calcium is administered as a slow infusion (10 mL 10% calcium gluconate in 100 mL 5% dextrose over 30 minutes) as calcium potentiates cardiac toxicity of digoxin.
- Measures to reduce plasma potassium concentration: insulin with glucose to increase cellular potassium uptake (by activation of Na^+/H^+ channels). The addition of glucose to the insulin bolus is necessary to prevent hypoglycaemia. In practice, 10 units of fast-acting soluble insulin are added to 50 mL of 50% dextrose and infused over 10–20 minutes. Insulin alone can be given to hyperglycaemic patients (blood glucose >14 mmol/L). During this treatment, the blood glucose should be monitored every 6 hours to ensure against hypoglycaemia.
- Removal of potassium from the body: ion exchange resins bind potassium in the gastrointestinal (GI) tract, in exchange for calcium or sodium, with resulting increased potassium excretion in the stool. Calcium resonium and Resonium A are commonly used, in an oral dose of 15 g t.d.s. together with an osmotic laxative. Ion exchange resins are most effective when potassium levels are moderately high (6.5 mmol/L).
- Haemodialysis is indicated in refractory severe hyperkalaemia and is more effective than haemofiltration or peritoneal dialysis. Maximum removal occurs in the first hour of dialysis. Serum potassium may decrease by 1.2–1.5 mEq/L/h if potassium free dialysate is used, which can precipitate hypokalaemia and arrhythmias. Generally a dialysate potassium concentration of 1.0 or 1.5 mmol/L is used.

Pulmonary oedema

This results from fluid overload and is usually accompanied by ventilatory failure, which, if significant, requires supplementary oxygen and non-invasive ventilation, or intubation and ventilation if severe. Pharmacological treatment consists of intravenous infusion of glyceryl trinitrate (50 mg in 50 mL 0.9% saline, at a rate of 2–20 mL/h) aimed at keeping the systolic blood pressure >95 mmHg) and administration of loop diuretics in large doses (furosemide 250 mg in 50 mL 0.9% saline) to achieve diuresis. If these interventions prove ineffective, RRT, haemodialysis or haemofiltration is indicated.

Acidosis

Severe metabolic acidosis (blood pH <7.2) is frequently present and used to be treated with the administration of sodium bicarbonate, although there is no evidence that this is beneficial and may be counterproductive as it increases the sodium load. Much lower concentrations – isotonic (1.26%) solutions – of sodium bicarbonate may have a role as fluid replacement therapy in stable patients with a moderate to severe acidosis who require fluid replacement and in whom the need for dialysis is not imminent. Otherwise haemodialysis or haemofiltration is required for the treatment of severe acidosis in oligoanuric patients.

Fluid balance

The optimal fluid is still debated. Normal saline and 4% albumin have clinical equivalence, as shown by a study of patients admitted to intensive care units. Once the patient is considered normovolaemic, care should be taken to avoid fluid overload and a maintenance regimen started, with careful fluid balance charts to take into account renal and insensible fluid losses, aimed at achieving a positive balance not exceeding 500 mL/day.

Relief of obstruction

Any obstruction of the urinary tract requires prompt relief. For bladder outflow obstruction, a urethral or suprapubic catheter is used. Either is considered necessary in all patients with ARF for accurate measurement of urine output. Relief of upper tract obstruction may require antegrade (percutaneous nephrostomy) or retrograde (cystoscopy and retrograde ureteral catheterization) approaches for the relief of the obstruction. A significant diuresis can complicate relief of complete urinary tract obstruction and has to be taken into consideration in the fluid balance.

General measures

Patients with ARF may develop a bleeding tendency from platelet dysfunction and coagulopathies. Correction of coagulopathy is with blood products and vitamin K. RRT may improve platelet function but desmopressin (DDAVP) and cryoprecipitate may be required. Carbohydrate and protein requirements should be tailored individually and ideally delivered via the enteral route, although parenteral administration may be necessary in some patients. Patients with ARF are also more susceptible to infections, which often result in clinical deterioration; infection control measures should be instituted. Finally, prophylaxis against deep venous thrombosis is indicated in patients with ARF.

Renal replacement therapy

The indications for RRT are:

- severe hyperkalaemia, unresponsive to medical therapy
- fluid overload with pulmonary oedema
- uraemia (blood urea >30–50 mmol/L)
- complications of severe uraemia: encephalopathy, pericarditis, neuropathy/myopathy
- severe acidosis (pH <7.1)
- drug overdose with a dialysable toxin.

Management of hypovolaemia

The management of the hypovolaemic patient entails:

- detection of the hypovolaemia, its cause and severity
- arrest of haemorrhage
- establishing good intravenous access with large-bore peripheral cannulas (two if hypovolaemia is severe)
- replacing the deficit
- repeated clinical observations and monitoring the patient.

Detection of hypovolaemia, its cause and severity

Although in the majority of patients the diagnosis of hypovolaemia is obvious, in some patients it is less clear-cut because of previous partial resuscitation and variable degrees of vasoconstriction. Diagnosis and assessment are thus based on clinical assessment, including careful history, clinical examination, estimation of observed losses, haemodynamic measurements (HR, pulse volume, arterial and venous pressures and haematocrit) and indices of tissue perfusion (nail bed capillary refill, peripheral skin temperature, urine output and level of consciousness). It must be stressed that the haemodynamic measurements are complementary to the clinical assessment, as a normotensive patient with a normal HR may still be hypovolaemic.

The severity of hypovolaemia correlates with the volume lost and is reflected in the clinical signs. In general, contraction of the CBV by more than 25% (1.5 litres) is regarded as severe hypovolaemia. The severity of the hypovolaemia is much more difficult to assess clinically when the hypovolaemia is secondary to deficits of water and salt. In these instances, careful reappraisal of the fluid balance charts gives the best estimate of the losses incurred.

Intravenous access and replacement of deficits

The principle of volume replacement, 'replace like with like', needs to be qualified in respect of the cause of the hypovolaemia. It applies fully to hypovolaemia associated with fluid and electrolyte losses. Burn patients may require blood in addition to crystalloids and protein solutions. A previously healthy adult is able to tolerate a blood loss of 25% of the CBV (1.5 litres) with volume replacement by crystalloids or plasma expanders only. Beyond this loss, blood transfusion becomes necessary as the oxygen-carrying capacity of the blood is then compromised by the significant reduction in the Hb content of the blood.

Although good intravenous access for volume replacement is an obvious necessity, it is often compromised by inability to insert an appropriately sized cannula (or two in severe hypovolaemia) because of the collapsed veins. Valuable time is often lost in persisting with efforts to cannulate percutaneously a peripheral upper limb vein. In these cases, a cut-down is made over a suitable vein. In recent years there has been a shift away from the use of crystalloid solutions in the resuscitation of patients with hypovolaemia due to blood loss because of the established risks of tissue and especially pulmonary oedema and the development of compartment syndromes. Major blood losses should be replaced with red cell concentrates, platelet transfusions and clotting factor concentrates according to established protocols. These protocols for massive blood transfusions are now in established practice in all major trauma centres. All such protocols for massive transfusion now focus on the prevention of coagulopathy and thrombocytopenia. A 1:1:1 ratio [equal parts packed red blood cells (PRBCs), fresh frozen plasma (FFP) and platelets] for blood component therapy is now recommended as a more physiological regimen aimed at prevention of complications. This approach is called haemostatic resuscitation because it emphasizes the early correction of coagulopathy, which is conducive to improved survival.

Hypovolaemia due to acute blood loss

The management entails:

- Replacing the volume at the same time as controlling the bleeding. Blood samples are taken for blood group/antibody screening, urea and electrolytes and haematology, i.e. Hb, packed cell volume (PCV) and platelet count. Rapid intravenous infusion is commenced with crystalloid solutions, e.g. isotonic saline or colloids (protein solutions or non-plasma colloid volume expanders). Several clinical trials have confirmed that colloid solutions are not superior to crystalloids for resuscitation but much larger volumes of crystalloids are needed. Resuscitation with isotonic saline should be avoided in patients with severe liver disease in view of the risk of sodium overload. For the same reason, only salt-poor albumin solutions should be administered to these patients. Dextran and hetastarch [Hespan, hydroxyethyl starch (HES)] should be limited to 1.5 L/24 h.
- Blood transfusion if losses exceed 1.5 litres.
- Administering oxygen by facemask or nasal catheter.
- Requesting an early coagulation screen.
- Repeating clinical observation and monitoring of the patient.

Massive blood transfusion

Massive blood transfusion is defined as that which is equivalent to or exceeds the patient's own blood volume within 12 hours. It carries high morbidity and mortality rates, primarily because of the underlying condition that necessitates the massive blood transfusion and, to a lesser extent, because of the adverse acute changes that are caused by the rapid infusion of large amounts of cold stored blood. Patients requiring massive blood transfusion form a heterogeneous group: young, previously healthy trauma victims, patients with major bleeding disorders, obstetric complications, etc. The nature of the underlying condition and the age of the patient largely determine the survival. Pre-existing renal and liver disease and old age militate against recovery.

Aside from being cold, stored blood has an acid pH, contains citrate anticoagulant and has an elevated plasma K^+ and ammonia and a reduced 2,3-DPG. The metabolic consequences therefore include hypothermia, acidosis, hyperkalaemia and an increased affinity of the transfused Hb for oxygen (reduced 2,3-DPG), thereby contributing to the tissue hypoxia. The reduced oxygen-carrying capacity is not a real problem nowadays with the use of modern anticoagulant preservative solutions that ensure adequate concentration of 2,3-DPG in stored blood for up to 14 days. For this reason, blood that is less than 14 days old is recommended for massive blood transfusions. The reduced oxygen-carrying capacity is likely to be important only in anaemic patients and in those with pre-existing cardiac disease. Hypothermia may lead to cardiac arrhythmias including ventricular fibrillation and asystole. For this reason, patient warming (heating blankets, etc.) and blood warming are necessary if the transfusion rate exceeds 50 mL/min. Unfortunately, the heating coils increase the resistance of the oxygen-giving circuit, but their use is essential in these patients. Citrate intoxication is due to the chelation of ionized calcium, which may result in the prolongation of the QT interval, but this does not materially affect cardiac function and the ionized calcium level rapidly returns to normal after the transfusion as the excess citrate is metabolized and excreted. Thus, the use of supplemental calcium is not justified, particularly as it may itself give rise to arrhythmias. Hyperkalaemia is seldom a problem as the excess plasma K^+ enters the red blood cells (RBCs) with warming to body temperatures. It is, however, a consideration in patients with acidosis and renal failure when calcium is administered as the physiological antidote.

Clotting factors and other blood component deficiencies that arise as a result of massive blood transfusion are more important than the metabolic complications:

- clotting factor deficiency, especially factors V and VIII
- thrombocytopenia
- disseminated intravascular coagulation (DIC)
- reduced plasma colloid osmotic pressure.

Stored blood is deficient in factors V and VIII and beyond 48 hours contains practically no functioning platelets. The situation is further compounded by the dilution that occurs in these patients because of infusion of crystalloids and plasma expanders before or in between units of blood. The breakdown of some of the transfused cellular components (RBCs, platelets, leucocytes) releases thromboplastin-like material and thus can trigger DIC.

Acute respiratory distress syndrome (ARDS) may complicate massive blood transfusion and is often multifactorial. Its incidence is influenced by the underlying condition (sepsis and major trauma), but microemboli from white cell and platelet aggregates and reduced plasma oncotic pressure (dilution) can contribute to the development of the syndrome. ARDS can also develop as a result of transfusion-related acute lung injury (TRALI; see below).

The modern practice of 'safe' massive blood transfusion consists of:

- replacing and maintaining blood volume by RBC packs: use stored blood less than 14 days old
- haemostatic resuscitation by administering a 1:1:1 ratio (equal parts PRBCs, FFP and platelets); this has replaced maintaining haemostasis based on the coagulation screen (platelet count, thrombin time and prothrombin time)
- maintaining oxygen-carrying capacity: ensure PCV >20 or Hb >80 g/L (repeat haematological testing)
- keeping the patient warm: heating coils on the blood circuit, heated blanket, etc.
- correcting or avoiding metabolic complications
- maintaining a normal plasma protein concentration: avoid excessive crystalloid infusions and monitor the plasma albumin level.

DIC is presumed if the thrombin time is more than double the control value. In these cases, 10 units of cryoprecipitate are administered in addition to FFP to correct the deficiency of clotting factors (V, VIII).

Monitoring of the hypovolaemic patient

The primary objectives of monitoring are to ensure that the CBV has been replaced and that tissue perfusion has been restored to normal. In addition, in the unstable patient monitoring provides early signs of either renewed bleeding or cardiac decompensation and thus the need for inotropic support. The extent of monitoring needed depends on the severity of the hypovolaemia, associated comorbid cardiorespiratory disease or trauma and cardiovascular stability of the patient.

Monitoring of the otherwise stable patient who recovers quickly with volume replacement includes:

- arterial blood pressure, core temperature and pulse rate
- central venous pressure (CVP): if values are equivocal, the effect of a fluid challenge on the CVP (100–200 mL over 2–3 minutes) will determine whether the patient is still hypovolaemic (CVP remains unchanged or may even drop as the vasoconstriction subsides) or is likely to be overloaded (sharp elevation in CVP)
- hourly urine output: an output >30 mL urine/h indicates adequate renal perfusion
- pulse oximetry: preferably one that also displays the pulse plethysmogram in addition to percentage saturation of the Hb.

More intensive monitoring is only required in cardiovascularly unstable patients, including those who sustain major trauma. This includes (in addition to the above):

- insertion of a radial artery cannula for continuous monitoring of the arterial pressure and to obtain samples for blood gas analysis
- core–peripheral temperature gradient: a useful, non-invasive indicator of peripheral perfusion
- insertion of a pulmonary artery flotation catheter (Swan–Ganz catheter): this allows monitoring of the right atrial pressure, pulmonary artery pressure and pulmonary capillary wedge pressure, measurement of the CO (by thermodilution) and sampling of the mixed venous blood for oxygen saturation (SvO_2). A number of important derived variables can be obtained from these measurements in conjunction with the results of blood gas analysis. These are pulmonary vascular resistance, systemic vascular resistance, oxygen extraction ratio and systemic oxygen consumption.

Gastrointestinal haemorrhage

It is customary to consider GI bleeding as occurring from either the upper or the lower GI tract. This classification, although in established usage, is not entirely satisfactory as it omits a group of disorders, albeit less common, that present with bleeding from lesions in the midgut (from the duodenojejunal junction to the proximal transverse colon). In the upper/lower GI classification, right colonic bleeding lesions are grouped with lower GI bleeding. The causes of GI bleeding by topographical site in the gut are outlined in Table 7.2.

Table 7.2 Causes of gastrointestinal bleeding by topographical site

Foregut	Midgut	Hindgut
Oesophagitis, oesophageal varices	Ulcers: usually drug induced Small bowel tumours	Colorectal tumours/polyps Inflammatory bowel disease
Erosive gastritis	Vascular anomalies: right colon and small bowel	Diverticular disease
Peptic ulcer: DU, GU	Hereditary telangiectasia	Angiodysplasia
Tumours: adenocarcinoma, smooth muscle, lymphoma	Peutz–Jeger polyps	Ischaemic colitis
Vascular anomalies	Jejunal diverticula	Trauma
Hereditary telangiectasia	Meckel's diverticulum: infants and children	Endometriosis
Anastomotic suture line: postoperative	Aortoenteric fistula: patients with aortic grafts	Anastomotic suture line: postoperative
Mallory–Weiss syndrome	Crohn disease	Portal hypertension
Trauma: including iatrogenic	Anastomotic suture line: postoperative	Haemorrhoids
Haemobilia	Right colon cancer/polyps	Anal fissure
Chronic pancreatitis	Portal hypertension: includes bleeding from stomal varices	Bleeding disorder*
Bleeding disorders	Aneurysms, sectorial portal hypertension	Parasitic infestations
	Bleeding disorder*	Endometriosis

DU, duodenal ulcer; GU, gastric ulcer.

*In at least 25% of patients bleeding occurs from a pre-existing lesion.

Irrespective of site, GI bleeding is best addressed from a clinical standpoint in accordance with presentation of the patient:

- chronic occult blood loss: the patient is unaware of the bleeding, presents with iron-deficiency anaemia and has a positive faecal occult blood
- overt minor episodes of blood loss that prompt the patient to seek medical advice from the general practitioner: common presentation of patients with haemorrhoids, rectal tumours and inflammatory bowel disease
- acute episode of GI bleeding that causes varying degrees of hypovolaemia, in some cases life-threatening
- recurrent obscure GI bleeding.

Chronic occult gastrointestinal bleeding

Presentation with anaemia is common in patients with gastric and especially right colon cancer. Occult bleeding forms the only proven basis of screening for colorectal cancer. Using the standard haemoccult test, which has a sensitivity for cancer of around 50%, it has been shown that screen-detected tumours have a much better prognosis than tumours that present with symptoms. More importantly, randomized population-based studies have shown categorically that groups offered faecal occult blood screening have a significantly reduced mortality for colorectal cancer.

Some patients present with dyspeptic symptoms and are found to be anaemic on examination, e.g. reflux oesophagitis, peptic ulceration. Other causes of occult bleeding are much less common and usually present diagnostic problems requiring special investigations (recurrent obscure GI bleeding).

Elective presentation with episodes of gastrointestinal bleeding

Nowadays, this presentation relates most commonly to patients with colorectal disease, e.g. polyps, cancers, inflammatory bowel disease and haemorrhoids. Both cancers and inflammatory bowel disease (ulcerative colitis, Crohn's colitis, indeterminate colitis, dysentery) are usually associated with alteration in bowel habit.

Acute upper gastrointestinal bleeding

Epidemiology

The overall incidence varies widely in Western countries (40–150/100 000), with regional differences within each country. Thus, within the UK, Aberdeen has an incidence of 116/100 000 whereas Oxford, at 47/100 000, pales by comparison. Irrespective of regional differences, the epidemiology of acute upper GI bleeding has changed during the past 40 years. The highest prevalence is nowadays encountered in the elderly. This is the main reason why mortality from acute upper GI bleeding has not declined significantly despite better and earlier diagnosis by endoscopy and advances in endoscopic control of bleeding and in blood transfusion practice. The fact is that elderly people do not tolerate severe hypovolaemia and are less likely to recover if they require operative intervention than young, fit patients. Age-specific data from the UK Office for Population Census Statistics for deaths from bleeding duodenal and gastric ulcers in England and Wales demonstrate the very significant effect of increasing age, with death rates rising 400-fold between the age ranges 0–49 years and 80+ years (Figure 7.1).

Causes of acute upper gastrointestinal bleeding

The causes of upper GI bleeding in descending order of frequency are given in Table 7.3. Duodenal and gastric ulcers account for the majority. Mortality is higher in patients with a bleeding gastric ulcer, again attributable to the older age group. In some 20% of patients, the diagnosis is not clear at presentation despite urgent upper GI endoscopy. This arises because (1) there is too much blood in the stomach to permit adequate inspection, (2) the lesion is missed (e.g. Mallory–Weiss

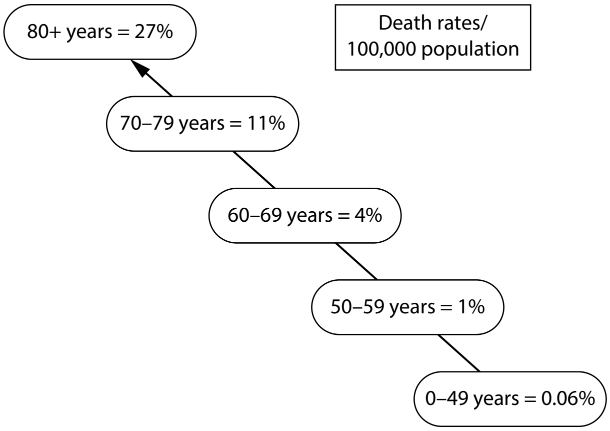

Figure 7.1 Deaths per 100 000 from bleeding duodenal and gastric ulcer in England and Wales in various age groups. Note the 400-fold increase between the age ranges 0–49 years and 80+ years.

Table 7.3 Causes of acute upper gastrointestinal bleeding: percentage distribution by disease category (average figures for the UK)

Disease category	Percentage distribution
Duodenal ulcer	29
Gastric ulcer	22
Oesophagitis and ulcer	12.0
Acute gastric lesions	7.0
Mallory–Weiss	7.0
Oesophageal varices	5.0

tear or Dieulafoy submucosal aneurysm), (3) the lesion has healed or (4) the source of bleeding is outside the stomach and proximal duodenum (upper jejunal, haemobilia, etc.).

Bleeding due to aspirin and non-aspirin non-steroidal anti-inflammatory drugs

Much of the misinformation concerning aspirin and non-aspirin non-steroidal anti-inflammatory drugs (NSAIDs) has arisen because of the poor quality of the early reports, which relied on contrast radiology for diagnosis and lacked proper controls. *All of these drugs cause drug-induced peptic ulcers in the stomach and duodenum* more commonly than acute gastric erosions, which account for only a small percentage of diagnosed cases. Aspirin increases the risks for both gastric and duodenal ulcers by two to four times, and, according to the results of a study by Faulkner *et al.* (1988), one in every 10 ulcer bleeds in patients aged 60 years or over is induced by aspirin.

The non-aspirin NSAIDs (e.g. fenbufen, benoxaprofen, indometacin, piroxicam, ibuprofen) pose a particular problem because they carry a higher risk of peptic ulceration than aspirin, and are taken largely by elderly patients who may be at increased risk of ulcer complications and death. Calculations based on published series indicate that 20% of all bleeding ulcers in patients over 60 years are caused by non-aspirin NSAIDs. A case–control study reported in 1997 demonstrated that the situation had not changed a decade later. Emergency admissions were more likely to be NSAID users than controls (31% versus 16%) and had significantly higher blood transfusion requirement, although NSAID usage did not influence mortality. On the basis of these data, it has been estimated that there are 65 000 emergency upper GI hospital admissions (perforation, bleeding, acute pain) per annum in the UK and of these 12 000 are caused by NSAID use, with 2230 deaths. A further 300 attributable deaths occur in the community (patients not admitted to hospital).

Overall, 30% of ulcer bleeds in patients aged above 60 years are due to aspirin or non-aspirin NSAIDs.

Cyclo-oxygenase inhibitors

Many agents, e.g. sucralfate, high-dose H_2 blockers and, more recently, proton pump inhibitors, have been shown to be effective in reducing duodenal lesions caused by NSAIDs, but all have been less successful in preventing gastric mucosal damage. This approach, although in established practice, is not the answer to the epidemiological problem. During the past decade there has been considerable pharmacological research aimed at the development of NSAIDs that are free of significant GI toxicity and this led to the development and clinical use of inhibitors of the cyclo-oxygenase (COX) system. COX was thought to be a single enzyme, but the subsequent research confirmed that there are two isoforms of COX: COX1 and COX2. COX1 (also known as constitutive cyclo-oxygenase) is always present and is responsible for most of the physiological prostaglandin production involved in cytoprotection, especially of the gastric mucosa. In contrast, COX2 (inducible COX) is involved in the synthesis of prostaglandins that mediate the inflammatory response (including joint inflammation). Thus, specific inhibitors of COX2 suppress the inflammatory response, while preserving the cytoprotective function of COX1. The first COX2 inhibitor to be launched in Europe was meloxicam, and this was followed by several others over a period of 10 years. The outcome of the clinical introduction of these drugs has been disappointing because their potential to decrease adverse GI effects has been more than offset by an increase in cardiovascular events, such as myocardial infarction (MI), stroke and sudden cardiovascular death in patients on long-term treatment with COX2 inhibitors. This problem was initially raised by the VIGOR study. Although this trial was designed to compare gastric toxicity between rofecoxib (COX2 inhibitor) and naproxen it demonstrated an increased risk of confirmed MI with the use of rofecoxib compared with naproxen. This was confirmed by several other clinical trials and a meta-analysis of 23 placebo- and NSAID-controlled studies with rofecoxib (including 26 000 patients), which concluded that treatment with rofecoxib was associated with an increased risk of thrombotic cardiovascular events when compared with naproxen, but not when compared with other classic NSAIDs (ibuprofen, diclofenac and nabumetone). A Prescription Event Monitoring study in the UK reported that the risk of cardiovascular events was greater in patients taking celecoxib or rofecoxib than in those taking the less selective COX2 inhibitor meloxicam. The Adenomatous Polyp Prevention on Vioxx (APPROVe) study, which was designed to evaluate the efficacy of rofecoxib in preventing recurrence of colorectal polyps in patients with a history of colorectal adenomas, was stopped prematurely because of an increased relative risk for confirmed MI during treatment with rofecoxib compared with placebo. Rofecoxib was then withdrawn from the market.

Studies have since shown that some COX2 inhibitors may tip the balance in favour of prothrombotic eicosanoids (thromboxane A_2) and thus lead to increased cardiovascular thrombotic events. COX2 inhibitors have also been shown to increase blood pressure as a result of alterations in the renin–angiotensin pathway and sodium and water retention by the kidneys. Currently, the choice of COX2 selective inhibitors for a particular patient should be selective and accompanied by information to the patients on their potential risks. Furthermore, they should be prescribed for short courses only and in the lowest effective dose.

Clinical presentation of acute upper gastrointestinal bleeding

Most patients are admitted as emergencies with haematemesis, melaena or both. Severity is dictated by the presence and extent of hypovolaemia into:

- mild: no significant hypovolaemia, includes patients who are anaemic
- moderate: hypovolaemia that responds to volume replacement (crystalloids and blood) and, thereafter, the patient is stable
- severe: active continued major bleeding rendering resuscitation with transfused blood difficult or recurrent major bleeding after successful resuscitation from the initial bleed; these are the patients at risk and include patients with bleeding oesophageal varices. In elderly patients with atherosclerosis, the hypotension may precipitate MI or a cerebrovascular accident.

Although this classification is useful as it dictates management, the category can change after initial assessment from mild to severe. Thus, complacency must be avoided and repeat clinical observation monitoring is essential even in patients with mild upper GI haemorrhage. This situation is best exemplified by the patient who develops an aortoenteric fistula after aortic replacement by a prosthetic graft. The initial (secondary) bleeds may appear trivial, yet they are warning manifestations of an impending catastrophic haemorrhage that is often fatal.

Some insist on differentiating between recurrent and persistent bleeding. The former is defined as a second episode of haematemesis or melaena associated with evidence of hypovolaemia after the initial successful resuscitation and a period of haemodynamic stability. In patients with ulcers, the endoscopic stigmata associated with increased risk of recurrence are an active spurting vessel, a visible vessel (Figure 7.2) and an adherent clot. Persistent bleeding is diagnosed when the patient requires 8 units (>60 years) or 12 units (<60 years) or more over a 48 hour period to maintain the Hb at 10 g/dL. In practice, both require measures to control the bleeding and the important decision is whether these patients should be treated endoscopically or surgically.

In addition to the severity of the bleed, the patient must be examined for stigmata of chronic liver disease that may indicate variceal haemorrhage, although these patients could equally bleed from ulcers or portal hypertensive gastropathy (see Chapter 24). Also necessary is clinical examination of the cardiovascular and respiratory systems with appropriate investigations (chest radiograph and ECG). Significant cardiorespiratory disease is an important determinant of morbidity and mortality and influences the approach used to control bleeding.

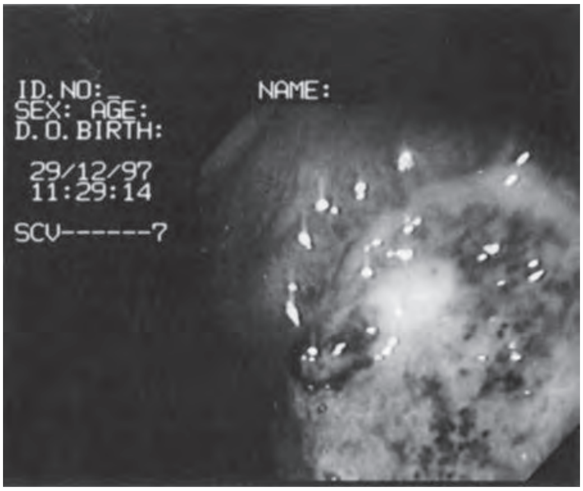

Figure 7.2 Endoscopic view of a visible vessel in a large gastric ulcer.

Management of acute upper gastrointestinal bleeding

The action plan is outlined in Figure 7.3. Diagnosis is based on upper GI endoscopy carried out within 24 hours of admission in haemodynamically stable patients and following resuscitation. The policy that all patients with acute upper GI haemorrhage should have a joint consultation by a surgeon and gastroenterologist soon after admission has much to commend it. Patients with severe continued bleeding require surgery concomitantly with volume replacement through two large-infusion cannulas.

All patients are kept on nil by mouth at least until endoscopy has been performed. The practice of insertion of a nasogastric tube is popular with surgeons but not gastroenterologists. If a tube is used, it should be of the Salem sump suction variety.

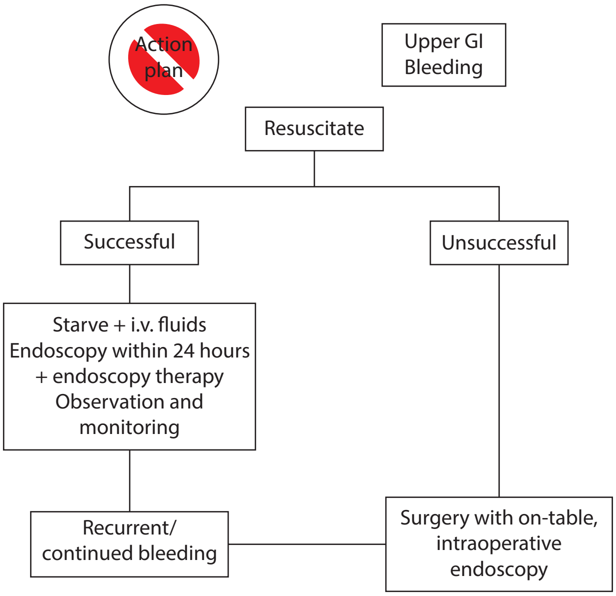

Figure 7.3 Action plan for patients with acute upper gastrointestinal bleeding.

Lavage through the tube with ice-cold saline to induce gastric mucosal vasoconstriction is practised in some North American centres but has never caught on in the UK. Without doubt, a nasogastric tube cannot be relied on to diagnose recurrent bleeding and certainly is no substitute for clinical observation and regular monitoring of pulse, blood pressure, CVP, pulse oximetry and urine output. Aside from this, nasogastric tubes may cause mucosal trauma. Thus, the case for nasogastric suction 'to keep the stomach empty', although established by surgical tradition, is by no means proven.

Pharmacological control of bleeding

The agents used are H_2 blockers, sucralfate, proton pump inhibitors, vasopressin (or analogues), somatostatin and tranexamic acid.

There has never been any material evidence that acid suppression with H_2 blockers imparts any benefit in patients with acute upper GI bleeding, although proton pump inhibitors may help. Likewise, there is no evidence that vasopressin and somatostatin are useful in ulcer bleeds. By contrast, tranexamic acid (oral or intravenous) has been confirmed by controlled, randomized studies to reduce the transfusion requirements, rebleeding rates (by 30%), need for surgical intervention (by 30–40%) and mortality (40%). The current recommended regimen consists of intravenous tranexamic acid for the first 3 days followed by oral administration for a further 3 days. To date, tranexamic acid is not widely used outside Scandinavia except as perioperative treatment for elective surgery in Jehovah's Witness patients.

Both vasopressin (and analogues) and somatostatin have been shown to be effective in the initial control of variceal bleeding (see Chapter 26).

Endoscopic treatment

Control of bleeding in the majority of patients (unless severe or catastrophic) is achieved with interventional flexible endoscopic techniques carried out by experts in a dedicated endoscopy suite with the necessary cardiovascular monitoring. Large diameter instrument channels (3.4 mm or greater) or twin-channel endoscopes (Figure 7.4) are used, as the standard endoscopes (instrument channel 2.8 mm) are very easily blocked by blood clots. The twin-channel endoscope has one channel for therapy and the other for suction. Its disadvantage lies in the large overall diameter of the instrument and consequent reduced flexibility. For this reason, some prefer the single large diameter instrument-channel endoscope and, if aspiration of luminal contents proves difficult when the therapeutic device is inserted, a nasogastric tube is passed alongside the endoscope for suction and irrigation.

The endoscopic techniques used for visible vessels and active bleeding can be classified as thermal, electrocoagulation, photocoagulation and injection therapy (Box 7.2). Sometimes, a combination of techniques, e.g. epinephrine (adrenaline) injection therapy with electrocoagulation or photocoagulation, is used and is reported to be beneficial by allowing a clearer target for the endoscopist and by reducing the heat-sink effect when thermal energy is applied.

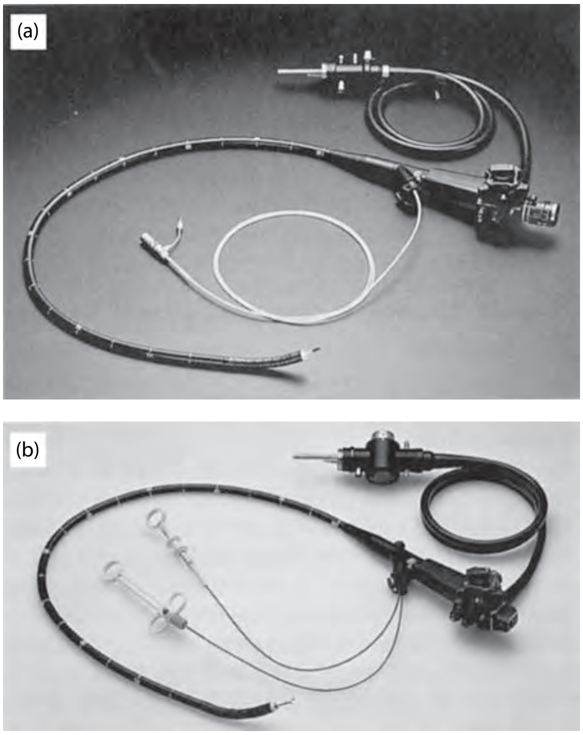

Figure 7.4 Large biopsy channel endoscopes: (a) single and (b) twin instrument channel. (Courtesy of Olympus, Japan.)

BOX 7.2 Techniques for endoscopic control of upper gastrointestinal bleeding

- Injection therapy: vasopressors, sclerosants, thrombin, mixtures
- Banding: alternative to injection sclerotherapy for oesophageal varices
- Endoscopic clipping
- High-frequency electrocoagulation: unipolar, bipolar, argon ion plasma coagulation
- Heater probe
- Photocoagulation: gas vapour lasers, diode array lasers:
  - Non-contact (laser beam)
  - Contact (with sapphire tip)

Vascular embolization

Vascular embolization is used for endoscopically or surgically inaccessible bleeding sites, e.g. liver in haemobilia, bleeding from pancreas (usually postpancreatic necrosis) and some lesions in the small intestine.

Indications for surgical treatment

With the expansion and increased efficacy of endoscopic techniques for the control of acute GI bleeding, fewer patients are treated surgically. Nonetheless, there are clear-cut clinical situations in which surgical treatment remains the patient's only hope of survival. The important determinant of survival in these seriously ill patients is a timely decision that surgical treatment is needed. Persistence with conservative management or endoscopic control until the patient's condition is seriously compromised by prolonged hypovolaemia inevitably results in demise of the patient, usually from multisystem organ failure.

The patients with acute upper GI bleeding who require surgical treatment are:

- Patients admitted with exsanguinating haemorrhage such that resuscitation by volume replacement cannot keep up with the losses. An on-table endoscopy after tracheal intubation and induction of anaesthesia is usually carried out and can be useful (e.g. detection of oesophageal varices), but often the endoscopy is unrewarding because of too much blood and clots in the stomach. Some would also include patients with an active arterial spurter in the surgical category requiring immediate surgery. Intraoperative enteroscopy (small bowel endoscopy by a long colonoscope introduced orally and guided by the surgeon through the duodenum and duodenojejunal flexure) may need to be done during the course of the operation, if the exact site of bleeding cannot be determined at laparotomy. This has replaced previous surgical manoeuvres, e.g. application of bowel clamps to different sections of the GI tract, to locate the bleeding source.
- Elderly patients (>60 years): the survival of these patients is compromised by surgical delay. Most surgeons would advise surgery if (1) more than 4 units of blood are necessary during the initial resuscitation of the hypovolaemia on admission, (2) the patient has one recurrence of bleeding after initial successful endoscopic control of bleeding and (3) there is persistent bleeding requiring 8 units of blood transfusion within 48 hours.
- Younger patients (<60 years): these usually tolerate bleeding better and therefore the threshold for surgical treatment is set higher: (1) patients requiring 8 or more units of blood during the initial resuscitation and (2) persistent bleeding requiring 12 units of blood over a 48 hour period.

Lower gastrointestinal bleeding

Epidemiology

Because rectal bleeding is common and as it rarely occasions admission to hospital, true rates are not easily ascertained. However, recent questionnaire studies indicate that about 80% of the population experience at least one episode of rectal bleeding at some stage during their lives, and, at any one point, about 7% of the population will have noticed rectal bleeding within the last 6 months. Clearly, this has very significant implications for the investigation and management of this condition.

Causes of rectal bleeding

It is useful to think of causes of rectal bleeding in terms of anatomical sites, i.e. anus, rectum, colon and upper GI tract. It is very important to remember that any lesion in the stomach, duodenum or small bowel that bleeds may present with overt rectal bleeding, if the rate of blood loss is fast enough. The causes of rectal bleeding are shown in Table 7.4.

Table 7.4 Causes of rectal bleeding by anatomical site

Anal causes	Rectal causes	Colonic causes	Upper GI causes
Haemorrhoids	Polyp	Polyp	Peptic ulceration
Fissure	Carcinoma	Carcinoma	Meckel's diverticulum (ectopic ulceration)
Perianal abscess/ fistula	Proctitis	Diverticular disease	Small bowel vascular lesion
Anal carcinoma	Rectal prolapse	Colitis (idiopathic, infective or ischaemic)	
		Angiodysplasia	

Of the common causes, haemorrhoids bleed because of trauma to the engorged vascular cushions; proctitis and colitis bleed from mucosal ulcerations; tumours bleed from dilated, fragile neoplastic, vessels; and diverticular disease from erosion of a vessel at the mouth of a diverticulum. Most overt rectal bleeding is minor in terms of amount, but, occasionally, it can be massive. When this occurs, it is usually caused by diverticular disease, angiodysplasia or an upper GI source, such as a small bowel vascular malformation or a duodenal ulcer.

Clinical presentation of lower gastrointestinal bleeding

Unlike upper GI bleeding, the vast majority of patients presenting to surgeons with rectal bleeding are seen at clinic, and only a minority are admitted as emergencies. In general, rectal bleeding can be categorized as:

- trivial
- troublesome
- suspicious
- massive.

Trivial

This type of bleeding is common and consists of occasional smears of blood seen on the toilet paper with no other symptoms. Often, there are no clinical findings, although the patient may have first- or second-degree haemorrhoids.

Troublesome

This is usually bright red, and, when caused by haemorrhoids, it typically occurs after defaecation and may drip into the toilet pan. This can be quite alarming, and, when profuse and frequent, it may lead to anaemia. Anal fissure also causes bright-red bleeding associated with defaecation, but, unlike haemorrhoids, it is usually accompanied by severe anal pain.

Suspicious

This type of bleeding should raise the clinical suspicion of colorectal cancer. Typically, rectal cancer causes quite fresh bleeding often associated with tenesmus. Left-sided colon cancer is more likely to present with dark blood mixed with or on the surface of the stool, and is frequently associated with change of bowel habit and/or lower abdominal pain. It should be noted that right-sided cancers tend not to cause overt bleeding or change of bowel habit, but rather present with iron-deficiency anaemia. This is because the faeces in the right side is still liquid, and the caecum and ascending colon are capacious and distensible. Thus, blood is well mixed with stool and obstructive symptoms are late to develop, except when the ileocaecal valve is involved.

Massive

In this case, the patient presents with profuse rectal bleeding and symptoms and signs of hypovolaemia. In many cases such bleeding stops spontaneously, but, if it does not, it constitutes a life-threatening surgical emergency. The most common cause of massive rectal bleeding is diverticular disease, but it may originate from vascular lesions of the colon or small bowel and from more proximal lesions, especially posterior duodenal ulcers. Blood acts as a cathartic, and profuse upper GI haemorrhage can pass rapidly through the small and large bowel and appear as fresh rectal bleeding. Traces of food, tablets, etc., in the blood suggest a source in the stomach or duodenum.

Management of lower gastrointestinal bleeding

Investigation

The investigation of lower GI bleeding depends on the clinical presentation (Figure 7.5). For the young patient with trivial rectal bleeding, a digital rectal examination is normally sufficient, whereas in older patients a rigid sigmoidoscopy should be carried out. With typical haemorrhoidal bleeding, a proctoscopy and rigid sigmoidoscopy should be carried out in all cases, and if no cause is found, or there is no response to treatment of haemorrhoids, a barium enema is ordered. If this is also negative, consideration should be given to flexible sigmoidoscopy and, finally, colonoscopy.

In the patient with bleeding that is suspicious of neoplasia, a thorough examination of the whole colon with barium enema and flexible sigmoidoscopy is mandatory, and, if no cause is found, with colonoscopy. Barium enema alone is not satisfactory, as the rectum is not well seen and a tortuous sigmoid colon is difficult to interpret radiologically. If polyps are seen on barium enema or sigmoidoscopy, then total colonoscopy should be arranged to visualize the whole colonic mucosa and perform polypectomy. It may be argued that colonoscopy should be carried out as a primary investigation instead of barium enema and sigmoidoscopy, but (1) it is more painful, (2) there is a higher risk of perforation and (3) in some countries the facilities and expertise for this policy are not widely available.

In massive rectal bleeding, the priority is resuscitation, but investigation must proceed promptly, usually during the resuscitation. The first step must be to exclude bleeding haemorrhoids by means of proctoscopy, and this should be followed by upper GI endoscopy. If these do not give the diagnosis and the patient remains unstable, most authorities recommend urgent mesenteric angiography, since if the bleeding is brisk enough (>0.5 mL/min) this will locate the bleeding point precisely. There is a school that favours acute colonoscopy with or without colonic lavage through a nasogastric tube, but this has been found to be impractical, and it cannot provide any degree of localization of small bowel lesions. For bleeding which is intermittent and does not show up on angiography, radionuclide-labelled red cell scanning may be used. Here, the patient's own red cells are labelled with ^{51}Cr and reinjected so that a gamma camera can be used to localize pooling of blood in the intestine. This, however, is of very limited practical value as it is necessary to carry out very frequent scans over a prolonged period.

Treatment

Medical

The only situation in which colonic bleeding can be treated effectively with drugs is an acute exacerbation of inflammatory bowel disease, the mainstay of therapy being high-dose steroids.

Endoscopic

Endoscopic treatment is used in the management of bleeding haemorrhoids in the form of sclerosant injection or banding, but it has no place in the treatment of acute colonic bleeding. There have been occasional case reports of injection therapy for bleeding diverticular disease using a colonoscope, and angiodysplasia can be treated by electrocoagulation and photocoagulation, but not usually in the acute bleeding phase.

Radiological

As with upper GI lesions, colonic bleeding can be treated by means of radiological embolization. However, more than with the small bowel, this is associated with a risk of necrosis and perforation of the bowel wall.

Surgical

The elective surgical treatment of haemorrhoids, anal fissure and colorectal causes of bleeding, such as large bowel cancer, is covered in Chapters 30 and 31. In the patient with massive bleeding from the colon or small bowel, appropriate surgical resection after attempts at preoperative localization is required. If the source is in the small bowel, it is helpful if the radiologist can leave a superselective catheter close to the bleeding site so that the surgeon can inject methylene blue down the catheter at the time of laparotomy to highlight the segment of bowel to be removed.

Occasionally, it is necessary to proceed to laparotomy without preoperative angiography, and in this case it is wise to perform intraoperative colonoscopy with on-table antegrade colonic lavage to try to localize the bleeding lesion. If this is impossible or unsuccessful, and blood appears to be confined to the colon, then colectomy and ileostomy, preserving the rectal stump for later reanastomosis, is the safest option.

Recurrent obscure gastrointestinal bleeding

This applies to patients who experience recurrent episodes of GI bleeding (both acute and chronic) in whom no identifiable cause can be established despite full routine, often repeat, investigations. Although fortunately rare, these patients often present a management problem. The presentation may be with:

- recurrent melaena
- fresh rectal bleeding
- anaemia
- haematemesis (rare).

In the majority of these patients, the source of the recurrent blood loss is in the midgut, i.e. small bowel below the duodenojejunal junction and the proximal colon. However, some are caused by missed lesions in the foregut. This is exemplified by the Dieulafoy lesion, which is a submucosal gastric microaneurysm or unusually large artery that runs in close contact with the mucosa. In more than 80% of patients, the lesion is situated within 6.0 cm of the gastro-oesophageal junction, where it is easily missed. Haemobilia is another (albeit rare) cause of obscure recurrent GI bleeding.

Within the small bowel, the most common cause is small bowel ulceration (drug induced or associated with systemic disease, e.g. systemic lupus erythematosus, polyarthritis nodosa,

If total colonoscopy is intended but is unsuccessful, completion barium enema must be arranged.

Figure 7.5 Investigation of lower gastrointestinal bleeding.

rheumatoid arthritis, Henoch–Schönlein purpura). Small bowel tumours account for only 2–3% of cases and the lesion is then most commonly an adenocarcinoma. Peutz–Jeghers jejunal polyps and other syndromes associated with GI polyposis (see Chapter 29) often present with recurrent occult bleeding. Vascular anomalies of the small bowel can be a cause of recurrent obscure GI bleeding and are being increasingly recognized with the advent of small bowel capsule endoscopy. Telangiectasia, either as part of the hereditary condition (Rendu–Weber–Osler syndrome) or as isolated flat intramucosal telangiectasia or haemangioma, can likewise cause GI bleeding from the small bowel. One of the most common causes of acute bleeding in children is Meckel's diverticulum from ulceration of ectopic gastric mucosa. Jejunal diverticulosis can bleed and usually presents with recurrent episodes of melaena. Other causes include radiation enteritis, aortoenteric fistula (grafted patients) and endometriosis in females.

However, the most common source of recurrent obscure GI bleeding is the proximal colon and the most frequent lesion responsible is angiodysplasia. Tiny areas of angiodysplasia (about 2 mm) are easy to miss, particularly in the caecum (see Chapter 30).

Management

The primary objective is to establish the cause of the bleeding. A vast array of specialized investigations is used to elucidate the cause in the elective situation. It is important that a sensible sequence is adopted to minimize patient inconvenience and to reduce costs. In the acute bleeding situation, the investigative options of practical benefit are fewer and essentially consist of emergency angiography and on-table enteroscopy and colonoscopy (Figure 7.6).

Angiography (aortic, selective visceral arteries) plays a crucial role in these patients and is the most effective investigation. Its exact role depends on the clinical situation. In patients with active bleeding, contrast angiography seeks to demonstrate the bleeding site by documenting extravasation of contrast, whereas in the elective situation (chronic bleeding) the aim is to detect abnormal vascular patterns (Figure 7.7). The success rates of angiography in acute haemorrhage depend on bleeding rate. Thus, if aortic injection is used, the lesion has to be bleeding at the rate of at least 5.0 mL/min. With selective visceral artery cannulation, however, localization can be obtained with lower bleeding rates (0.5–2.0 mL/min).

Barium meal and follow-through is virtually useless in these patients. Much higher yields are obtained, especially for

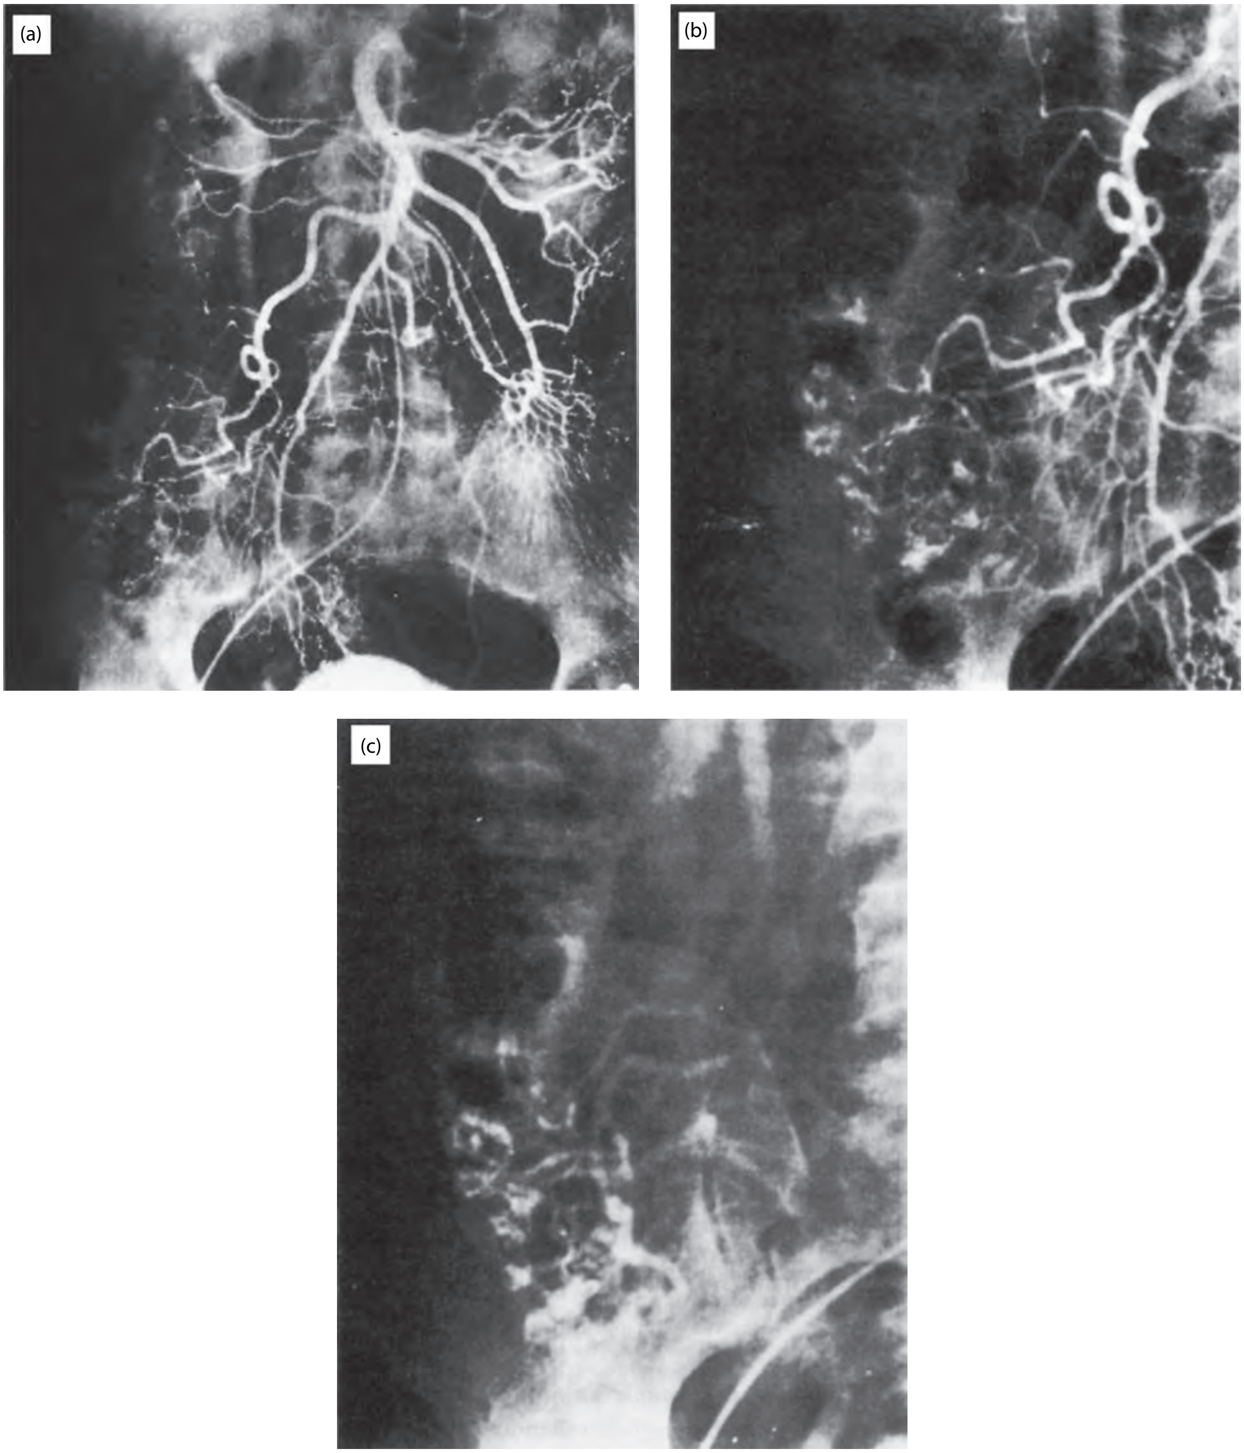

Figure 7.7 Selective superior mesenteric angiogram in chronic bleeding demonstrating vascular abnormality in the caecum. The angiographic features are: (a) prominent and early filling of clusters of irregularly dilated small vessels with the caecal wall supplied by the ileocolic artery; (b) persistence of contrast within the clusters of small blood vessels; and (c) early and profuse filling of enlarged draining veins from the affected area.

the detection of small bowel tumours, ulcers and strictures, by enteroclysis (small bowel enema) with compression fluororadiology. Radionuclide scanning is used for three purposes: (1) to quantify blood loss in the chronic situation (5 day test using ^{51}Cr-labelled autologous RBCs); (2) for localizing blood loss by technetium-99m (^{99m}Tc)-sulphocolloid in the first instance, followed by labelled autologous RBCs; and (3) for the diagnosis of bleeding Meckel's diverticulum, when ^{99m}Tc-pertechnetate is used to display the ectopic gastric mucosa (not the ulcer or the bleeding point itself). Endoscopic retrograde cholangiopancreatography is useful in cases of suspected haemobilia or if the bleeding is likely to be of pancreatic origin.

Ultimately, the treatment depends on the nature of the lesion, its surgical accessibility, the severity of the clinical situation and the condition of the patient. In general, all patients with life-threatening bleeding from the gut itself require laparotomy. Those in whom bleeding is from liver and pancreas are best managed with radiological embolization in the first instance.

Retroperitoneal haemorrhage

Retroperitoneal haemorrhage is always caused by a serious condition and, aside from hypovolaemia, which may be extreme and life threatening, it is also often accompanied by adynamic ileus. Retroperitoneal haematoma/bleeding is caused by:

- contained rupture of an abdominal aortic aneurysm (commonest)
- severe haemorrhagic pancreatitis
- severe pancreaticoduodenal trauma
- warfarin therapy
- haemophilia and other coagulopathies
- renal (renal cell carcinoma and angiomyolipoma) and adrenal tumours (rare)
- polyarteritis nodosa (rare)
- nephritis (rare)
- segmental arterial mediolysis (very rare)
- primary amyloidosis (very rare).

Common clinical settings include patients with leaking abdominal aneurysms and victims of retroperitoneal trauma involving pancreas, duodenum and kidney (see Chapter 14). Retroperitoneal bleeding, which is particularly difficult to control, is encountered in some patients as a complication of severe necrotizing pancreatitis see Chapter 27). This combination is often fatal. An iatrogenic cause of retroperitoneal bleeding that has been responsible for some fatalities is aortoiliac trauma inflicted most commonly by the Veress needle during the induction of a closed pneumoperitoneum, although some of these injuries have been caused by the first (optical) trocar/cannula. These mishaps are entirely preventable by adoption of the proper technique, use of open laparoscopy or visually guided insertion systems.

Treatment

Patients with retroperitoneal haematoma/bleeding are managed in high-dependency/intensive care units because of their unstable condition and need for monitoring and resuscitation, including blood transfusions. Patients with coagulopathy or inherited clotting disorders require appropriate clotting factor replacement therapy and, in these patients, conservative treatment is indicated. Patients bleeding as a result of warfarin therapy are treated with an infusion of prothrombin complex concentrates which contain all the deficient factors (II, VII, IX and X). Emergency surgery is required for ruptured aortic aneurysm and ruptured retroperitoneal tumours.

Spontaneous rupture of the kidney affects either the collecting system or parenchyma and, in most cases, the non-traumatic rupture is associated with underlying renal disease. Rupture of the collecting system can be managed satisfactorily by drainage (percutaneous nephrostomy or ureteral tube drainage). Rupture of the renal parenchyma accompanied by severe renal haemorrhage requires emergency surgical exploration of the kidney and nephrectomy.

Transfusion of blood and plasma products

Rather than the administration of whole blood, modern blood transfusion is based on the selective intravenous infusion of the required component of the blood that is necessary in a particular patient. This practice ensures safe, economic use and increases the therapeutic scope. Thus, a single donation may be used for treating a variety of disorders.

Essentials of safe blood transfusion practice

Modern safe blood transfusion practice is based on:

- careful selection and testing of donors
- quality assurance testing of blood and blood products prepared and issued by the transfusion centres
- blood grouping, antibody screening and cross-matching
- standardized blood-ordering policies
- strict guidelines for administration and monitoring of patients receiving blood products by the clinicians
- local and central reporting of adverse effects when encountered.

Two blood samples (clotted and anticoagulated in EDTA) are sent with the completed request form to the blood transfusion department once the decision is taken that the patient needs a transfusion. The patient's red cells are grouped for ABO and rhesus (Rh) (D). The antibody screen is carried out on all serum samples to detect the presence in the recipient of any clinically important antibody that would haemolyse the transfused cells. Cross-matching entails testing the red cells from the donor units against the patient's serum. This constitutes the final safeguard against incompatibility. In some countries cross-matching is considered unnecessary if detailed blood group and screening have been performed, but within the UK it remains, by general consensus, standard practice.

The final step in the safe administration of blood is the check by two people that the information on the transfusion request form, the labels on the unit of blood and the patient identification (from case notes and wrist band) all agree. Regrettably, this remains the weakest link in the safety chain and most deaths from blood transfusion in the UK are tragic consequences of errors in identification.

General and medicolegal aspects

Different regulations concerning the transfusion of blood and plasma products apply within various countries. In the UK, plasma products fall within the scope of the UK Medicines Act (1968) and the associated European Community Legislation. All such plasma products have thus to be licensed and thereafter are considered as prescription-only medicines (POM; i.e. can only be prescribed by a fully qualified medical practitioner); each must be accompanied by an approved summary of product characteristics.

In contrast, whole blood and blood components are exempt from the UK Medicines Act (1968) and are therefore supplied by the regional blood transfusion centres as unlicensed products. However, blood components are considered in clinical practice as POM. It is a medicolegal requirement within the UK that details of any blood component infusion are fully documented in the patient's case notes: *indication, date/time of issue, donation number, ordering physician, duration of infusion, who gave the infusion, who checked it prior to administration and time the infusion was commenced. The written procedures for infusing blood and blood components are issued by the hospital blood transfusion department. The hospital management is responsible for ensuring that the written procedures are updated and made available to all staff (medical and nursing) who may have to administer transfusions.*

In the UK, all blood and plasma products are derived from voluntary, non-remunerated donors aged 18–65 years. In accordance with the policy of the Department of Health, donors are carefully selected and all donations are tested for known markers of disease. Currently, these are syphilis, human immunodeficiency virus (HIV) 1, HIV-2, hepatitis B and hepatitis C. Sterilization of other transmitting agents not detected by donor screening is not guaranteed. Thus, the risk of disease transmission, although very low, cannot be ignored. Pertinent examples of this include the transmission of acquired immunodeficiency syndrome (AIDS) to haemophilic patients and their partners in the recent past. The current concern is with the recently identified hepatitis G virus.

Plasma products

Plasma products are produced at protein fractionation centres from pools derived in the UK from voluntary, non-remunerated donors. These products (Table 7.5) do not require ABO compatibility with the patients and are used in clinical practice for the following purposes:

- As coagulation factors for specific deficiency states, either to stop spontaneous bleeding or to cover an operation/intervention in a patient with such a deficiency, e.g. haemophilia A (congenital factor VIII deficiency).
- To provide passive immunity to non-immunized individuals exposed to a serious infective agent (viral or bacterial), e.g. human tetanus immunoglobulin.
- In the prophylaxis of haemolytic disease of the newborn due to Rh incompatibility and sensitization of Rh (D)-negative women. Human anti-D immunoglobulin is also used in the management of Rh (D)-incompatible blood transfusion following the accidental transfusion of Rh (D)-negative individuals with Rh (D)-positive blood.
- In the management of autoimmune thrombocytopenic purpura (AITP). High-dose intravenous human immunoglobulin can produce remissions of varying duration. IgG is also used to treat acute haemorrhage from this condition when conventional therapies have failed and to cover patients with idiopathic thrombocytopenic purpura requiring surgery including elective splenectomy.
- As volume replacement fluid (ALBA 4.5%), as a plasma volume expander and in short-term management of hypoproteinaemic patients (human albumin solution 20%).

Intravascular (serum) albumin accounts for 40–45% of the total body albumin. Under normal conditions, albumin has a half-life of 15–20 days. The normal level is achieved by a balance between synthesis (in the liver) and breakdown (predominantly intracellularly by lysosomal proteases) through a feedback regulation controlled by the oncotic pressure of the hepatic extravascular space. Serum albumin is a key protein in circulatory and transport physiology. In the first instance, it accounts for more than 50% of the total plasma proteins and, for this reason, it is the principal agent responsible for the plasma oncotic pressure essential for the exchange of fluid (and thus oxygen, nutrients and waste products) between the microcirculation and the interstitial fluid space. Albumin, through its oncotic action, ensures the re-entry of fluid from the interstitial space to the capillary bed and, in this fashion, it stabilizes the CBV. Hypoalbuminaemia from any cause thus results in fluid sequestration in the interstitial space and serous cavities (oedema/ascites) with contraction of the effective circulatory blood volume. Serum albumin also provides an important transport service as a carrier for hormones, enzymes, drugs, metabolites (e.g. bilirubin) and toxins. The combination with albumin renders all of these substances water soluble and inactive.

ALBA 4.5% is iso-osmolar and is supplied in bottles of 400 mL containing approximately 45 g/L plasma protein, of which >95% is albumin. It is indicated in acute blood volume loss (instead of or with crystalloids), and in the treatment of burns after the first 24 hours (when crystalloids are preferred) to maintain a plasma albumin close to 25 g/L. This is necessary to ensure a colloid osmotic pressure above 20 mmHg (2.7 kPa) and thus the return of fluid to the circulation at the venous end of the capillaries. ALBA 4.5% is also useful in surgical practice in conditions characterized by severe acute albumin losses, e.g. acute pancreatitis and small bowel infarction. Rapid infusion of ALBA 4.5% can cause vascular overload with pulmonary oedema in patients with diminished cardiorespiratory reserve or hypertension. Thus, administration in these patients should be cautious and always monitored by a CVP line. Less than 10% of the infused albumin leaves the intravascular compartment during the first 2 hours after infusion. Thus, the CBV will increase from 1 to 3 hours after administration and CVP monitoring in these patients should be continued for at least 4 hours after the albumin infusion has been stopped.

Human albumin solution 20% is an aqueous solution containing 20% w/v protein in 100 mL with albumin forming 95% or more of the protein. The solution is hyperosmolar, i.e. it acts as oncotic agent, drawing fluid from the extravascular compartment to the intravascular compartment. Hence, there is a real danger of overload in susceptible patients, e.g. patients with diminished cardiorespiratory reserve and hypertensive patients. For this reason, human albumin solution 20% is usually contraindicated in patients with severe anaemia or cardiac failure. Human albumin solution 20% is indicated in the short-term management of severely hypoproteinaemic patients with diffuse oedema that is resistant to diuretic therapy (e.g. nephrotic syndrome) and in the initial management of patients with leakage due to damage of major lymph trunks in

Table 7.5 Plasma products used in clinical practice

Plasma product	Indication	Route of administration	Shelf life	Storage
Coagulation factors				
Factor VIII concentrate	Haemophilia A	i.v.	24 months	Light-protected storage at +2–8°C
Factor IX concentrate	Single/multiple congenital deficiency of factor IX, II or X Single/multiple acquired prothrombin complex factor deficiency (including reversal of Coumarin anticoagulant therapy)	i.v.	36 months	Light-protected storage at +2–8°C
Immunoglobulin products				
Human immunoglobulin	X-linked primary hypogammaglobulinaemia Late-onset hypogammaglobulinaemia Hypogammaglobulinaemia secondary to haematological malignancies Children with symptomatic HIV infection who have recurrent bacterial infections Idiopathic thrombocytopenic purpura Kawasaki disease In allogeneic bone marrow transplant to prevent infections and graft-versus-host disease	i.v.	Lyophilized product = 24 months. Used immediately after reconstitution	Light-protected temperature not exceeding 25°C
Human normal immunoglobulin (250 mg protein per vial, 90%+ = IgG)	Hepatitis A prophylaxis Prevention of measles in immunocompromised patients Replacement therapy in primary immunodeficiency syndromes	Deep i.m.	36 months	Light-protected storage at +2–8°C
Human hepatitis B immunoglobulin (1000 IU per vial)	Prophylaxis of hepatitis B after parenteral exposure or contamination of a wound/conjunctiva by blood/secretions containing HBsAg, recent sexual contacts of diagnosed hepatitis B cases Newborn babies whose mother has had acute hepatitis B in the last trimester or is a known HBsAg-positive carrier	Deep i.m.	36 months	Light-protected storage at +2–8°C
Human tetanus immunoglobulin (250 IU per vial)	Used in conjunction with tetanus toxoid in patients with 'at-risk wounds' of tetanus and who have not been adequately immunized against tetanus or whose immune status is in doubt	Deep i.m.	36 months	Light-protected storage at +2–8°C
Human anti-D immunoglobulin (various strengths)	Rh (D) sensitization in Rh (D)-negative mothers and Rh (D)-incompatible blood transfusion	Deep i.m.	24 months	Light-protected storage at +2–8°C
Human varicella zoster immunoglobulin (250 mg HVZ immunoglobulin per vial)	Prophylaxis of immune compromised individuals/patients exposed to varicella or zoster	Deep i.m.	36 months	Light-protected storage at +2–8°C
Human rabies immunoglobulin (800 IU per vial)	Used in conjunction with rabies vaccine in individuals exposed to rabies and who are not considered adequately immunized	Deep i.m.		Light-protected storage at +2–8°C
Albumin products				
Human albumin solution 4.5%	Acute blood volume loss. Severe burns after first 24 hours. Therapeutic plasmapheresis Severe acute albumin losses	i.v.	36 months	Light-protected storage below 25°C
Human albumin solution (20%)	Short-term management of hypoproteinaemic patients Chronic liver disease with refractory ascites and peripheral oedema Severe burns requiring plasma volume expansion	i.v.	18 months	Light-protected storage below 25°C

HBsAg, hepatitis B surface antigen; HVZ, human varicella virus; Rh, rhesus.

the chest or peritoneal cavities (chylous ascites, chylothorax) following surgical interventions (usually radical resections for oesophageal and gastric cancer). In this instance, human albumin solution 20% is administered to maintain the serum albumin above 25 g/L until surgical treatment designed to secure the intrathoracic or intra-abdominal lymph leak is carried out as a matter of some urgency because of the daily profound losses. Surgical control is much preferable to peritoneovenous shunting for chylous ascites, as it constitutes definitive therapy and prevents the risks of peritoneovenous shunting, which include episodes of DIC and infection. Human albumin solution 20% is also used in patients with hypoproteinaemia associated with refractory ascites and peripheral oedema due to chronic liver disease, and in the clinical management of patients with severe burns in whom plasma volume expansion is required.

Other plasma products

Other plasma products are listed in Box 7.3. The important ones, from a surgical standpoint, are fibrin glue, intravenous human immunoglobulin, tetanus immunoglobulin and intravenous hepatitis B immunoglobulin.

Human fibrin glue

There are a number of proprietary preparations of this glue based on a similar formulation (Tisseal-Immuno; Fibrin Sealant Kit-SNBT). The two solutions (thrombin and fibrinogen) are derived from pooled non-remunerated donations and heat inactivated against all known human viruses. The two solutions have to be reconstituted immediately prior to use and special delivery sets for both open and laparoscopic surgery are needed for application to the bleeding surface or suture line. Essentially, the delivery sets consist of twin syringes (one for each of the two solutions) with a Y-connection to a twin barrel segment, with the two barrels joining at the end to allow mixing of the two solutions and thus the polymerization of fibrinogen to fibrin (see also Chapter 2).

Human immunoglobulin for intravenous use

Human immunoglobulin for intravenous use (IVIgG) can be used in the following:

- patients with AITP to cover surgery and childbirth
- antibody-deficient states, e.g. primary and secondary hypogammaglobulinaemia (due to myeloma and chronic lymphatic leukaemia and children with AIDS) to prevent recurrent bacterial infections.

IVIgG is not a substitute for orthodox management of AITP including steroids and splenectomy (when steroid therapy fails). It is used in the management of thrombocytopenic bleeding in which high-dose therapy (1–2 g/kg over 1–5 days) can produce a significant rise in the platelet count, but this is of a variable duration. When a patient with AITP requires surgery (including splenectomy), IVIgG is administered preoperatively if the platelet count is very low. High-dose IVIgG can cause renal failure, especially in the elderly. Thus, it is administered cautiously and only when strictly necessary in the elderly and in patients with pre-existing renal disease.

Blood components

Whole blood and blood components are prepared in regional transfusion centres from individual donations or pools of a small number of donations. The ABO and Rh (D) of each unit of whole blood and cell preparations are stated on the pack label of each unit and these products can only be administered after cross-matching to ensure compatibility with the patient's serum, except in dire life-threatening emergencies, when non-cross-matched group O Rh (D)-negative blood may be given. The ABO group of platelet concentrates is usually compatible with that of the patient but, although highly desirable, this is not essential. Platelets from Rh (D)-positive donors may produce anti-Rh (D) antibodies when transfused to Rh (D)-negative patients (important in a female of childbearing age). The ABO group of FFP should be compatible with that of the patient. The ABO compatibility of cryoprecipitate with that of the patient is desirable, although not essential.

BOX 7.3 Other plasma products

- High-purity factor IX concentrate
- Human immunoglobulin (for intravenous use) 10 g dose size
- Fibrin glues
- Human fibrinogen concentrate
- Human thrombin
- Intravenous tetanus immunoglobulin
- Intravenous cytomegalovirus immunoglobulin
- Intravenous hepatitis B immunoglobulin

Ordering of blood

Emergency transfusion

The decision to administer an emergency blood transfusion (i.e. administering blood that has not been fully cross-matched) is entirely the responsibility of the senior clinician concerned in the management of the patient. In the UK, NHS hospitals keep a small stock of emergency blood (O negative, Kell negative) in the blood bank refrigerator for this purpose. Each emergency unit has a blood bank form attached that should be completed as soon as possible and returned to the blood bank. When such units are used, the blood transfusion staff must be informed immediately. Extra care should be taken to monitor the patient closely for at least the first 5–10 minutes of infusion to detect any evidence of acute reactions. Unused units should be returned to the blood bank refrigerator within 20 minutes of collection if not required. If blood is transferred with a patient to another unit the blood transfusion department should be informed so that a transfer docket can be prepared for the receiving hospital.

Elective situation

Unnecessary ordering of cross-matched blood constitutes bad practice and is wasteful of a limited resource. Many operations do not usually require a perioperative blood transfusion, others may do and some incur a need for red cells as a matter of routine. Nowadays, blood for elective surgery is ordered in accordance with the 'blood tariff' policy. This is based on the average requirement of a particular operation (Table 7.6).

Type and screen (group and hold, group and save) is all that is required for all operations that do not usually require blood. The patient's ABO and Rh (D) type are determined and the serum is screened for IgG antibodies against red cells. The patient's serum is kept in the blood transfusion laboratory for 7 days. Should blood be required, cross-matched red cell units can be available in 15 minutes.

Predeposit

The benefit of this approach (autologous as distinct from allogeneic transfusion) is the elimination of disease transmission and allergic and incompatible reactions (other than procedural errors). There are established UK guidelines for autologous blood transfusion. Patient selection includes establishing the fitness of

Table 7.6 Blood tariff for elective surgery

Operation	**Blood requirements**		
	Routine tariff group and screening(G + S) procedure, no units cross-matched	**Increased tariff considerations**	**Indication leading to increased tariff**

the patient for the procedure. Predeposit is arranged through the blood transfusion department and between 2 and 4 units can be harvested preoperatively. The blood is collected, labelled and stored as in allogeneic (donor) voluntary donations, and the autologous units ABO and Rh (D) are grouped and cross-matched with the patient's serum. Despite the initial enthusiasm, the experience with predeposit has been disappointing. It is more expensive that allogeneic blood transfusion. The blood is wasted if the patient does not need perioperative transfusion as it cannot be administered to other patients, and if the patient requires blood in excess of the predeposited units, all possible advantage is lost. Currently, autologous blood transfusion seems a sensible option in fit patients (aged 18–65 years, free from cardiovascular, cerebrovascular and respiratory disease, no sepsis, malignancy or haematological abnormality) requiring an operation that is very likely to require modest amounts of perioperative blood transfusion and who live near the hospital.

Controlled haemodilution

In this procedure, the patient is bled immediately before surgery (after induction of anaesthesia) down to a haematocrit of 25–30% with CVP monitoring while the blood volume is maintained by infusion of crystalloids. The collected autologous blood is transfused after the operation. Aside from reducing the need for donor blood, controlled haemodilution by preoperative isovolaemic bleeding has a number of advantages, which emanate from the reduction in the blood viscosity: increased capillary perfusion, and lower incidence of deep vein thrombosis and postoperative renal failure. Controlled haemodilution is used extensively in cardiothoracic surgery and for patients undergoing major orthopaedic operations. It is practised less frequently in general surgery. Hb-based blood substitutes are being used for controlled 'balanced' haemodilution (see Blood substitutes).

Intraoperative blood salvage

This includes automated blood salvage by the cell-saver equipment (Haemonetics) and more simple manual systems for storage and reinfusion of red cells, as exemplified by the Solcotrans autologous collection system. Both techniques are only applicable to clean operative sites without bacterial, bowel or tumour cell contamination. The Haemonetics cell-saver system is a completely automated device that aspirates, anticoagulates and filters the extravasated blood from the operative field. The red cells are then washed before being transfused in a PCV of 0.50. It is used extensively during liver transplantation and in Jehovah's Witness patients undergoing major surgery.

The manual techniques have limited capacity (a few units), such that their usefulness is suspect, and it has been argued that in many instances they are employed under circumstances in which blood transfusion was probably unnecessary.

Transfusion of fresh blood

The transfusion of fresh blood for bleeding disorders has been largely replaced by FFP and therapy with other blood components, depending on the nature of the deficiency as determined by the coagulation screen.

Whole blood

Whole blood has a haematocrit of 0.35–0.45. The cells are suspended in 300 mL of a 4:1 mixture of donor plasma and a nutrient citrate anticoagulant solution. With storage (maximum 35 days at 2–6°C), changes occur in both the composition of the supernatant solution and the haematocrit. Thus, at expiry the K^+ level averages 9.0 mmol (1.0 mmol for fresh blood), the lactate 10.0 mmol (1.0 mmol for fresh blood) and the hydrogen ion activity 55.0 nmol (20 nmol per unit of blood for fresh blood). Thus, with storage, whole blood becomes increasingly acidotic. The deterioration is much more rapid when whole blood is kept out of the refrigerator or blood transport box. If the unit of whole blood has been left out at room temperature for more than 30 minutes prior to commencement of infusion, the unit should be discarded. The transfusion of each unit of blood should be complete within 4 hours of spiking the pack. A blood warmer is used when large volumes of whole blood are transfused over a short time and when the patient's plasma contains cold-acting antibodies. Whole blood is not suitable for the correction of symptomatic or critical anaemia.

Red cell preparations

As with whole blood, each unit of red cells is obtained from a single donor and consists of RBCs suspended in a total volume of 300 mL. There are minor differences in the red cell preparations from various regional transfusion centres. The Scottish National Blood Transfusion Service supplies two preparations: red cells and red cells in additive solution. A unit of red cells has a haematocrit of 0.65–0.75 with 80 mL of a 4:1 mixture of donor plasma and a nutrient citrate anticoagulation solution. A unit of red cells in additive solution has a haematocrit of 0.55–0.65 with 100 mL of storage medium and only a small residue of anticoagulated plasma. Both preparations have a much lower Na^+ (15–20 mmol) and hydrogen ion activity (2–5 nmol) than whole blood. They are used primarily to increase tissue oxygenation after haemorrhage and in patients with anaemia. They are both stored at 2–6°C and their maximum shelf-life at this temperature is 35 days. The same precautions on safe usage apply as with transfusion of whole blood.

Platelets

Platelet preparations are available as concentrates from single or multiple donors, with each unit containing 55×10^9 platelets suspended in 50–69 mL of a 4:1 mixture of donor plasma and nutrient anticoagulant solution. They can also be prepared from a single donor by an apheresis procedure (platelet apheresis). Each unit of the latter contains at least 240×10^9 platelets suspended in 120–250 mL of a 4:1 mixture of donor plasma and a nutrient anticoagulant solution. Patients with platelet alloimmunization (usually because of previous sensitization) can only receive platelet apheresis units and these have to be human leucocyte antigen (HLA) compatible or be cross-matched and shown to be compatible with the patient's serum. Patients with profound cellular immunodeficiency or those receiving transfusions from related donors should be transfused with irradiated platelets.

Infusion of platelets is indicated (usually prophylactically) in thrombocytopenia or in the presence of a functional abnormality of the platelets (e.g. Glanzman disease) when these are associated with bleeding problems. In surgical practice, platelet cover is needed when the count falls below 50 000. In AITP, human IgG is administered to raise the platelet count before platelet transfusion is considered. The indications for platelet transfusion are summarized in Box 7.4.

The development of antibodies to HLA class I antigens occurs in approximately 50% of patients who receive intensive blood product support. These antibodies cause febrile reactions, reduce successful take of a bone marrow transplant in patients with aplastic anaemia, and can also lead to platelet refractoriness. This is diagnosed if the patient's platelet count fails to rise by at least 10×10^9 on the day after a platelet transfusion. Platelet

BOX 7.4 Indications for platelet transfusion

- Surgical
  - Bleeding and thrombocytopenia
  - Cover for operative interventions: platelet count: <50 000, platelet dysfunction
  - Acute DIC (with FFP)
  - Massive blood transfusion
  - Postcardiac bypass thrombocytopenia
- Medical
  - Marrow-suppressed patients (intensive care)
  - Aplastic/hypoplastic anaemia
  - Disorders of platelet function: Glanzmann disease, Bernard–Soulier syndrome, platelet storage pool deficiency

refractoriness due to alloimmunization can be prevented to some extent by leucocyte-depleted platelet transfusion (by either plateletpheresis or the use of filters to remove the leucocytes).

Fresh frozen plasma

Each unit is obtained from a single donation and consists of 200–300 mL of plasma with 40–60 mL of citrate anticoagulant nutrient mixture. The plasma proteins in FFP are in similar concentrations to those in normal plasma. FFP is stored at –30°C and with this frozen storage has a shelf-life of 12 months. It is thawed rapidly at 37°C immediately before use and infused intravenously through a standard blood component transfusion set containing an on-line filter. The ABO group of the FFP must be compatible with that of the recipient. The infusion of 1 unit of FFP should be completed within 4 hours of thawing.

FFP is used in the following clinical situations:

- to correct isolated plasma protein deficiencies, e.g. isolated deficiencies of factors II, V, VII, X, XI, XIII, pseudocholinesterase, antithrombin III and C1 esterase inhibitor
- to reverse oral anticoagulation with warfarin/coumarin compounds if prothrombin complex concentrate is not available; normally, reversal of anticoagulant is indicated in the presence of bleeding
- in patients with liver disease, major hepatic resections and severe liver injuries to provide haemostatic support and to cover operations and interventions
- in the treatment of patients with DIC to replace factors consumed by the pathological process
- in patients who develop a bleeding diathesis after large-volume blood transfusion; in this situation, however, platelet transfusion is more commonly needed first
- in the treatment of thrombotic thrombocytopenic purpura, in which FFP is usually combined with plasma exchange.

Cryoprecipitate

Cryoprecipitate is a concentrate of factor VIII, von Willebrand's factor and fibrinogen, and is obtained by freezing and thawing plasma. One unit of cryoprecipitate consists of 20 mL containing 150–300 mg of fibrinogen and 80–120 IU of factor VIII. It is stored at –30°C and at this temperature has a shelf-life of 12 months. It is thawed rapidly at 37°C immediately before use and infusion should be complete within 4 hours of thawing.

Cryoprecipitate is used for the following conditions:

- fibrinogen deficiency and dysfibrinogenaemia
- uraemic bleeding
- von Willebrand's disease.

Special blood components

These include irradiated components, frozen, thawed and washed red cells, components for neonatal use, leucocyte-depleted cellular components, CMV-negative cellular components, apheresis plasma and cryosupernatant. Washed red cells are used in patients who develop non-haemolytic transfusion reactions. Frozen, thawed and washed red cells are indicated in patients who have rare antibodies.

As infection with cytomegalovirus (CMV) can be lethal in patients following bone marrow transplantation, leucocyte-depleted components or CMV-negative cellular components are administered in these patients if they are CMV negative. CMV-negative cellular components are also administered in all patients with haematological malignancy until their CMV status is known. CMV-negative cellular components are also indicated in patients undergoing solid organ transplantation when both the donor and recipient are CMV negative.

Adverse effects of transfusion of blood and blood products

It is the recommended clinical practice that every patient is monitored closely during the first 15–30 minutes of the infusion of each unit of blood. This enables the early detection of the clinical manifestations of severe acute reaction due to incompatibility or bacterial infection, when the infusion is stopped and the necessary action taken (see below).

Within the UK, the Serious Hazards of Transfusion (SHOT) group set up a voluntary confidential reporting system for serious adverse effects excluding infectious complications in 1966. The objectives of this confidential reporting system are (1) to increase awareness of the serious adverse events, (2) to determine the factors which contribute to their occurrence (risk analysis) and (3) to issue reports based on the centralized database that recommend the necessary changes in practice designed to improve the safety of blood transfusion. The practice of SHOT is equivalent to that adopted by high-risk industries (e.g. aerospace) over many years to prevent accidents due to both malfunction and human error, thus achieving the ALARP (risk is As Low As is Reasonably Possible) endpoint. The medical co-ordinator of SHOT is Dr Elizabeth Love at the Manchester Blood Centre (http://www.shotuk.org/home/). The reporting service set up by SHOT is not designed to replace the advice and investigation of any adverse event by the local blood transfusion centre. Infectious complications must be reported to the local blood transfusion centre as soon as the diagnosis is suspected. Complications that develop in patients receiving fractionated plasma products should be reported to the Committee for Safety of Medicines using the existing yellow card system.

As the mechanisms involved in transfusion-related complications are varied, these are usually classified under separate aetiological categories. In addition, some of the adverse effects are immediate (acute), whereas others are late (Box 7.5).

Non-haemolytic febrile transfusion reactions

The routine establishment of quality control in the manufacture of both intravenous fluids and disposable giving sets has virtually eliminated pyrogenic reactions. Pyrexia following blood transfusion is nowadays the result of alloimmunization to leucocyte and platelet antigens in patients who have been immunized by previous blood transfusion or pregnancy (antibodies to class I HLA antibodies). The symptoms are rigors followed by fever, usually within 30–60 minutes after the start of the transfusion. The management includes cessation or slowing of the transfusion and the administration of an antipyretic such as paracetamol.

BOX 7.5 Complications of transfusion of blood and blood products

- Acute
  - Allergic
  - Anaphylaxis
  - Haemolytic
  - Metabolic
  - Transfusion-related acute lung injury (ARDS)
  - Circulatory overload
  - Non-haemolytic febrile transfusion reactions
  - Haemostatic: dilution of clotting factors and thrombocytopenia
  - Septic shock (bacterially infected units)
- Late
  - Delayed haemolytic transfusion reactions
  - Sensitization/alloimmunization
  - Haemolytic disease of the newborn
  - Immune suppression
  - Graft-versus-host disease
  - Transfusion iron overload (haemosiderosis)
- Disease transmission
  - Bacterial (brucellosis, syphilis, Chagas disease)
  - Helminthic (filariasis)
  - Protozoal (babesiosis, kala azar, malaria, trypanosomiasis, toxoplasmosis)
  - Rickettsial (relapsing fever, Rocky Mountain spotted fever)
  - Viral (human parvovirus B19, CMV, Epstein–Barr virus, HIV-1 and -2, human T-cell leukaemia virus (HTLV) I and -II, hepatitis A, B, G and yellow fever)

Patients who require repeated transfusions and who have experienced non-haemolytic febrile transfusion reactions are pretreated with paracetamol 1.0 g orally before the start of the transfusion, with a second dose 4 hours later. The patient is kept warm and the transfusion is administered slowly (4 hours for red cells and 2 hours for platelets). Leucocyte-depleted cell components (buffy coat-depleted red cells or filtered red cells; apheresis platelets) are given if the above measures fail.

Allergic reactions and anaphylaxis

The other non-haemolytic reactions include *allergic reactions* and *severe anaphylaxis*. The symptoms of allergic reactions are urticarial rash and itch within minutes of the start of the transfusion. Treatment is with antihistamines (chlorpheniramine 10 mg by slow intravenous or intramuscular injection) and reduction of the transfusion rate with observation of the patient. If symptoms do not progress over the next 30 minutes the transfusion is continued. Patients who had previously experienced allergic reactions to transfusion are pretreated with chlorpheniramine 8.0 mg orally 30 minutes before the transfusion.

Severe anaphylaxis is a rare (1:20 000 transfusions) but potentially fatal reaction. Occasionally, it is caused by antibodies to IgA in patients who have extremely low levels of this immunoglobulin in their plasma. Whatever the cause, anaphylaxis results in the release of vasoactive peptides and activation of complement with the development of profound hypotension, laryngeal oedema and/or bronchospasm and cutaneous flushing. Anaphylaxis is treated with immediate termination of the transfusion, intravenous crystalloids, maintenance of airway, oxygen, epinephrine, intravenous antihistamines and salbutamol. Epinephrine (0.5–1.0 mg) is given immediately by the intramuscular route and the dose repeated, if necessary, every 10 minutes, depending on the improvement in the blood pressure and pulse. Chlorpheniramine 10–20 mg is administered by slow intravenous injection after the epinephrine treatment and is continued for 24–48 hours. Salbutamol is administered by nebulizer. Because of its delayed action, hydrocortisone is of secondary value in this severe complication but its (controversial) use may prevent further deterioration. Severe anaphylaxis can only be predicted in patients with low serum IgA. Transfusion should be avoided, if at all possible, in these patients. If deemed essential they can only receive special products.

Acute haemolytic reactions

These are usually the result of ABO incompatibility resulting from human error at the bedside (blood given to the wrong patient) or in the laboratory (faulty cross-matching). The transfused cells react with the patient's own anti-A or anti-B antibodies or other alloantibodies to red cell antigens.

Incompatible blood transfusion is a serious complication and carries an average mortality of 3%, or higher if more than 200 mL of incompatible blood is administered. The reaction is usually most severe if group A red cells are administered to a group O patient. The syndrome is caused by the release of the polypeptide products of complement (C3a, C4a, C5a) in the plasma. These cause contraction of smooth muscle and degranulation of mast cells with release of vasoactive peptides (bradykinin and serotonin). Procoagulant substances are released from the stroma of the lysed red cells. These, together with antigen–antibody complexes, initiate DIC. The clinical features in the conscious patient include pain at the infusion site and along the vein, facial burning, chest and back pain, fever, rigors and vomiting. The patient becomes restless, breathless, flushed and hypotensive, and develops oozing from vascular access sites and wounds (DIC). The only manifestations of incompatible blood transfusion in unconscious or anaesthetized patients are sudden hypotension and bleeding due to DIC. The extensive intravascular haemolysis results in haemoglobinaemia and haemoglobinuria. Oliguria rapidly supervenes and progresses to ARF. The differential diagnosis is between incompatibility and the infusion of bacterially contaminated blood.

The management entails immediate recognition *with cessation of the transfusion and replacement of the giving set.* Adequate hydration is maintained by intravenous infusion of crystalloids (isotonic saline or Hartmann's solution). An attempt is made to force diuresis with intravenous large-dose furosemide (150 mg). If this fails, a 20% solution of mannitol (100 mL) is administered. If diuresis is obtained, a high urine output is maintained (100 mL/h) by large-volume crystalloid infusions. Often, however, these patients progress to ARF, necessitating haemodialysis. The other problems that require immediate support are bleeding from DIC (blood component therapy guided by clinical state and coagulation screen) and hyperkalaemia. Intravenous glucose–insulin (50 mL 50% glucose + 10 units of insulin) is administered if the serum K^+ rises above 6.0 mmol/L. This is followed by an intravenous infusion of 10% glucose containing 10 units of insulin over a period of 4 hours. *After the initial resuscitation is completed, the investigation of such an incident is essential and is outlined in Box 7.6.*

Acute haemolytic reactions giving a similar picture may arise from acute haemolysis caused by preformed antibodies in the patient's blood (anti-Rh (D), Rh (E), Rh (C) and Kell, etc.) as a result of alloimmunization to minor blood group antigens in the donated unit. These may be encountered in patients requiring repeated blood transfusions. Those caused by anti-Rh (D) (rare nowadays since patients receive Rh (D)-compatible cells) are not usually severe as they do not activate complement.

Delayed haemolytic transfusion reactions (DHTRs) are rare but can occur in patients whose level of antibodies to the blood group antigen is so low that it escapes detection by the pretransfusion screen. Following transfusion, the secondary immune response raises the antibody titre to a level that results in the delayed destruction of the transfused cells. Thus, the manifestations, which include fever, falling Hb, jaundice and haemoglobinuria, appear some 5–10 days after the transfusion. DHTRs are seldom fatal.

Transfusion-related acute lung injury

TRALI is one cause of ARDS and was previously thought to result from pulmonary microvascular occlusion by microaggregates of platelets, leucocytes and fibrin (50–200 μm), which are known to be present in stored blood. For this reason, microaggregate filters were recommended for transfusions in excess of 5 units of blood. A more definite cause is donor blood containing antibodies to the patient's leucocytes (nearly always donations from multiparous women). Following transfusion, the patient develops fever, increasing breathlessness, non-productive cough and hypoxaemia. The chest radiograph shows the typical features of ARDS with perihilar infiltrates leading to a whiteout in severe cases. The management is that of ARDS.

Metabolic and haemostatic complications

These complications are confined to patients who, because of severe haemorrhage, receive a massive blood transfusion of stored blood. *Massive blood transfusion is defined as that which is equivalent to or exceeds the patient's own blood volume within 12 hours.* Aside from being cold (4°C), stored blood has an acid pH and a reduced 2,3-DPG, and contains citrate anticoagulant, elevated plasma potassium and ammonia. The metabolic consequences therefore include hypothermia, acidosis and an increased affinity of oxyhaemoglobin for oxygen that is not readily released to the tissue, thereby contributing to defective tissue oxygenation. Hypothermia may lead to cardiac arrhythmias including ventricular fibrillation and asystole. For this reason, blood warming is necessary if the transfusion rate exceeds 50 mL/min. Unfortunately, the heating coils increase the resistance of the giving circuit, but nonetheless their use is essential in these patients. Citrate intoxication is due to the chelation of ionized calcium, which may result in prolongation of the QT interval, but this does not usually materially affect cardiac function and the ionized calcium levels rapidly return to normal after the transfusion as the excess citrate is metabolized and excreted. Thus, the use of supplemental calcium is not justified, particularly as it may itself give rise to arrhythmias. Hyperkalaemia is seldom a problem as the excess plasma K^+ enters the RBCs with warming to body temperature. It is, however, a consideration in patients with acidosis and renal failure when calcium is administered as the physiological antidote.

BOX 7.6 Investigation of an acute haemolytic transfusion episode

1 Report incident to the blood transfusion department
2 Establish that the unit has been issued to the patient receiving it
3 Obtain fresh samples of patient's blood (clotted and in EDTA) for re-cross-matching and serological testing
4 Send sample of the blood unit for culture
5 Return unit to the blood transfusion department
6 Obtain further blood samples from the patient for clinical chemistry (electrolytes, urea, free Hb) and coagulation screen
7 Discuss any further transfusion requirements with the blood transfusion officer

Stored blood is deficient in platelets and labile clotting factors (V and VIII). For this reason, massive transfusion of stored blood induces a dilution of the labile clotting factors in addition to a moderate thrombocytopenia. The deficiency of the labile clotting factors can be circumvented by the administration of 2 units of FFP for every 8 units of blood.

Platelet-specific alloantibodies may cause *post-transfusion purpura*, which is most commonly encountered in females and may prove fatal. The syndrome becomes manifest some 5–9 days after the transfusion with severe bleeding associated with extreme thrombocytopenia. Initially treatment is with high-dose corticosteroids and high-dose intravenous immunoglobulin. If platelets are needed they have to be compatible with the patient's alloantibodies.

Circulatory overload

This is encountered when blood is administered too rapidly or in large volumes. It is most commonly encountered during the transfusion of anaemic patients, particularly those with severe and chronic anaemia. These patients must be transfused very slowly and only with packed cells (with or without concomitant diuretic therapy). In addition, transfusion is restricted to 1 unit in any 12 hour period. In some patients, an exchange transfusion has to be carried out to avoid severe congestive failure.

Pulmonary oedema consequent on left ventricular failure is common after massive blood transfusion and must be differentiated from ARDS.

Immune suppression

There is no doubt concerning the immunosuppressive effect of blood transfusion which, indeed, was employed specifically for this purpose in patients before renal transplantation to improve graft survival prior to the introduction of cyclosporin, the effective immunosuppression of which has made prerenal transplant transfusion unnecessary. In the context of general surgery, perioperative blood transfusion, by virtue of this immunosuppressive effect, which is additive to that inherent to the operative trauma, has undoubted undesirable consequences. Aside from the risk of circulatory overload, perioperative blood transfusion enhances the risk of infective complications (proven), and may increase recurrence rate and reduce disease-free survival in patients after extirpative surgery for cancer. Although the latter is unproven, there is circumstantial evidence for this adverse effect, especially in patients undergoing resections for colorectal cancer.

Transfusion haemosiderosis

Every unit of blood contains 250 mg of iron that is retained by the body. Iron overload of the monocyte–macrophage system is caused by repeated red cell transfusions over many years and becomes significant after 100 units have been administered, when the liver, pancreas, myocardium and the endocrine glands become damaged. It is especially a problem in childhood anaemias (e.g. thalassaemia) and in patients with chronic refractory anaemia. The iron overload is reduced in these patients by iron chelation therapy with desferrioxamine.

Graft-versus-host disease

This is a rare but usually fatal complication that occurs mainly in immunodeficient patients, e.g. recipients of allogeneic marrow transplants and fetuses receiving intrauterine transfusions. However, graft-versus-host disease has also been documented in immunocompetent patients after transfusion of blood from a relative. The disease is caused by the T-lymphocytes and starts some 4–30 days after the transfusion. The patient develops a high fever and a diffuse erythematous skin rash progressing to erythroderma and desquamation, GI symptoms, severe hepatic dysfunction and pancytopenia. Graft-versus-host disease is prevented by administering gamma-irradiated cellular components to immune-deficient patients. Similarly, blood donated from relatives should be gamma irradiated.

Transmission of infectious disease

A wide spectrum of infectious diseases can be transmitted by the transfusion of blood and blood products, although, with the modern practice of screening of blood donors and heat treatment of blood protein products, the risk is extremely small. The most commonly transmitted viral disease is hepatitis C (<1 per 30 000 components transfused). Post-transfusion hepatitis B is now extremely rare in the UK. Hepatitis A can very occasionally be transmitted by blood products. Hepatitis G has only been recently identified. Currently, it can only be identified by gene amplification technology and there is no screening test. It is not known whether hepatitis G can cause serious disease and whether the existing plasma fractionation and heat treatment inactivate it, although this is thought likely.

Human parvovirus B19 may not be inactivated by current plasma fractionation and heat treatment. It causes depressed erythropoiesis in some patients. Human T-cell leukaemia virus (HTLV)-related disease following transfusion is extremely rare in the UK and, for this reason, donors are not screened for HTLV-I/II infection. However, the prevalence of HTLV-I is high in some countries, notably Japan and the Caribbean. HTLV-I causes neurological disease and a rare form of adult T-cell leukaemia, usually for many years after the transfusion.

CMV is a problem as 50% of UK donors have antibodies to CMV but fortunately only a fraction of antibody-positive donations transmits the virus. Post-transfusion CMV is important in premature infants born to CMV antibody-negative mothers and in CMV-negative recipients of bone marrow allografts from CMV-seronegative donors. These patients should receive CMV-negative products or leucocyte-depleted blood components. The HIV problem has largely been resolved by donor selection and testing.

Transfusion of bacteriologically contaminated or infected blood

This disastrous complication is fortunately rare in the UK (2 per million units transfused). The pathogens are usually cold-growing strains of *Pseudomonas fluorescens* or *Yersinia enterocolitica*. Skin organisms such as staphylococci can proliferate in platelet concentrates stored at 20–22°C. The clinical picture is similar to that of ABO-incompatible blood transfusion reaction. Despite aggressive supportive therapy, the majority of patients do not survive this complication.

Solutions for intravenous infusion

These include colloid solutions (ALBA 4.5% and synthetic colloids), isotonic crystalloid solutions, hypertonic saline solutions and red cell substitutes. There has been debate regarding the comparative efficacy of crystalloids versus colloids for volume replacement in the resuscitation of critically ill patients. A meta-analysis of published randomized trials (Schierhout and Roberts, 1998) indicated that resuscitation with colloids is associated with an increased absolute risk of mortality of 4%, i.e. four extra deaths for each 100 patients resuscitated. *This systemic review does not support the continued use of colloids.*

Synthetic colloid solutions: plasma expanders

Synthetic colloids are preferred to ALBA during resuscitation of hypovolaemic patients (except in burn patients), largely on the grounds of costs. Thus, for example, 1 unit of ALBA 4.5% costs £35, whereas the equivalent 500 mL solution of gelatin retails at £3–4. Synthetic colloidal solutions are used, as an alternative to isotonic crystalloids, in the resuscitation of hypovolaemic patients before blood is available or when it is unnecessary. Three types of preparation are available: dextrans, gelatins and hetastarch (HES) (Table 7.7).

The clinical effects of a synthetic colloid depend on its colloid osmotic pressure, its plasma half-life and its capillary permeability. The colloid osmotic pressure is expressed by the molecular weight and concentration of the colloid, but, as these are non-uniform solutions (particles are not of uniform weight), their molecular weight is better expressed by the 'number average' (M_n) rather than 'weight average' (M_w). M_n represents the mean osmotically active particle weight and is compared with the molecular weight of albumin (70 000).

Dextrans

These are solutions of inert glucose polymers produced from hydrolysed starch, which are available in various molecular sizes (dextran 40, dextran 70, etc.). As the renal threshold for these inert polysaccharides is of the order of 50 000, dextran 40 molecules are filtered through the glomeruli, whence they may block the renal tubules and cause ATN, especially in patients with reduced renal blood flow. For this reason, dextran 40 is rarely used nowadays. Dextran 70 is free from this side effect and can be used for volume replacement (up to 1.5 L/24 h in an adult). It is available either in saline (0.9%) or in 5% dextrose (when added Na$^+$ is undesirable). The colloid osmotic pressure of dextran 70 is 268 mmH$_2$O (lower than those of other plasma substitutes), but, because of its half-life (12 hours), its effect is relatively prolonged.

Dextran 70 infusion affects the coagulation system by inhibiting platelet aggregation and rendering fibrin more susceptible to fibrinolysis. For these reasons, dextran 70 is used in some centres in the prophylaxis of postoperative deep vein thrombosis. Large infusions (more than 20 mL/kg/day) can reduce factor VIII levels and induce capillary oozing. This limit of 1.5 litres of dextran 70 must not be exceeded during volume replacement. As dextran 70 interferes with blood cross-matching by inducing rouleux formation *in vitro,* a blood sample should be obtained before the infusion is commenced.

Adverse effects of dextran infusion are well documented. These are usually mild anaphylactoid reactions (1:2000 infusions) but serious reactions can occur, although they are rare (1:6000 infusions).

Hetastarch (Hespan)

This is not frequently used in the UK but is widely employed in the USA, where gelatin preparations are not available. It consists of a 6% solution of HES (chemically modified maize starch) in 0.9% saline. Its average particle size ($M_n = 70\,000$) and colloid osmotic pressure are equivalent to those of 5% albumin. Although the smaller molecules are removed by glomerular filtration (40% within 24 hours), the larger polymers undergo slow hydrolysis by plasma α-amylase, and some are then filtered once the size is reduced below the renal threshold. Approximately 30% of the infused dose ultimately leaves the vascular compartment and is taken up by the monocyte–macrophage system, predominantly in the liver and spleen. There are some concerns over the potential for impaired function (blockade) of this system following large infusions of hetastarch. In any event, the final elimination from the body is a slow process, and, at 4 months, the plasma concentration averages 1% of the original value. The half-life of hetastarch in the plasma is considerably longer than any of the other plasma substitutes and averages 17 days. In animals, infusions of HES exceeding 20 mg/L (equivalent to 1500 mL in a 70 kg patient) impair platelet function and coagulation. Hetastarch administration may be followed by a rise in the serum amylase but there is no evidence of any pancreatic damage. In a recent report, one serious and 13 mild reactions were encountered in 16 000 infusions.

Table 7.7 Synthetic colloid solutions: plasma expanders

Product	Nature	M_n	COR (mmH$_2$O)	Half-life
Dextran 70	Hydrolysed starch	70 000	268	12 hours
Hetastarch, Hespan, HES	Hydroxyethyl maize starch	70 000	350	17 days
Gelofusine	Succinylated gelatin	22 600	465	4 hours
Haemaccel	Polygeline	24 500	350–390	5 hours

COR, colloid osmotic pressure; M_n, number average.

Gelatin solutions

The modern preparations consist of solutions of heat-degraded cattle bone gelatin: succinylated gelatin (Gelofusine) and polygeline (Haemaccel). Although both are made up in balance crystalloid solution, the calcium concentration is different. Haemaccel contains over 10 times more calcium (6.25 mmol/L) and potassium (5.1 mmol/L) than Gelofusine. The high calcium content of Haemaccel can lead to clotting in the warming coils when this colloid is mixed with citrated blood or FFP. Whereas the colloid osmotic pressure of Haemaccel (350–390 mmH$_2$O) is similar to that of plasma, that of Gelofusine is greater (465 mmH$_2$O), i.e. it tends to draw fluid into the intravascular compartment from the interstitial space. As their particle weight is small (Haemaccel $M_n = 24\,500$; Gelofusine $M_n = 22\,600$), they are rapidly filtered by the renal glomeruli and cause an osmotic diuresis which is beneficial. This too accounts for their short half-life: 5 hours for Haemaccel and 4 hours for Gelofusine. As neither preparation affects either the bleeding time or coagulation time (except by dilution), they are perfectly safe for large-volume colloid replacement. There is some evidence that some of the gelatin complexes may leave the vascular compartment and become sequestered in the interstitial space, particularly the lung. These extravasated complexes may contribute to the increased lung water, which may retard the return of pulmonary gas exchange to normal.

The original version of Haemaccel led to a number of histamine-induced adverse reactions when the solution was infused rapidly, but, since 1981, the manufacturing process has been altered to reduce the amount of cross-linking agent responsible for the plasma histamine released. The incidence of minor reactions with the modified Haemaccel is nine per 1334 infusions. The reported serious anaphylactoid reactions with Gelofusine infusion vary from 1:6000 to 1:12 000. Within the UK, the concern with gelatin solutions is their bovine origin, possible contamination with the prion protein responsible for bovine spongiform encephalopathy (BSE) and the possible development of new-variant Creutzfeldt–Jakob disease but, to date, no health warnings have been issued. Presumably, the heat-degradation process destroys the prion protein. It seems likely that the original gelatin will be obtained from BSE-free herds in the future.

Crystalloid solutions

These are isotonic balance salt or dextrose solutions (Table 7.8). The two most commonly used for volume replacement are isotonic saline (0.9%) and Ringer's lactate (Hartmann's solution), which approximates most closely to the electrolyte composition of plasma. This and the less acidic pH of Hartmann's solution (6.5 versus 6.1) account for its preferment over isotonic saline by some surgeons, while others consider the lactate content of Hartmann's solution to be a disadvantage since shock is accompanied by elevated blood lactate, and, for this reason, prefer isotonic saline. Amid this minor controversy, all are agreed that 5% dextrose has no place in resuscitation. It is equivalent to the safe intravenous administration of water and the little dextrose it contains is not metabolized. As distinct from colloid following intravenous infusion, crystalloid solutions are rapidly distributed between the intravascular and interstitial spaces roughly in the proportion of 3:1. This is not a disadvantage, as in shock both compartments are contracted. However, the amount required to restore the CBV is significantly larger (by at least a factor of 3) then when colloid solutions are used. Thus, the replacement of 1.0 litre of circulating blood requires the infusion of 3.0 litres of Hartmann's or isotonic saline, as opposed to 1.0 litre of colloid. The extent of expansion of the body fluid compartments limits the magnitude of losses that can be replaced solely by crystalloid solutions and crystalloid solutions predispose to oedema and the compartment syndrome.

Combined crystalloid–colloid blood replacement

The current widely practised compromise for blood volume replacement entails the infusion of a mixture of crystalloids and synthetic colloids in a ratio of 2:1. Stored blood or red cell concentrates are added when the blood loss exceeds 1.5 litres or if the haematocrit falls below 25%.

Hypertonic saline and hypertonic saline solutions

Intravenous infusions of hypertonic crystalloid solutions (500 mmol/L) have been reported to have beneficial effects in patients with refractory shock, in whom they may increase the survival rate. Several formulations have been proposed. The Sackford solution contains the following in mmol/L: Na^+ 250, Cl^- 100, lactate 63, K^+ 4 and Ca^{2+} 9. These hypertonic solutions increase CO and possibly improve cerebral oxygen delivery in severely shocked patients. The exact mechanism of action is unknown but is possibly vagally mediated by the arrival of the hypertonic bolus in the pulmonary vasculature. Some reports indicate that hypertonic solutions reduce the peripheral resistance and are accompanied by a lesser weight gain than ordinary isotonic crystalloid solutions. The duration of the effect on the circulation of hypertonic solutions is short lived and probably does not exceed 1 hour. Although there is good experimental evidence from animal studies of the benefit of hypertonic saline/hyperoncotic solutions in hypovolaemia due to blood loss from rapid expansion of blood volume, improvement in cardiac index and stimulation of the immune system with improvement in survival, the published studies on use of these solutions in humans remain limited, lack appropriate controls and there have been no randomized studies. A major publication (Oliveira *et al*. 2002) has reviewed the published experimental evidence on the use of these hypertonic solutions in sepsis and septic shock and concluded that they appear to have the potential to benefit patients with sepsis or septic shock, and possibly in the prophylaxis of septic shock and the systemic inflammatory response syndrome.

Table 7.8 Crystalloid solutions for intravenous use (mmol/L)

Solution	Na^+	K^+	Cl^-	HCO_3^-	Ca^{2+}
Isotonic (N) saline	154	–	154	–	–
Dextrose 5% N saline	154	–	154	–	–
Dextrose 5% N/2 saline	77	–	77	–	–
Hartmann's solution (Ringer lactate)	131	4	110	(28)*	3
Ringer's solution	147	4	155	–	4
Dextrose 5%	–	–	–	–	–

*As lactate.

Several clinical studies in trauma patients have indicated potential benefits, although the reported data are not conclusive. In one study, stable patients with septic shock were administered 2–4 mL/kg hypertonic saline in HES. This resulted in minor improvement in oxygenation through an increased CO and oxygen delivery.

In another study, administration of 250 mL hypertonic saline in dextran significantly improved the cardiac index and pulmonary artery occlusion pressure compared with administration of an equivalent volume of normal saline. Hypertonic solutions are known to stimulate the immune system and exhibit an anti-inflammatory effect, which may prevent or minimize the severity of multiple organ failure. The probable advantages of using hypertonic solutions in patients with sepsis include: (1) rapid and sustained expansion of plasma volume with improved cardiovascular function, (2) restoration of microcirculatory perfusion, (3) improved immune function and (4) reduced bacterial translocation from the gut. However, prospective clinical studies are needed to confirm the safety and efficacy of hypertonic solutions in clinical practice, and especially in the treatment and prophylaxis of septic shock.

Red cell and platelet substitutes

In principle artificial blood products are needed to address the chronic deficiency relative to the clinical needs of blood and blood products obtained from voluntary human donations. In addition, these substitutes have certain benefits.

Artificial blood products have the following benefits:

- readily available and have a long shelf-life
- they can be filtered and pasteurized to eliminate microbial contamination and disease transmission
- they do not require blood typing, so they can be infused immediately
- they do not cause immunosuppression in the recipient.

Blood substitutes

Red cell substitutes, despite considerable research over many years, are still in the development phase and their use in clinical practice, largely limited to clinical trials, has become possible only recently. Blood substitutes are either Hb based or synthetic perfluorocarbons (PFCs).

Haemoglobin substitutes

The modified Hb solutions consist of polymerized Hb complexed with pyridoxine-5-phosphate and dialysed to remove vasoconstrictor substances present in the red cells. When Hb is extracted from the RBCs, it rapidly loses its 2,3-DPG, which is necessary for its low affinity for oxygen (essential for the release of oxygen to the tissues). This problem is overcome by complexing the Hb with pyridoxine-5-phosphate, which restores the normal oxygen affinity. Polymerization is necessary to increase the molecular size as non-polymerized Hb rapidly leaves the vascular compartment and is filtered through the glomeruli into the urine. However, the previously held view that Hb is nephrotoxic has been shown to be incorrect. Renal damage is caused by the red cell stroma and not the released Hb. The polymerization process is also viricidal and results in a fourfold increase in the half-life of the Hb (20 hours). Modified Hb solutions contain up to 150 g/L of Hb.

An alternative approach is to encapsulate the Hb/pyridoxine-5-phosphate in lipid membrane microspheres of equivalent size to the RBCs. The half-life of solutions made of Hb-containing microspheres is similar to that of polymerized Hb solutions.

The Hb substitutes are made from human, animal or recombinant Hb. There are justifiable concerns regarding animal Hb substitutes as this is obtained from cows' blood and there is a risk of transmission of prions that cause BSE. Recombinant Hb is produced following insertion of the human gene into bacteria followed by isolation and purification from the bacterial culture. The problem with all Hb substitutes is that the infused Hb rapidly breaks down from its tetramer configuration to dimers and monomers. Thus, stabilization of the Hb tetramer structure is necessary and is achieved by cross-linking with sugars and certain polymers or by pyridoxylation. The latter creates a substitute with near-normal oxygen binding. Another problem is that free Hb binds with nitric acid, and this complex then causes vasoconstriction and hypertension.

Hb can be polymerized with surface amino acid groups by glutaraldehyde. Polymerized Hb is the only substitute that does not cause significant vasoconstriction after infusion and has been used successfully in phase III clinical trials. Hemolink is another substitute created from human Hb polymerized with oraffinose. PolyHeme, also produced from human Hb, has been used in phase III trials in trauma patients, who received up to 10 units of PolyHeme with minimal side effects. In contrast, Hemopure is made from bovine Hb. A multicentre trial in patients undergoing infrarenal aortic reconstruction reported that 27% of patients receiving Hemopure were able to avoid transfusion of allogeneic blood.

Perfluorocarbon substitutes

In contrast to the chemical reaction involved in oxygen transport by Hb, emulsions of PFCs carry oxygen in physical solution at high partial oxygen pressures, although they readily release the oxygen when the PO_2 is low, i.e. at tissue level. The need for high partial oxygen pressure required for adequate oxygen uptake from the lung limits their clinical usefulness, although some of the newer formulations have overcome this problem to some extent. PFCs have a short intravascular half-life and, following extravasation, are taken up by the cells of the monocyte–macrophage system. One advantage of these solutions is their low viscosity, which offers advantages in some clinical situations, e.g. limb salvage and patients with myocardial infarction. Recent solutions consist of combinations of a mixture of three PFCs with HES. The 20% solution requires inspired oxygen of 100%, but the 35% solution can be used with 60% inspired oxygen, rendering it more acceptable for general clinical use.

PFC-based solutions have the capacity to dissolve up to 50 times more oxygen than plasma. The problem is that PFC solutions do not mix well with blood and thus have to be emulsified with lipids. Additionally, patients have to be on 100% oxygen during infusion ($PaO_2 \geq 350$ mmHg). The PFC-based solutions include Oxygent, which is currently in phase III clinical trials in cardiac and general surgical patients. It can be used for augmented controlled normovolaemic haemodilution before major surgery as a means of avoiding allogeneic blood transfusion. PFC-based substitutes are acceptable to Jehovah's Witnesses.

Adverse reactions to blood substitutes

The following indicate their limitations and the need for improved substitutes:

- Hb-based substitutes:
  - elevations in blood pressure
  - gastrointestinal dysmotility
  - mild, transient increase in pancreatic enzymes
  - jaundice
  - interfere with laboratory testing
  - short duration of action – 24 hours
  - expensive.
- PFC substitutes:
  - mild thrombocytopenia (10–15%)
  - flu-like syndrome
  - oxygen toxicity with prolonged use as the patients have to be on 100% inhaled oxygen
  - short action – 24 hours
  - expensive.

Platelet substitutes

The two problems necessitating the development of platelet substitutes are (1) short shelf-life, typically 5 days, and (2) need for storage at room temperature with the risk of bacterial overgrowth. The various platelet substitutes under development include:

- infusible platelet membranes (IPMs)
- thrombospheres
- lyophilized human platelets.

Infusible platelet membranes

These are produced from outdated human platelets which are fragmented, virally inactivated and lyophilized, enabling storage for up to 2 years. They are currently in phase II clinical trials. IPM infusions are indicated in patients who have become refractory to platelet transfusions because of the formation of antiplatelet antibodies. IPMs appear to be clinically effective in stopping bleeding and are safe.

Thrombospheres

Thrombospheres (Hemosphere) are composed of cross-linked human albumin bound to human fibrinogen. They are still in the experimental phase of development but studies indicate that they are effective in enhancing platelet aggregation. A similar product (Synthocytes) is undergoing clinical trials in Europe.

Lyophilized human platelets

Lyophilized platelets are produced by fixing human platelets in paraformaldehyde prior to freeze-drying in an albumin solution. The adhesive properties of the platelets appear to be maintained. This product is not as yet in clinical use.

Oedema

Oedema is defined as the excessive accumulation of tissue fluid, mainly in the interstitial but also in the intracellular space. Under physiological conditions, the Starling forces (capillary pressure and plasma oncotic pressure) ensure the orderly bidirectional movement of fluid between the intravascular compartment [more specifically the effective circulatory volume (ECV)] and the interstitial space. Thus, during the course of 1 day, some 20 litres of fluid leave the capillaries at the arteriolar end and 18 litres are absorbed back across the capillary membrane at the venous zone of the capillary network, leaving an excess of 2 litres, which is returned to the circulation by the lymphatics. Oedema represents a breakdown of this balanced fluid transport with a net accumulation of tissue fluid.

Oedema may be *localized* (e.g. inflammatory, neurogenic, local hypersensitivity reaction), when only an imbalance of the Starling forces and other locoregional factors (e.g. increased vascular permeability) are operative, or *generalized*, when the role of the kidney is of paramount importance, irrespective of the aetiology (cardiac, hepatic or renal disease).

Mechanisms of generalized oedema formation

Chronic disease

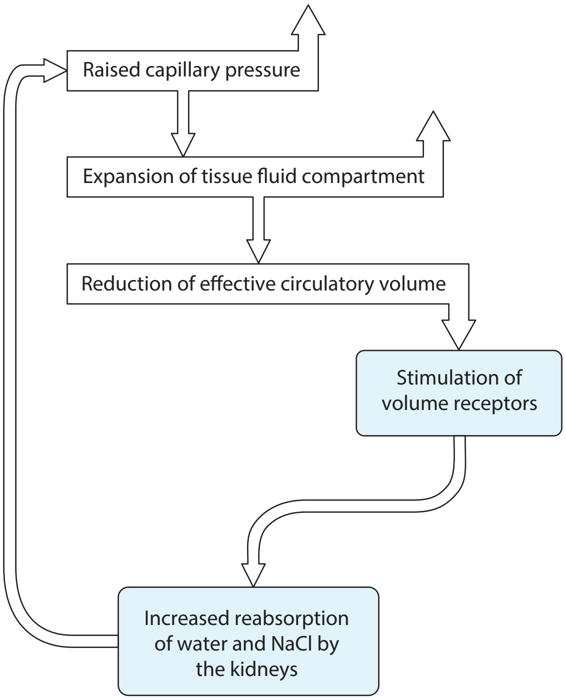
The basic mechanisms that are common to all disorders accompanied by excessive water and salt retention causing oedema with or without ascites or hydrothorax are outlined schematically in Figure 7.8. In addition, other factors that are disease specific may be involved, e.g. hypoalbuminaemia in chronic liver and renal disease and relative excess of aldosterone (secondary hyperaldosteronism) in cirrhosis, but these are less important in the aetiology of interstitial tissue fluid overload.

The common causes of oedema are:

- pregnancy
- renal disease
- cardiac failure
- chronic pulmonary disease
- thyroid disease
- chronic liver disease
- diabetes
- arthritis
- malnutrition
- drugs, e.g. corticosteroids, calcium channel blockers for hypertension
- contraceptive pill.

In heart failure, chronic hepatic and renal disease, the raised capillary pressure is due to an elevated venous pressure that is transmitted to the capillary bed. This reduces the amount of fluid reabsorbed from the interstitial space back into the intravascular compartment. The net result is a contraction of the plasma volume which, in itself, would tend to limit the pathological process. However, the low-pressure volume receptors in the atrium and pulmonary vessels detect a reduction in the ECV and trigger the excess reabsorption of water and NaCl by the kidneys, so that the plasma volume is restored. The net outflow of fluid to the interstitial space is continued until a steady state is reached. This occurs when the pressure in the interstitial space is raised sufficiently to counter the elevated capillary pressure. In essence, this means that tissue perfusion is impaired.

In some disorders, the oncotic pressure is reduced. This may be due to the reduction in the serum albumin from increased permeability of the glomerular capillaries in certain forms



Raised capillary pressure
Expansion of tissue fluid compartment
Reduction of effective circulatory volume
Stimulation of volume receptors
Increased reabsorption of water and NaCl by the kidneys

Figure 7.8 Basic mechanisms involved in generalized oedema.

of renal disease (e.g. nephrotic syndrome) or to defective synthesis (e.g. chronic liver disease) or protein malnutrition (e.g. kwashiorkor). The reduced oncotic pressure augments the effect of the raised capillary pressure in the net accumulation of tissue fluid in liver and kidney disease.

Clinically, oedema is often dependent, and, for this reason, is commonly found around the ankles in ambulant patients or over the sacral area when the patient is bed-bound. The cause of this distribution can be directly ascribed to the greater venous (and hence capillary) pressures in these regions and to the effects of gravity. Oedema is also prominent in patients with renal disease in the periorbital regions, where the tissues are lax. Certain individuals, usually female, suffer from a deficiency of renal handling of sodium and this leads to cyclical oedema manifesting in puffiness of the hands, feet and face.

Critically ill patients

Generalized oedema is often encountered in critically ill patients on ventilatory and inotropic support (major trauma and advanced sepsis). This is usually multifactorial, e.g. excess crystalloid infusion with pathological expansion of the interstitial space, third space losses, low CO, increased capillary permeability and low plasma oncotic pressure (dilution). The concept of the 'third space' arose from the observation that surgical trauma and inflammatory disease resulted in increased capillary permeability and sequestration of extracellular fluid in the traumatized or inflamed tissue (e.g. oedematous bowel in intestinal obstruction or peritonitis). The generalized oedema of critically ill patients responds to intravenous fluid restriction (haemodynamic monitoring permitting) if the patient's condition improves. Diuretics are seldom indicated as most of these patients are in renal failure. Haemodialysis with hyperosmolar dialysate may be necessary.

Mechanisms of localized oedema formation

Here, the important pathological variables are vasodilatation and increased permeability of the capillary endothelium. The vasodilatation of the precapillary sphincters results in elevation of the capillary pressure with excess transudation over reabsorption across the capillary membrane.

Inflammatory oedema

The increased permeability of the capillary endothelium, which is caused by the cytokine cascade, components of complement following activation by the classic or alternative pathway, kinins, prostaglandins, proteases (e.g. granulocyte elastase), etc., results in the escape of both fluid and albumin in the interstitial space. The extravasated albumin, by raising the oncotic pressure of the tissue fluid, further accentuates the net accumulation of fluid in this compartment. These mechanisms operate irrespective of the aetiology of the condition: bacterial inflammation, inflammatory oedema of healing wounds, oedema due to anaphylaxis, neurogenic oedema, etc.

Apart from its local and systemic effects, inflammatory oedema is important from a technical aspect in relation to tissue approximation (closure of wounds and intestinal anastomosis). Oedematous tissue sustains a marked reduction in its tensile strength and, for this reason, when the edges are approximated by sutures, there is a tendency for the sutures to cut through with breakdown of the wound or dehiscence of the anastomosis.

Limb oedema

In patients with oedema affecting one limb, the usual cause can be found in some problem within the deep venous system. Often, this is the result of previous deep venous thrombosis, which leads to the postphlebitic syndrome (marked lower limb oedema, eczema, pigmentation and ulceration). In a small proportion of patients, compression of the left common iliac vein by the right common iliac artery may be responsible for left-sided leg oedema.

Less commonly, limb swelling may arise from lymphoedema owing to blockage or insufficiency of the lymphatic trunks draining the limb. The most common variety is secondary lymphoedema from blockage or disruption due to trauma, surgical excision of lymph nodes (postmastectomy), radiotherapy for cancer, infiltration by malignant disease, parasitic infestations, e.g. filariasis, etc. In primary lymphoedema, the mechanism is insufficiency rather than obstruction (hypoplastic or incompetent lymphatics).

Whatever the cause of lymphoedema, the accumulated fluid has a high protein content, which induces a fibrotic reaction in the subcutaneous region and is particularly prone to infection, especially by streptococcal organisms. These inflammatory episodes aggravate the subdermal fibrosis so that the skin becomes thick, dry, scaly and rough (elephantiasis). Long-standing lymphoedema does not pit on pressure, although early lymphoedema does. Lymphoedema predisposes to recurrent bacterial infection of the affected limb, which aggravates the fibrosis and induration. Hence, prophylactic personal hygiene is an essential part of the management of these patients (see Chapter 11).

Other unusual causes of limb swelling include: *disuse oedema*, when the patient holds the limb completely immobile for long periods, *post-traumatic osteodystrophy* (very painful swelling such as to make the limb useless, accompanied by osteoporosis, also known as Sudeck's atrophy) and *local gigantism*, which may be due to arteriovenous malformations or Klippel–Trenaunay syndrome (combination of congenital varicose veins, abnormal deep veins and capillary naevi).

Angio-oedema

This is caused by the acquired or congenital absence of C1 esterase inhibitor. As a result of this deficiency, afflicted individuals are prone to episodes of unchecked activation of complement with marked oedema formation that often affects the upper airway, leading to life-threatening asphyxia. Angio-oedema occurs in a subset of patients with immunological urticaria. In affected patients the C1 esterase inhibitor deficiency leads to release of complement-derived kinins, which are the immediate mediators of the oedema. Acquired angio-oedema is also encountered in patients on angiotensin-converting enzyme (ACE) inhibitors owing to inhibition of kinin breakdown by ACE.

Hereditary and acquired C1 inhibitor deficiency is screened by assay of serum C4, which, if low, requires quantitative and functional assays of the C1 esterase inhibitor to confirm the diagnosis.

Treatment of C1 esterase inhibitor deficiency

Maintenance therapy is only necessary for patients with symptomatic recurring angio-oedema. Anabolic steroids are used in most patients but may cause virilizing side effects. Tranexamic acid is also used for maintenance but is contraindicated in patients with a history of thrombosis. Prophylaxis before elective surgery includes tranexamic acid started 3–4 days before the planned intervention or by increasing the dose of tranexamic acid or anabolic steroids in patients on maintenance therapy. C1 inhibitor concentrate or FFP is used for emergency treatment of serious angio-oedema attacks or as prophylaxis before emergency surgery, especially when intubation is necessary. Epinephrine is ineffective in angio-oedema caused by C1 esterase inhibitor deficiency. Acute episodes are treated by infusion of C1 esterase inhibitor derived from plasma and antihistamines. Patients may require endotracheal intubation or tracheostomy.

CHAPTER 8

Cardiovascular pathophysiology

PRIYA GEORGE, JACOB GEORGE AND ALLAN D. STRUTHERS

Introduction

The cardiovascular system is a complex system designed to deliver oxygen to peripheral tissues. Oxygenated blood is delivered in an optimum fashion by the careful regulation of regional blood flow to each organ or tissue. This regulation of flow of blood is in turn dependent not only on the overall total blood volume but also on the local pressure differences within each organ. Pressure, flow and volume within the cardiovascular system are influenced in turn by both nervous impulses and circulating hormones.

In a young healthy adult, at rest, each ventricle fills during diastole to reach an end-diastolic volume of 120 mL of blood. During the following systole, 70 mL of blood is ejected [i.e. the stroke volume (SV)]. Unlike systemic organs, coronary perfusion, however, occurs during diastole. The normal ejection fraction is therefore of the order of 58%, but can lie anywhere between 55% and 75%. Overall, cardiac output (CO) is determined by two factors: SV and heart rate (HR):

$$\mathrm{CO} = \mathrm{SV} \times \mathrm{HR}$$

Starling's law states that, in a healthy heart, the force of contraction increases as diastolic stretch of the heart is increased, i.e. the more the ventricle fills with blood, the more blood will be expelled at each beat; thus, the ejection fraction is relatively constant but the absolute volume of blood ejected increases as the end-diastolic volume increases. The control of the CO is, however, more complex than just Starling's law. CO is, in fact, determined by several variables:

- *Preload*, i.e. venous filling. This influences CO by Starling's law (see above). The two main determinants of preload are the circulating blood volume and venous tone. In a normal subject, a reduced preload will reduce the CO, but this is not true in myocardial disease (see below).
- *Cardiac contractility*. The optimal sarcomere length is 2.2 μm. Stretching of the sarcomere will increase the number of actin–myosin bridges and therefore result in an increased generation of force.
- *Afterload*, i.e. arterial resistance. Arterial resistance acts as an impediment to cardiac ejection. The main contributors to arterial resistance are the arterioles and not the large arteries. A reduced afterload due to an arterial vasodilator will normally increase the CO because it reduces the restraining effect of arterial stiffness.
- *HR*. This obviously influences CO, since CO = SV × HR.

In turn, these three components (CO, SV and HR) are influenced by several regulatory mechanisms:

- Sympathetic nervous activity: the sympathetic nervous system causes norepinephrine (noradrenaline) to be released within synaptic clefts, which then increases HR, cardiac contractility, preload and afterload.
- Circulating catecholamines.
- Parasympathetic nervous system.

Circulating catecholamines

Epinephrine (adrenaline) is a circulating hormone released by the adrenal medulla at times of extreme stress. It is mainly a β-agonist with some α-agonist activity. Its β_1 activity increases HR and cardiac contractility, whereas its β_2 activity causes peripheral vasodilation of both arteries and veins, hence causing decreased afterload and decreased preload.

Norepinephrine is very different from epinephrine in that norepinephrine is principally the neurotransmitter for the sympathetic nervous system. It mainly acts locally in tissues but it does spill over from the synaptic clefts to appear in the bloodstream. Although norepinephrine is mainly a neurotransmitter, the 'spilled over' part of norepinephrine does circulate in the bloodstream and act as a circulating hormone.

Norepinephrine is mainly an α-agonist with a little β_1-agonist activity. Its α-agonist effect leads to peripheral vasoconstriction of both arteries and veins, and therefore increased preload and afterload, whereas its β_1 activity increases cardiac contractility and HR. It is worth noting that epinephrine decreases preload and afterload whereas norepinephrine increases preload and afterload. Both substances increases HR and cardiac contractility.

Parasympathetic nervous system

This regulates cardiac function through the vagus (X) nerve. The principal effect of vagal stimulation is to reduce the HR, partly by slowing conduction at the atrioventricular (AV) node. Indeed, the intrinsic HR of a young adult is about 110 beats/min but the tonic influence of the vagus reduces this to a normal resting rate of 70 beats/min. The vagus has little effect on preload, afterload or force of contraction.

Peripheral circulation

The large arteries passively channel the blood ejected from the left ventricle to the peripheries. To designate this, these vessels are normally called *conduit vessels*. On the other hand, the arterioles have a muscular wall that is thick by comparison with their lumen and they make the largest contribution to afterload, which is why they are called the *resistance vessels* of the body. It is likely that at any one time some arterioles are open and some closed. The open arterioles offer little resistance. Therefore, peripheral resistance is mainly determined by the number of arterioles which are closed at any one time.

Capillaries, like arterioles, are in the state of being either open or closed. For example, in skeletal muscle at rest, only two or three capillaries are open in each mm^3 of tissue, whereas this goes up to 200–300 during exercise. In the skin and other tissues, there are numerous arteriovenous anastomoses that allow a variable amount of blood to bypass the capillary bed altogether. The venous bed, especially the venules of the liver and spleen, act as a reservoir for the majority of the circulating blood volume. To designate this, the peripheral veins are normally called the *capacitance vessels* of the body. Small veins and sinusoids contain about 45% of the intravascular volume while the large central veins hold about the 18%. Mean right atrial pressure is approximately 0 mmHg whereas the capillary pressure is about 15 mmHg, so that the return of blood to the heart through the veins is a passive process, assisted by the pumping action of skeletal muscles, which compress segments of veins and hence propel blood towards the heart.

Blood pressure

Blood pressure (BP) is a composite term involving both CO and total peripheral resistance (TPR). The reason that BP remains a commonly used parameter is really to do with the fact that, in any given patient, BP is easily measured repeatedly and by non-invasive means, and also because a chronically elevated BP has prognostic implications in the long term. In the case of a low BP, however, its individual components (CO and TPR) give much more useful information about the state of the cardiovascular system but their measurement is more complex and more invasive. For example, shock can usually be defined as a low BP but this in itself is little guide to the cause or the treatment required. Knowledge of the CO and TPR would help enormously since cardiogenic shock is characterized by a very low CO (with a normal or high compensatory TPR) whereas septicaemic shock is characterized by a low TPR (with a normal or high compensatory CO).

Hypertension

Hypertension is defined as an elevated systemic BP. The current National Institute for Health and Clinical Excellence guidelines define hypertension as a BP measurement of systolic, diastolic or both above 140/90 mmHg on two separate occasions. The threshold for commencing treatment is if the patient either has a BP of 160/100 mmHg or greater, *or* has a BP of 140/90 mmHg *and* one of the following two criteria (1) a 10 year cardiovascular disease risk >20% or (2) existing cardiovascular disease/target organ damage. It appears, however, that the cardiovascular system changes as time goes on in a patient with hypertension. In the early stages of essential hypertension, the CO is increased while the TPR is normal. After an undefined period of years, the CO returns to normal but the TPR rises. Indeed, an increased TPR is the main cardiovascular hallmark of established essential hypertension.

The vast majority of hypertension is chronic and not immediately life-threatening, but it must be appreciated that there is a form of disease called accelerated or malignant phase hypertension. Often, malignant phase hypertension develops in a patient who has for many years had benign, albeit poorly controlled, hypertension. The factors that trigger benign hypertension to change into malignant hypertension are unknown. Malignant hypertension is characterized pathologically by fibrinoid necrosis in small arteries and arterioles, this being particularly obvious in the renal arterioles. Clinically, malignant phase hypertension presents as a grade 3 retinopathy (haemorrhages and exudates) or a grade 4 retinopathy (papilloedema) in a patient with a markedly elevated BP (diastolic BP >120 mmHg). Patients usually also have proteinuria and an elevated plasma creatinine, although neither of these are diagnostic as they can occur in the late stages of benign hypertension. The prognosis of malignant phase hypertension was extremely poor (median survival 6 months) in the 1950s before antihypertensive therapy was available. Nowadays, malignant phase hypertension is treated by immediate hospital admission and the institution of oral antihypertensive medication with the aim of reducing the BP into the normal range over the course of the next 3–4 days. Parenteral antihypertensive therapy is not usually indicated but may be used if patients are ‘nil by mouth’ preoperatively or have impaired swallowing reflexes.

The vast majority (approximately 90%) of patients have essential hypertension, in which there is no known cause for the elevated BP. When there is known cause, this is called secondary hypertension. These are various causes for secondary hypertension and these will be dealt with in turn. Secondary hypertension represents a minority of hypertensive patients, but they are a group of particular importance because surgery may play a crucial role in their management.

Hypertension and surgery

Pre-existing hypertension is the most common medical reason for delaying surgery. The hypertensive patient is obviously at greater risk during surgery than the normotensive patient. For example, the risk of postoperative myocardial infarction (MI) is doubled in a hypertensive patient. These increased haemodynamic risks of MI and ischaemia are reduced if the BP is treated prior to surgery. If diastolic BP is >110 mmHg, then it is wise, if possible, to postpone surgery until, ideally, diastolic BP is 85–95 mmHg. In a study by Goldman and Caldera, patients with diastolic BP <110 mmHg did not appear to be at significantly higher operative risk. The significance of systolic hypertension was not commented upon but, in practice, values >160 mmHg are often taken as a reason to delay surgery.

Some consider that regional anaesthesia is safer than general anaesthesia in a hypertensive patient, but epidural anaesthesia can itself cause marked vasodilation and BP swings, which are themselves poorly tolerated in untreated hypertensives. If regional anaesthesia is employed, then careful monitoring and careful attention to fluid balance are essential.

In the postoperative period, BP can be particularly unstable if there is a prolonged hypotensive effect of anaesthesia owing to impaired renal or hepatic clearance, blood loss, sepsis or pain. Another important cause of labile (usually low) BP postoperatively is the development of atrial fibrillation with uncontrolled ventricular rate (so-called 'fast AF'). As 20% of CO is dependent on atrial contraction ('atrial kick'), the loss of this, especially in patients with heart failure, can result in hypotension, breathlessness and compensatory sympathetic activation. Inadequately controlled pain or bladder distension will cause sympathetic activation that can elevate the BP and cause tachycardia. Both of these will increase myocardial O_2 consumption, which may precipitate myocardial ischaemia or infarction. Therefore, it is sensible to monitor and control both BP and HR in the postoperative period.

Therapeutic management of hypertension

Most oral antihypertensive agents can be taken with small sips of water on the morning of surgery. The therapeutic options available for parenteral use at this time are sodium nitroprusside (SNP), hydralazine, nitrates, dihydropyridine calcium channel blockers, beta-blockers, fenoldopam or enalaprilat (last two not available in UK). The first two have the disadvantage that they can both cause a reflex tachycardia so that they may need to be combined with a cardioselective beta-blocker (e.g. metoprolol 5 mg i.v.) if tachycardia becomes troublesome. SNP is a potent arterial and venous vasodilator. Cyanide toxicity can also occur with prolonged use (>24 hours) of SNP, especially in patients with vitamin B_{12} deficiency. B_{12} is a cofactor for the mitochondrial enzyme rhodanase that catalyses the conversion of cyanide to the relatively harmless thiocyanate. Intravenous glyceryl trinitrate (GTN) has the advantage of similar action to SNP (but predominantly venodilation) without the risk of cyanide toxicity. It is particularly useful in patients with known angina.

In the UK, the only dihydropyridine calcium channel blocker available in intravenous preparation is nimodipine. It is reserved for the treatment of intracranial hypertension only. In other parts of the world, both clevidipine and nicardipine are available. Clevidipine is very short acting but, unlike other dihydropyridine calcium channel blockers and GTN, does not cause reflex tachycardia. Nicardipine and enalaprilat are long-acting agents and therefore may be of limited use because of the risks should the patient have hypotension secondary to other causes such as bleeding or sepsis.

It is also crucial in the preoperative and postoperative phases that all regular medication be continued. This is especially true of antihypertensive or antianginal medication, for which parenteral administration may be required, e.g. atenolol 4 mg/h by continuous i.v. infusion. Similarly, antiarrhythmic therapy must be continued by parenteral administration.

Secondary hypertension

Renovascular hypertension (renal artery stenosis)

Renovascular disease or renal artery stenosis can be either unilateral or bilateral. It can be caused in young, usually female, patients by fibromuscular dysplasia or in older patients of either sex by atheromatous disease. It should be suspected in patients younger than 30 years, in those with treatment-resistant (more than three agents) hypertension, in patients with known peripheral vascular disease with sudden worsening of control, diabetic patients or patients on angiotensin-converting enzyme (ACE) inhibitors/angiotensin receptor blockers whose renal function deteriorates (>20% worsening) on initiation of therapy or dose uptitration. An initial renal ultrasound scan is appropriate to determine renal structure and cortical thinning. Further investigations can be done by MAG-3 (radioisotope imaging) or magnetic resonance renal angiogram. However, the largest clinical trial to date, the Angioplasty and Stenting for Renal Artery Lesions (ASTRAL) trial, showed no difference in all significant endpoints between patients who underwent stenting and the control group. There are many reasons that this may be so, not least because the population studied was heterogeneous. A meta-analysis by Leertouwer *et al.* showed that the cure rate from stenting was approximately 20%, and 30% of patients also experienced an improvement in their renal function.

The crucial point about renovascular disease is that BP may unfortunately remain high in some patients even after surgical correction. The reason for this is unclear, but it may be because the patient had underlying essential hypertension to begin with or because, once established, an elevated BP may perpetuate itself. Because surgery may not always be curative in all patients, a great deal of effort has gone into trying to predict the BP response after surgery in individual patients. Several tests have been suggested, such as measuring the renal vein renin ratio or the renin response to an ACE inhibitor. Both tests give some guide but are not reliable enough to be used alone in individual patients. The decision on whether to attempt correction is therefore usually based on a composite of several clinical features such as:

- age
- level of BP on medical therapy
- rate of renal function decline
- hemodynamic significance of the lesion
- patient preference.

In other words, each patient should be assessed on an individual basis.

The choice of treatment lies between one of three options:

1 intervention by percutaneous transluminal angioplasty (PTA)
2 medical therapy but excluding an ACE inhibitor
3 medical therapy including an ACE inhibitor.

In fibromuscular dysplasia in young subjects, intervention by surgery or PTA is usually advocated. In atheromatous disease, medical therapy is more standard with consideration of intervention if BP is uncontrolled or if overall renal function deteriorates. As for medical therapy, it is normal to include a β receptor antagonist (beta-blocker) as this helps lower the normally elevated plasma renin activity. ACE inhibitors may well help control BP effectively but they have a high likelihood of worsening overall renal function. This is because, in the ischaemic kidney, angiotensin II (ATII) levels are high in order to constrict the glomerular efferent arteriole and maintain the glomerular filtration rate (GFR). An ACE inhibitor is likely to remove the protective effect of ATII and cause the GFR to fall dramatically. If this occurs in bilateral disease, plasma creatinine will rise; if this occurs in unilateral disease, the plasma creatinine may well stay normal owing to the other kidney functioning, although the drug will effectively have produced a 'medically unilateral nephrectomy'. In short, the physician may try an ACE inhibitor but only if the renal function is carefully monitored. The patient will not thank the doctor for having a normal BP at the cost of acute kidney injury.

Primary hyperaldosteronism

This will be dealt with fully in Chapter 20. The main problem is in distinguishing a single adrenal adenoma from bilateral adrenal hyperplasia. The gold standard for making this differentiation is selective adrenal vein sampling with measurement of the aldosterone/cortisol ratio in each vein but this is a very invasive procedure. This is often not required as CT scanning and/or ^{131}I-iodocholesterol scans with dexamethasone suppression will often distinguish between single adenomas and bilaterally nodular hyperplasia.

Medical therapy with spironolactone is preferred in bilateral hyperplasia. In those with a single adenoma, preoperative spironolactone for 3–4 weeks helps to control the BP prior to surgery. Surgery is curative only in those patients who have unilateral disease with a success rate of up to 60%. Laparoscopic adrenalectomy is the procedure of choice since it is associated with shorter recovery times and fewer complications than open procedures.

Phaeochromocytoma

This is dealt with in more detail in Chapter 20. The classic triad of symptoms includes episodic headaches, tachycardia and sweating. Less common symptoms include weight loss, polyuria and postural hypotension. It is worth emphasizing that, although a rare diagnosis, it is a crucial diagnosis to make since 10% are malignant. It is also worth bearing in mind that phaeochromocytomas may be part of a multiple endocrine neoplasia syndrome type 2.

Phaeochromocytoma is screened for by measuring at least two 24 hour urinary free catecholamines collections, plasma or urinary metanephrines or plasma chromogranin A. These biochemical tests should also be carried out in patients who have incidental adrenal masses detected on CT/MRI. Preoperative localization involves CT or MRI. If there is high biochemical suspicion but negative CT/MRI, functional localization with an MIBG (metaiodobenzylguanidine) scan or ^{111}In-pentetreotide scintigraphy nuclear scanning and/or venous sampling along the whole length of the superior and inferior venae cavae with samples from most of their tributaries can be considered.

Preoperative treatment should first aim to replete the contracted intravascular volume with saline. Hypovolaemia and sodium excretion is catecholamine driven. Pharmacological treatment with an alpha-blocker *before* beta-blockade is crucial. The alpha-blocker of choice is phenoxybenzamine (initially 10 mg b.d.). The dose should be increased to produce mild postural hypotension and it should be given for 1–3 weeks before surgery. More selective alpha-blockers such as doxazosin or prazosin may be used but are less effective than phenoxybenzamine. The beta-blocker must not be given without the phenoxybenzamine since endogenous catecholamines will then stimulate α receptors to cause profound vasoconstriction without the restraining influence of coincidental vasodilatory β_2 receptor stimulation. Despite this careful preparation, preoperative swings in BP are common, often requiring intravenous fluid or intravenous SNP.

The electrocardiogram

The contraction of any muscle is associated with electrical changes called depolarization and these changes can be detected by electrodes attached to the surface of the body.

The two atria contract together to produce the P wave, which is therefore due to atrial depolarization; the QRS complex represents rapid depolarization of the ventricles, and the subsequent T wave is the result of ventricular repolarization.

While recording an ECG, the speed at which the paper runs is constant (25 mm/s) so that the HR can be determined by counting the number of large squares on the ECG paper between one QRS complex and the next QRS complex. The HR in beats/min is calculated by dividing the number 300 by the number of large squares on the ECG paper that separate two consecutive QRS complexes. A simple trick to determine the exact rhythm in a tachycardic patient is to increase the speed of the ECG acquisition to 50 mm/s. This has the effect of 'slowing' the trace to enable the visualization of ECG complexes.

An ECG is not just one view of the heart rhythm. It is, in fact, six vector views (I, II, III, aVR, aVL, aVF; Figure 8.1) and six surface views (V_{1-6}) of the heart. The 12 views coming from each of the 10 leads of the standard ECG. The upward (R wave) deflection in leads V_1 and V_2 reflects the electrical activity of the right ventricle while the upward (R wave) deflection in leads V_5 and V_6 reflects the electrical activity of the left ventricle. Similarly the downward (S wave) deflection in V_1 and V_2 reflects the left ventricle while the downward deflection in V_5 and V_6

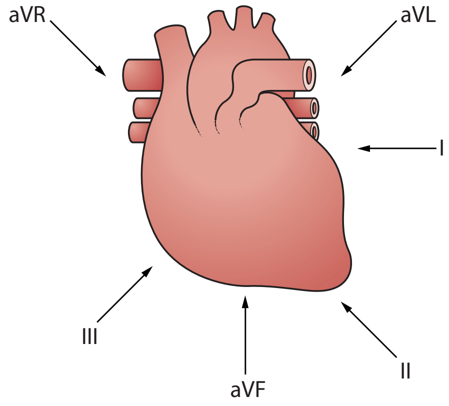

Figure 8.1 Diagrammatic representation of the angle from which each of the limb leads views the heart

reflects the right ventricle. Hence, an enlarged left ventricle will produce a tall R wave in V_6 and a large deep S wave in V_1. The ECG criterion for left ventricular hypertrophy is therefore:

$RV_6 + SV_1 > 35$ mm (i.e. seven large vertical boxes on ECG paper)

Similarly, right ventricular (RV) hypertrophy is diagnosed by an R wave in V_1 that is so tall as to be larger than the S wave, which is normally predominant in V_1, i.e. in RV hypertrophy:

$$RV_1 > SV_1 \text{ or } R/S \text{ in } V_1 > 1$$

Each limb lead views the heart from a certain position: aVR views the heart from the right arm, aVL from the left arm and aVF from the floor. Therefore, the inferior surface of the heart is best seen by II, III and aVF, so that an inferior MI produces ECG changes which are mainly or exclusively seen in leads II, III and aVF. By contrast, an anterolateral MI is mainly or exclusively seen in leads II, III and aVF. By contrast, an anterolateral MI affects mainly the left ventricle so that the ECG changes will be mainly seen in I, aVL, V_5 and V_6 since these are the leads that produce the best view of the left ventricle.

Arrhythmias

In any abnormal rhythm, the first point to note is the shape and duration of the QRS complex. If it is narrow and lasts for <0.12 seconds (three small squares or 0.04×3), the rhythm is supraventricular in origin (this includes sinus rhythm and other supraventricular rhythms). If the QRS is broad and lasts for >0.12 seconds, the rhythm is either ventricular in origin or supraventricular with bundle branch block of some kind. Ventricular rhythms have bizarre and broad QRS complexes. Apart from ventricular extrasystoles, other ventricular rhythms are ventricular tachycardia, idioventricular rhythm or ventricular fibrillation. Ventricular tachycardia is at least three ventricular extrasystoles in a row when the rate is >100 beats/min. Idioventricular rhythm is at least three ventricular extrasystoles in a row when the rate is <100 beats/min; both, but especially the latter, can occasionally be well tolerated and produce little haemodynamic upset. Ventricular fibrillation is chaotic irregular electrical activity in which no formed P, QRS or T wave complexes are discernible and in which the patient invariably becomes unconscious owing to loss of cardiac output and therefore a cardiac arrest has occurred.

There are many different types of supraventricular rhythms. The commonest is atrial fibrillation, in which the baseline ECG is irregular with no P waves and narrow normal looking QRS complexes occurring at irregular intervals. Atrial flutter is similar but the baseline has a saw tooth appearance with regular flutter waves instead of true P waves; in atrial flutter, the shape of the QRS complexes is normal although they may occur either regularly or irregularly. Sometimes it is not possible to differentiate in a given patient between atrial fibrillation and atrial flutter so that the term atrial flutter/fibrillation is used. Since the treatment (with digoxin, beta-blocker, verapamil, diltiazem or DC shock) is the same, it is not crucial to differentiate flutter from fibrillation. The third group of abnormal supraventricular rhythms are generally called supraventricular tachycardia (SVT). SVT can be further divided into atrial tachycardia or junctional (= nodal) tachycardia, but this distinction is fairly academic as treatment is the same for both types of SVT. In both kinds of SVT, the QRS complexes are narrow, normal in shape and the HR is ≥150 beats/min.

The HR itself is a useful clue as to whether a tachycardia is just a sinus tachycardia or SVT. The former are usually <135 beats/min whereas the latter are usually >145 beats/min. Clinically this is an important distinction to make as heart failure often causes sinus tachycardia and treatment should be directed to the heart failure and not specifically to the sinus tachycardia. By contrast, SVT often causes a degree of heart failure and treatment should be directed initially against the SVT rather than the heart failure.

Heart block

In first-degree heart block, the PR interval is greater than 0.2 seconds (or one large square).

Second-degree heart block has several subtypes. Second-degree heart block is usually below the level of the AV node/His bundle and therefore categorized as 'infra-Hissian'. It is divided into the following broad categories:

- *Mobitz type I (Wenkebach type):* there is progressive lengthening of the PR interval followed by a P wave with no subsequent QRS.
- *Mobitz type II:* fixed prolonged PR interval with one isolated P wave is not followed by any QRS.
- *A regular pattern* (e.g. 2:1 or 3:1) in which every second or third P wave has no subsequent QRS complex.

In third-degree (or complex) heart block, the P waves and the QRS complexes occur independently and at different times from each other.

Heart block can also occur in the right and left bundle branches. In bundle branch block, the QRS complex is widened (>0.12 seconds or more than three small squares). Right bundle branch block is best seen in V_1 in which there is an RSR pattern to the QRS complex. Left bundle branch block is best seen in V_6 in which the QRS complex forms an M pattern. In both cases, the subsequent T wave is inverted.

In MI, there are four characteristic ECG changes:

1. hyperacute T waves (early on)
2. ST elevation
3. T wave inversion
4. Q waves (later on).

These changes are seen mainly in II, III and aVF in inferior MIs and in I, aVL, V_4–V_6 in anterolateral MIs. Other leads may show reciprocal changes (i.e. marked T wave inversion only). One subgroup of MIs are non-ST elevation MIs (NSTEMI), in which the infarcted muscle is less extensive. In NSTEMIs, either no Q waves are found but very prominent T wave inversion occurs or new left bundle branch block occurs. Surgery should preferably be delayed for at least 3 months after any kind of MI. This is not the case after an episode of angina so that it is often important to ascertain whether an episode of chest pain has been ischaemia or infarction as confirmed from troponin T (or I) levels and clinical diagnosis.

An elevated ST segment is due either to an MI or to pericarditis. In the former, the ST elevation is usually convex in shape and limited to certain ECG leads. In pericarditis, the ST elevation is concave and is widespread over many ECG leads. In contrast, ST depression often coincides with T wave inversion and this combined pattern occurs in many situations, e.g. in the presence of ischaemia, bundle branch block, ventricular hypertrophy ('strain pattern'), hypokalaemia or in any patient receiving digoxin therapy.

Pulmonary embolism

The ECG changes seen in pulmonary embolism (PE) are:

- sinus tachycardia (most common)
- T wave inversion V_{1-3} (greatest sensitivity for diagnosis of PE)
- right bundle branch block
- SI QIII TIII is a sign of acute cor pulmonale (sensitivity of 54% and a specificity of 62% often quoted, and also been reported in air embolism and pneumothorax; see Ferrari *et al.*)
- right ventricular hypertrophy and strain (i.e. tall R in V_1, tall P waves).

These changes can be used as tentative support only to a clinical suspicion of PE. The clinician should confirm the diagnosis of PE by either a *V/Q* scan (if the patient has a normal chest radiograph) or a CT pulmonary angiogram before long-term anticoagulation is begun. Pregnant patients should undergo a perfusion scan only to minimize fetal radiation exposure.

Cardiac arrest

Cardiac or circulatory arrest can occur under numerous and varied circumstances, which makes it inappropriate to define a rigid and didactic strategy for its management. The correct approach to cardiopulmonary resuscitation (CPR) is therefore a flexible one that can then be tailored to individual circumstances.

There is a wide differential for causes of fairly sudden loss of consciousness, including vasovagal syncope, cerebrovascular accident, epilepsy, hypoglycaemia, drug overdose or trauma. These should be considered if both a carotid pulse and respiration are still present in a suddenly unconscious patient. If on initial assessment a carotid pulse is palpable but respiration absent, then this is respiratory arrest and attention should be focused on maintaining a good airway and artificial ventilation. If no carotid pulse is present then cardiac arrest can be assumed to have occurred and CPR should be undertaken.

Types of cardiorespiratory arrest

Ventricular fibrillation/pulseless ventricular tachycardia

Causes include:

- ischaemic heart disease (usually post-MI)
- structural heart disease (e.g. hypertrophic cardiomyopathy/dilated cardiomyopathy)
- severe electrolyte abnormalities
- drug-induced/congenital long QT interval.

Pulseless electrical activity/electromechanical dissociation: electrical activity on ECG but no pulse

Causes include:

- hypothermia
- hypoxia
- hypo-/hyperkalaemia
- hypovolaemia
- tension pneumothorax
- PE
- cardiac tamponade
- toxic/overdose.

Asystole

Respiratory arrest alone (carotid pulse present)

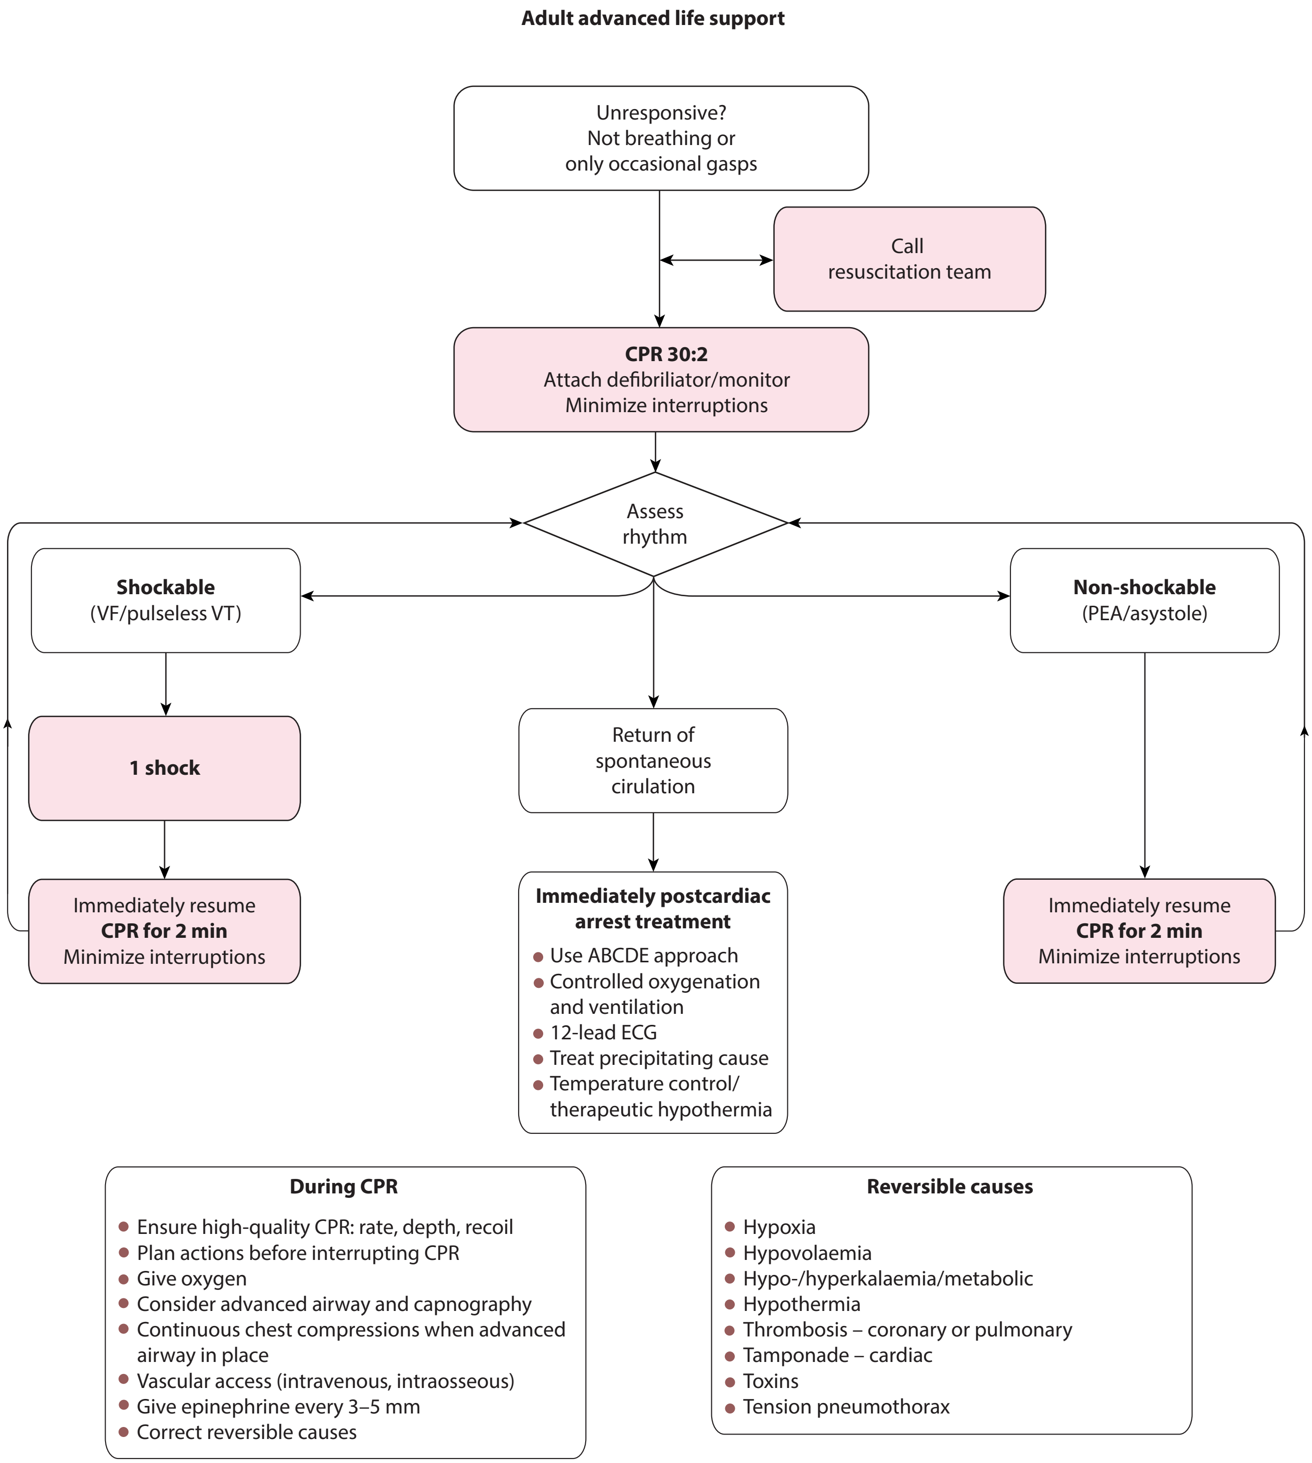
Causes include:

- respiratory disease, e.g. foreign body, pneumothorax
- respiratory depressant drug (e.g. intravenous diazepam for a minor surgical or dental procedure).

Initially, the patient should be positioned flat on the floor or on a firm surface. The head should be extended and the airway inspected so that any foreign matter can be removed directly from the larynx. Artificial ventilation should be begun using a Guedel airway, a mask and a respirator bag. As soon as personnel are available, the patient should be intubated and ventilated with 100% oxygen. It must be checked by stethoscope that both lungs are being ventilated equally in order not to overlook a pneumothorax, a lodged foreign body or an endotracheal tube that has been pushed past the tracheal bifurcation. The latest Resuscitation Council guidelines are shown in Figure 8.2.

At this stage, as well as obtaining an ECG, intravenous access should be secured. This should ideally be via a jugular, subclavian or femoral vein but an antecubital vein is better than none.

If resuscitation is successful, it is crucial to review possible reversible causes to prevent repetition of the arrest. Blood should be assessed for full blood count, glucose, electrolytes, arterial pH and gases. A full 12-lead ECG should be taken to exclude MI, arrhythmia, heart block or PE. A chest radiograph should also be taken to exclude pneumothorax, aspiration, tamponade, aortic dissection and to check the position of any endotracheal tube.



Adult advanced life support
Unresponsive? Not breathing or only occasional gasps
Call resuscitation team
CPR 30:2
Attach defibriliator/monitor
Minimize interruptions
Assess rhythm
Shockable
(VF/pulseless VT)
1 shock
Immediately resume
CPR for 2 min
Minimize interruptions
Return of spontaneous cirulation
Immediately postcardiac arrest treatment
Use ABCDE approach
Controlled oxygenation and ventilation
12-lead ECG
Treat precipitating cause
Temperature control/ therapeutic hypothermia
Non-shockable
(PEA/asystole)
Immediately resume
CPR for 2 min
Minimize interruptions
During CPR
Ensure high-quality CPR: rate, depth, recoil
Plan actions before interrupting CPR
Give oxygen
Consider advanced airway and capnography
Continuous chest compressions when advanced airway in place
Vascular access (intravenous, intraosseous)
Give epinephrine every 3–5 mm
Correct reversible causes
Reversible causes
Hypoxia
Hypovolaemia
Hypo-/hyperkalaemia/metabolic
Hypothermia
Thrombosis – coronary or pulmonary
Tamponade – cardiac
Toxins

Cardiac failure

Pathophysiology

This is defined as an inability of the heart to meet tissue requirements for oxygen. In the vast majority of cases this is due to myocardial disease causing a low CO (low output cardiac failure). In a minority of cases, this is because of an increase in tissue requirements for oxygen such as thyrotoxicosis, anaemia, AV malformation or Paget disease of the bone – the so-called ‘high output failures’. In these cases, the CO is increased but is still insufficient for tissue requirements.

Heart failure is divided into right- and left-sided heart failure depending on the relative degrees of impairment of each ventricle. Classification can also be based on whether the impairment is in systolic or diastolic (also known as heart failure with normal ejection fraction) function. The commonest cause of left heart failure is ischaemic heart disease leading to MI that makes part of the left ventricle non-contractile. Cardiomyopathy or cor pulmonale are other causes of heart failure but the medical treatment of all three of the above forms of heart failure are similar so that it is not quite so crucial to differentiate them. Almost all the evidence base for therapy in heart failure comes from trials in systolic dysfunction. At present, there are no therapies that have been proven to improve survival in diastolic heart failure and therefore these patients are managed primarily for symptom control with diuretics and treatment of other cardiovascular risk factors such as hypertension.

It is therefore mandatory to think what has caused heart failure in any given patient since the treatment is very different depending on the underlying causes. Too often, for example, it is not noticed that the cause of heart failure in a given patient is the arrhythmia of uncontrolled atrial fibrillation. Diuretics alone do little to help such patients whereas bringing the ventricle rate down to 80 beats/min from 140 beats/min by the correct use of digoxin, beta-blockers or DC cardioversion will effect a more meaningful change in their cardiac function. An ECG and echocardiogram is essential in every dyspnoeic patient to establish the heart rhythm. Fast atrial fibrillation is often precipitated in a surgical patient by a postoperative chest infection.

It is essential to remember that a patient may have more than one cause for heart failure. For example, a patient with mitral valve disease will often have fast atrial fibrillation, the substrate being an enlarged left atrium. Similarly, an older patient with aortic valve disease may in addition have had a previous MI leading to poor ventricular function. If the latter disease is more severe than the former, then aortic valve surgery may have little impact on symptoms and the correct procedure would be optimization of medical therapy for the ischaemic heart disease. All patients with heart failure therefore require to be thoroughly assessed for the underlying cause or causes: if more than one cause exists, then the relative contribution of each cause must be thoroughly assessed in order to plan the correct treatment in that individual.

Whatever its aetiology, one of the clinical hallmarks of heart failure is renal sodium and water retention, which ultimately causes ankle oedema, raised jugular venous pressure and pulmonary oedema. Sodium (and therefore fluid) retention occurs as a maladaptive compensatory process in response to many pathophysiological changes seen in heart failure. For example, reduced tissue perfusion from forward pump failure and reduced intravascular volume from poor backward negative ‘suction’ pressure from the right ventricular dysfunction. This can easily be inferred from the fact that a major part of the treatment of heart failure is diuretic therapy, which is designed to reverse this sodium and water retention.

Principles of treatment

It is crucial to appreciate that the aims of therapy in acute and chronic heart failure are very different with acute cardiac decompensation being more relevant to surgical practice. In the acute case, the aim is often to support cardiovascular function until it recovers spontaneously as a result of the natural healing processes which occur after surgery (or even after MI). This is achieved by consideration of ventricular function curves and the correct use of combined therapy with diuretics, inotropic drugs and vasodilators, in order to increase systemic BP and SV while also decreasing filling pressures. It is felt that optimizing these three haemodynamic parameters keeps patients alive longer so that spontaneous healing is given a longer timescale in which to operate. Chronic heart failure is very different in that optimizing haemodynamic parameters would seem to be a logical step but, surprisingly, there is little correlation between the acute haemodynamic effects of various drugs and their long-term effects on morbidity and mortality so that the acute haemodynamic effects of drugs are of lesser importance. Invasive haemodynamic monitoring is therefore of relevance only to the acutely ill cardiac patient.

The Starling curve is a physiological mechanism that occurs in normal man. In heart failure, the pattern is rather different: the ventricular function curve lies below the normal curve. In addition, the curve is much flatter so that the large increase in end-diastolic pressure produces only a small, if any, increase in SV (Figure 8.3).

It is important to realize that there are clinical implications to this ventricular function curve (Figure 8.4). If this renal sodium/water retention overshoots, then the end-diastolic pressure rises excessively and pulmonary oedema occurs.

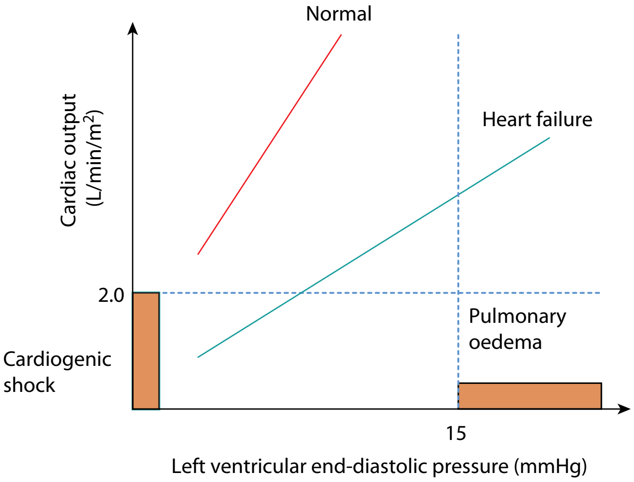

Figure 8.3 The ventricular function (or Starling) curve for a normal heart and for a patient with heart failure showing when cardiogenic shock and pulmonary oedema occur.

Left ventricular end-diastolic pressure (mmHg)

Figure 8.4 The effect of various drugs on ventricular function.

In older terminology, this is called 'backward failure' of the heart because fluid accumulates prior to the left ventricle, i.e. in the lungs. In this situation, venous pressure is very high, CO is moderately low but systolic BP is maintained. The correct treatment here is either intravenous diuretic therapy or venodilator therapy such as nitrates. Diuretics will reduce the circulating volume, hence reducing the end-diastolic pressure with it – the symptoms of pulmonary oedema. Nitrates will more directly reduce end-diastolic pressure and pulmonary oedema by reducing preload. The opposite clinical problem occur when SV falls excessively, then the syndrome of cardiac shock will ensue. This used to be called 'forward failure' of the heart. In this situation, CO and systolic BP are both very low while venous pressure is only moderately increased. Hence the correct treatment is to increase the SV: this could be achieved best by administering an inotropic drug such as dobutamine. In some other situations, the SV can be augmented not only by a directly acting inotropic drug but also by an arterial vasodilator drug. This is because, often, a low CO is due to resistance to flow in the arterial tree so that an arterial dilator will reduce afterload and hence indirectly boost SV. In the precise case of cardiogenic shock, this would not be as valuable a strategy since the arterial vasodilator might further reduce an already low systemic BP but it would be useful therapy in myocardial failure with a reasonable level of systemic BP. Therefore, in deciding about therapy of heart failure, there is a third parameter that must be considered – the systolic BP. The treatment of heart failure involves optimizing the systolic BP, the cardiac index and the pulmonary artery wedge pressure (PAWP), and in devising treatment in heart failure it is a useful exercise to think through what effect each administered drug will have on each of these three parameters.

Knowledge of the ventricular function curve for each individual allows medical therapy to be monitored more precisely. This involves the insertion of a Swan–Ganz catheter so that cardiac index and PAWP are directly measured in an individual patient. The insertion of a Swan–Ganz catheter is not justified in every case of heart failure but should be considered in the following situations:

- in severe heart failure not responsive to initial (e.g. diuretic) therapy
- in hypotensive shock, to establish its aetiology and to monitor treatment.

In both situations the aim is to optimize the three parameters of systolic BP, cardiac index and PAWP. The more specific aims are to reduce the PAWP pharmacologically, to prevent pulmonary oedema and/or to boost the CO and systolic BP in order to prevent cardiogenic shock. Some guidelines are suggested in Table 8.1.

The clinical situation in which the Swan–Ganz catheter is most useful is the patient with pulmonary oedema who is receiving intravenous nitrate therapy when knowledge of the PAWP and cardiac index will help the clinician to use a nitrate infusion rate that will reduce PAWP into an acceptable range without dropping systolic BP or cardiac index by too much. Invasive Swan–Ganz catheters are rarely used today as the management of acute heart failure has progressed to cardiac support using intra-aortic balloon pumps (IABP) and continuous positive airways pressure (CPAP).

Table 8.1 How to interpret invasive haemodynamic parameters

Systolic BP (mmHg)	PAWP (mmHg)	Cardiac index (L/min)	Diagnosis	Treatment
Normal	<15	2.7–3.5	Normal	Nil
<100	<15	<2.7	Hypovolaemic shock	Plasma expansion
<100	>18	<1.8	Cardiogenic shock	Inotropes
>100	>18	<1.8	Pulmonary oedema	Diuretics/ nitrates/ ultrafiltration

BP, blood pressure; PAWP, pulmonary artery wedge pressure.

IABPs are devices that are inserted percutaneously via the femoral artery and, as the name implies, are situated in the descending aorta. These devices inflate in synchrony with the ECG and the central aortic pressure waveform. The objective of the IABP is to inflate in diastole and therefore improve coronary perfusion (which occurs during diastole) and deflate at the end of systole, reducing afterload and therefore improving CO.

CPAP on the other hand is a non-invasive method of oxygenating the alveolar spaces by positive airway pressure. It is particularly useful in the setting of type I respiratory failure (hypoxia) due to left ventricular failure. The starting settings are usually 5 cmH_2O and are increased in increments of 2.5 cmH_2O up to 10 cmH_2O.

Another newer therapy in acute decompensated heart failure is ultrafiltration. This is in fact very similar to dialysis in that the free water component of the intravascular volume is removed. The UNLOAD trial showed significantly greater fluid loss and fewer heart failure hospitalizations with ultrafiltration than with intravenous diuretics. Perhaps most impressively, there were no statistically significant differences in creatinine levels either. Ultrafiltration is often limited by the patient's BP and must be discussed with a renal specialist in advance if a patient is not responding to intravenous diuretic therapy.

It must be emphasized that postoperative heart failure may not be simply due to myocardial dysfunction and it is crucial to exclude other cause, e.g. pericardial tamponade. This differentiation can be remarkably difficult as both conditions can produce the same findings on clinical examination, chest radiograph, ECG, echocardiography and even on Swan–Ganz catheterization. Bedside echocardiography is invaluable and can be used to help make this distinction clinically. In myocardial dysfunction, the low cardiac ejection function is evident but there are no specific pericardial abnormalities on the scan.

Cardiac pharmacotherapy

Inotropic drugs

Some, but not all, inotropic drugs also cause vasodilation. One major limitation here is that all inotropic drugs can cause arrhythmias, so that they tend to be reserved for acutely ill patients and to be used for as short a time period as the clinical situation permits. None of the inotropic agents in acute heart failure have been shown to improve survival from the condition.

Dobutamine

This acts as a β-agonist, principally on the β_1-adrenergic receptor to cause an inotropic and chronotropic effect. It can only be given intravenously. Peripheral vasodilation is also seen to a modest extent, but it does not specifically dilate renal arteries. The problem with administering dobutamine is twofold: dobutamine loses its effectiveness in time (tachyphylaxis) because of downregulation of the constantly stimulated β receptors, and, second, a proarrhythmic effect can occur. For these two reasons, dobutamine is used mainly as a temporary measure in states of acute cardiac decompensation (cardiogenic shock) but is not generally used routinely in chronic heart failure. In the latter condition dobutamine probably improves haemodynamics initially but leads to an earlier arrhythmic death (Table 8.1).

Dopamine

This if very different from dobutamine, although, like dobutamine, it also can only be given intravenously. At low dose, dopamine stimulates specific dopaminergic receptors and at higher doses it stimulates α and β receptors, although the α receptor stimulation predominates. Dopaminergic stimulation at low dose causes widespread vasodilation, especially of the renal arteries, which helps to reverse early acute renal failure. At higher dose, α receptor stimulation causes the opposite effect of vasoconstriction and decreased renal blood flow. High-dose dopamine will raise systemic BP owing to peripheral vasoconstriction, but this advantage is offset by the fact that high-dose dopamine will cause renal vasoconstriction and so increase the tendency to acute renal failure. Commonly, therefore, the dose of dopamine is kept as low as possible in order to improve any decline in renal function. Recent large multicentre, randomized controlled trials have demonstrated that low-dose dopamine administered to critically ill patients who are at risk of renal failure does not confer clinically significant protection from renal dysfunction and therefore this regimen is not currently used in routine clinical practice.

Phosphodiesterase inhibitors

β_1 and β_2 receptor stimulation leads to an increase in intracellular cyclic AMP (cAMP), which then causes their inotropic, chronotropic and vasodilatory effects. An alternative way of producing the same beneficial effects is to block the breakdown of intracellular cAMP. cAMP phosphodiesterase is the enzyme involved here so that a phosphodiesterase inhibitor will have similar effects to a β_1 and β_2 agonist. There are two such phosphodiesterase inhibitors: amrinone and milrinone. However, clinical trials such as OPTIME-CHF showed no benefit, and possibly some harm, from milrinone therapy.

Nesiritide

Nesiritide is a recombinant form of plasma B-type natriuretic peptide, which has natriuretic and vasodilator properties. Clinical trials have shown that, although nesiritide improves cardiac parameters, it did not improve survival and may worsen renal function in patients with acute decompensated heart failure.

Digoxin

Digoxin can be classified as an inotropic drug. It is used as an inotropic in chronic heart failure in sinus rhythm but here its usefulness is being disputed. It is little used in acute cardiac decompensation in which dopamine, dobutamine and amrinone are generally used for inotropic support before digoxin is given. The clearest indication for digoxin is in treatment of atrial fibrillation. Here it causes conduction delay at the AV node, which benefits patients with fast atrial fibrillation because it reduces the rate of the ventricular response to the fibrillating atria.

Digoxin has a very narrow therapeutic index, which means that its toxic dose is only marginally higher than its therapeutic dose. Hence, it is important to measure plasma digoxin levels and alter the dose of digoxin accordingly. Digoxin has a long half-life so that, even with normal renal function, only one-third of a digoxin dose is excreted within the first 24 hours after ingestion. Digoxin accumulates to potentially dangerous levels in the presence of even mild renal impairment so that monitoring of plasma digoxin levels is mandatory in the presence of any renal dysfunction.

Other vasodilators

Unfortunately, the term vasodilator includes different groups of drugs to different people. There is no doubt that nitrates, nitroprusside, hydralazine and minoxidil are vasodilators, and that the precise mechanisms of action of these drugs are uncertain. With other groups of drugs their mechanism of action is known, so that, although they are also vasodilators, they are often classified by their mechanism of action rather than under the general heading ‘vasodilators’. In other words, α_1-antagonists, calcium antagonists and ACE inhibitors are strictly speaking vasodilating drugs but, in practice, when the term ‘vasodilator’ is used, it sometimes does and sometimes does not include the α-antagonists, calcium antagonists or ACE inhibitors.

Nitrates dilate mainly the venous bed, whereas hydralazine and calcium antagonists are mainly arterial dilators. Many drugs such as nitroprusside, α_1-antagonists (prazosin) and ACE inhibitors produce a mixed pattern with dilatation of both the arterial and venous beds. Therefore, hydralazine will principally increase CO and tissue perfusion whereas nitrates will reduce pulmonary congestion.

These drugs can, of course, be used together to produce the desired effect on the ventricular function curve. In addition, they are often used along with inotropes to optimize therapy, e.g. dobutamine and nitroprusside.

The third factor which must be considered and which is not on the ventricular function curve is the systemic BP, which all vasodilators will tend to reduce and which is a limiting factor in the use of vasodilator therapy. This is another reason for combining inotropes and vasodilators to prevent excess BP reduction.

All vasodilators are contraindicated in obstructive valvular stenosis or hypertrophic obstructive cardiomyopathy but they are very helpful in valvular incompetence.

Invasive monitoring is desirable when vasodilators are used in acute cardiac decompensation in order to titrate the dose to prevent excessive reduction of preload or of CO and BP.

Nitrates

Nitroglycerin can be given sublingually, as a spray, as skin patches or as a buccal preparation, but these are mainly for use in chronic stable angina. Isosorbide mononitrate or dinitrate can also be given orally or intravenously and it is the latter which is most relevant to surgical patients with acute cardiac decompensation or patients with post-bypass hypertension.

One problem with all nitrates is that patients become tolerant to them very rapidly. After discontinuing a nitrate, a patient will rapidly lose this nitrate tolerance. Ideally, therefore, nitrates should be given only intermittently, e.g. for 12 hours of each day only, although this is difficult to achieve in an acutely ill patient.

Nitroprusside is ideal in this situation because of its rapid onset of action and its rapid cessation of activity.

Hydralazine

This is available for oral and intravenous use. Hydralazine has a delayed onset and offset of action so that unpredictable hypotension is not immediately reversible on stopping hydralazine. Intravenous hydralazine is of some value in heart failure following cardiac surgery. The combination of hydralazine and nitrates has been shown to be particularly useful in black patients in the African-American Heart Failure (A-HEFT) trial.

α_1-Antagonists

Doxazosin is the most commonly used α_1-antagonist but it is only available orally; therefore, it is mainly used to treat chronic hypertension or chronic heart failure. It is seldom used in acute cardiac decompensation.

The most relevant use of α_1-antagonists to the surgeon is in patients with phaeochromocytomas. Phenoxybenzamine is given orally for several weeks prior to surgery. Phentolamine is a different drug that is given intravenously when acute alpha-blockade is desired as, for example, during an acute hypertensive crisis due to a phaeochromocytoma. Although doxazosin, phentolamine and phenoxybenzamine sound alike and are all α-antagonists, their individual properties and their clinical uses are very different.

Other drugs

Calcium antagonists and ACE inhibitors are of lesser relevance to surgeons. Although there are three main calcium antagonists (nifedipine, diltiazem and verapamil), only diltiazem and verapamil produce AV block and hence help in the management of supraventricular arrhythmias.

ACE inhibitors are in widespread use in the treatment of chronic heart failure and essential hypertension. Many such patients will come to surgery for other reasons and an area of uncertainty exists here. The renin–angiotensin system is activated at times of hypovolaemia (e.g. during perioperative blood loss) to prevent the BP falling too much. ACE inhibitors will block the renin–angiotensin system and hence prevent this defence mechanism. Monitoring of BP and central venous pressure may thus be even more important if a patient is pretreated with an ACE inhibitor.

Antiarrhythmic agents

This topic is complex and of little relevance to surgeons except in the context of postoperative arrhythmias. There is a detailed Vaughan Williams classification of antiarrhythmic drugs but this classification is of pharmacological interest only and is of little therapeutic relevance. The problem with all antiarrhythmics drugs is twofold. They are nearly all cardiodepressant so that the minimum dose possible should be used in cardiac failure. Second, all antiarrhythmics drugs can actually promote arrhythmias (be proarrhythmic) in some subjects. The management of ventricular tachycardia and fibrillation is discussed in Cardiac arrest.

Postoperative atrial fibrillation should be managed by digoxin (if blood pressure is low and not in acute renal injury) or beta-blockers. Decision on anticoagulation must be made on an individual patient basis balancing the risk of a thromboembolic event with bleeding risk.

With supraventricular arrhythmias, the key issue is the rate at which the ventricle is beating. When the ventricular rate is >120 beats/min then the ventricle does not have enough time to fill and empty efficiently so that the CO is low. Often, therefore, reducing the ventricular rate by increasing the degree of block at the AV node (by digoxin, beta-blocker, verapamil or diltiazem) will improve the patient's clinical state dramatically. They might return to sinus rhythm, but often with digoxin, beta-blocker, verapamil or diltiazem they will remain in atrial fibrillation but at a satisfactory ventricular rate. In other words, these treatments aim to minimize the adverse haemodynamic effects of the arrhythmia but not to abolish the arrhythmia. If abolishing the supraventricular arrhythmia is the desired clinical goal, then the measures to consider are elective DC cardioversion, flecainide, disopyramide, amiodarone or overdrive pacing. Prior to these measures, carotid sinus massage or a Valsalva manoeuvre are worth trying but only in the specific case of supraventricular tachycardia since they have no useful effect in fast atrial fibrillation or atrial flutter.

CHAPTER 9

Pulmonary insufficiency

ELIZABETH STARREN, WILLIAM L. OLDFIELD AND ONN MIN KON

Anatomy

The airways consist of multiple tubes connected in both series and parallel fashion that can be classified into two sections according to function: the conducting zone and the respiratory zone. The conducting zone encompasses the oronasopharynx, larynx and trachea, which divides into the right and left main bronchi at the level of the second thoracic vertebrae. These subsequently subdivide into the lobar (secondary) bronchi, segmental (tertiary) bronchi and then terminal bronchioles (diameter <1 mm). This section of the lung is known as the conducting zone as its rigid, largely cartilaginous structure facilitates the passage of inspired air to the respiratory zone and the ciliated epithelium humidifies and filters air before gas exchange occurs. The first 16 divisions or orders of branching airways make up the minority of the lung volume and its blood supply is from the bronchial circulation that originates from the left side of the heart.

The respiratory zone refers to the respiratory bronchioles, alveoli, alveolar ducts and sacs. Branching orders 17–23 contain approximately 300 million alveoli, thus providing a vast surface area available for gas exchange. The primary function of the lung – gas exchange – occurs by passive diffusion of oxygen (O_2) and carbon dioxide (CO_2) across thin alveolar–capillary membranes. This gas–blood barrier comprises type I (squamous epithelial) pneumocytes, type II (surfactant producing) pneumocytes, elastic fibres, alveolar macrophages and networks of pulmonary capillaries. The blood supply is via the pulmonary circulation that originates from the right side of the heart. The pulmonary artery branches repeatedly alongside the course of the bronchi to eventually form the capillary networks that encompass the alveoli. Each red cell spends 0.75 seconds within the pulmonary capillaries to complete gas exchange. Blood is returned via the pulmonary veins.

Ventilation

The transport of oxygen and carbon dioxide

Gas transport between blood and tissues occurs, as in the lungs, by passive diffusion across a concentration gradient. Approximately 98% of O_2 is transported as oxyhaemoglobin (HbO_2), hence O_2 carriage is reduced in the anaemic state. The remaining 2% is carried as dissolved O_2. The O_2 dissociation curve (Figure 9.1) defines the relationship between O_2 tension and haemoglobin (Hb) saturation. A right shift occurs at increased hydrogen (H^+)

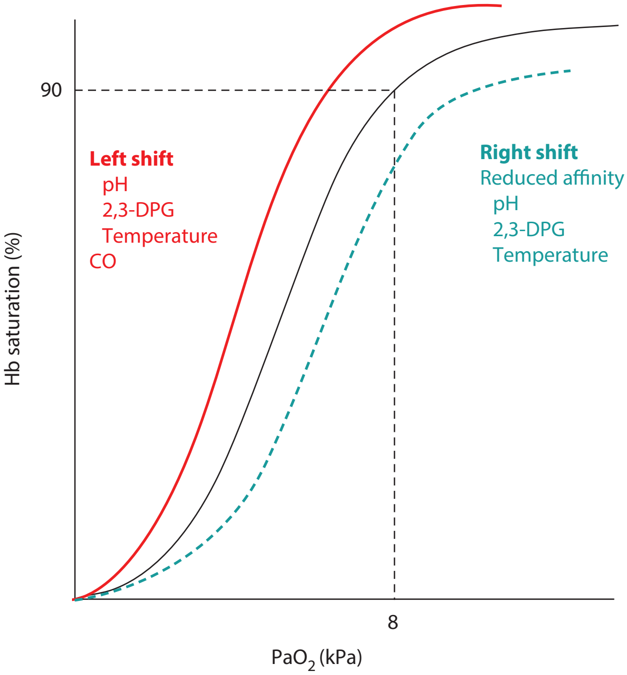

Figure 9.1 Oxygen dissociation graph. 2,3-DPG, 2,3-diphosphoglycerate; Hb, haemoglobin.

ion concentration, CO_2 tension, 2,3-diphosphoglycerate (2,3-DPG) concentration in red blood cells and body temperature, and facilitates O_2 delivery to tissues in the active, hypoxic state. A left shift occurs at reduced H^+ ion concentration, CO_2 tension and body temperature as well as in the presence of carbon monoxide. In these situations, O_2 has a higher affinity for Hb and thus unloading to tissue is reduced.

CO_2 is highly soluble and is transported within the red blood cells as dissolved CO_2, carbamino-haemoglobin (CO_2 + Hb) and bicarbonate (HCO_3). In the presence of carbonic anhydrase, carbonic acid ($CO_2 + H_2O$) is formed within the red cells and, in turn, bicarbonate is formed from the dissociation of hydrogen ions from this compound. In summary:

$$CO_2 + H_2O \leftrightarrow H_2CO_3 \leftrightarrow H^+ + HCO_3^-$$

The resultant free hydrogen ions are responsible for the Haldane effect as deoxyhaemoglobin (reduced Hb) is a greater proton acceptor than oxyhaemoglobin. In the presence of deoxyhaemoglobin (H + Hb), which is abundant in peripheral tissues, the equations are shifted right and CO_2 carriage is increased. In the presence of oxyhaemoglobin (HbO_2), as at the alveolar–capillary membrane, CO_2 is displaced and thus eliminated. In summary:

$$H^+ + HbO_2 \leftrightarrow H^+Hb + O_2$$

The pH of blood is maintained around 7.4 and small deviations in this value of blood pH can lead to severe metabolic consequences. Blood buffering is therefore extremely important in maintaining this level. Although blood contains numerous cations (e.g. Na^+, K^+, Ca^{2+} and Mg^{2+}) and anions (e.g. Cl^-, PO_4^{3-} and SO_4^{2-}) that can play a role in buffering, the primary buffers in blood are Hb in erythrocytes and bicarbonate in the plasma. This buffering by Hb is achieved by ionization of the imidazole ring of histidines in the protein.

Gas exchange

Optimal gas exchange requires a matched supply of inspired gas and blood to each alveolus; however, an inherent physiological ventilation (*V*)/perfusion (*Q*) mismatch exists in humans. Blood flow is greatest in the dependent bases when standing owing to hydrostatic pressure, whereas ventilation is reduced owing to orthostatic pressure. The converse applies at the lung apices. Respiratory diseases exacerbate the disparity between ventilation and perfusion, leading to respiratory failure. In chronic obstructive pulmonary disease (COPD), bronchial constriction impairs airflow and destruction of alveolar walls limits gas exchange. In lobar pneumonia inflamed oedematous alveoli inhibit diffusion and in pulmonary emboli (PE) sections of lung lack blood supply but remain adequately ventilated. In critical care, patients are sometimes positioned so that their healthy lung is in the dependent position to improve blood flow and thus gas exchange; an example of this is prone ventilation in acute respiratory distress syndrome (ARDS).

Mechanics of ventilation

During inspiration, thoracic cavity volume increases owing to the inferior movement of the diaphragm and elevation of the ribs by intercostal muscle contraction. In turn, intrapulmonary volume increases (owing to effective pleural adhesion of the thoracic wall and lung) and generates a relatively negative intrapulmonary pressure. The gradient between this and the atmospheric pressure draws air into the lungs. When performing thoracic or abdominal surgery in patients with neuromuscular disorders (poliomyelitis, myasthenia gravis, motor neurone disease) respiratory failure is predictable and can be reduced by protective measures such as head-up positioning, chest physiotherapy and nocturnal non-invasive ventilation. Similarly, chest wall and spinal deformity (kyphoscoliosis, pectus excavatum) may restrict ventilation and should be considered preoperatively.

During resting ventilation, expiration is passive. Elastic recoil causes compression of the alveoli, resulting in increased alveolar pressure and diffusion of gases outwards towards the lower atmospheric pressure. Forced expiration utilizes both thoracic and abdominal muscles.

Airflow within the airways is laminar during quiet breathing but becomes turbulent at high flow velocities; therefore, any state that increases the rate of breathing will increase the work of breathing. Airflow resistance is increased by narrowing of the airways, thus bronchoconstriction, secretions and mucosal oedema all restrict airflow.

Compliance is defined as the force required to overcome the combined resistance provided by the counteracting elastic properties of the chest wall, pleura, lungs and abdomen in order to alter lung volume. The relationship dictates that the lower the compliance, the greater the pressure required to achieve a given change in volume (‘stiff lungs’). Different diseases are associated with decreased or increased compliance (Table 9.1).

Table 9.1 Conditions associated with changes in lung compliance

Decreased compliance	Increased compliance
Pulmonary fibrosis	COPD
Asthma Pneumonia	The ageing lung
Atelectasis/lobar collapse	
Pulmonary oedema	
Obesity	
Chest wall deformity	
Thoracic surgery	

COPD, chronic obstructive pulmonary disease.

Control of ventilation

Respiratory rate and tidal volume are controlled to maintain alveolar tensions of O_2 in the region of 13.3 kPa and CO_2 at 5.5 kPa and a consequent arterial pH of 7.45. Central (located on the ventral surface of the medulla) and peripheral (located in the carotid and aortic bodies) chemoreceptors detect increases in CO_2 and H^+ concentration in cerebrospinal fluid and arterial blood, and decreases in arterial O_2 tension to stimulate hyperventilation via the brainstem respiratory centre (located in the pons and medulla). Local mechanical receptors such as stretch, J and irritant receptors also influence ventilation through feedback mechanisms. The cerebral cortex can exhibit voluntary control over breathing.

Innervation of the lungs

The pleura and the lungs are innervated by anterior and posterior pulmonary plexi, which consist of parasympathetic (vagal) and sympathetic fibres. Parasympathetic efferent fibres control smooth muscle bronchoconstriction, vasoconstriction and gland secretion. Conversely, sympathetic efferent fibres relax and inhibit these processes. Visceral sensory fibres sense touch, pain and stretch.

The diaphragm is innervated by spinal nerves C3–5 via the phrenic nerves. The intercostal muscles are supplied via the intercostal nerves from spinal nerves T1–11.

Phrenic nerve damage is a serious, well-recognized complication of thoracic procedures which results in diaphragm paralysis. The diagnosis is made with a chest radiograph (raised hemidiaphragm), thoracic ultrasound ('sniff test' demonstrates paradoxical diaphragm movement) and nerve conduction studies. Lung function testing can be useful (low volumes and worse in supine position). Management includes head-up positioning and non-invasive ventilation. Recovery is possible but is usually protracted given the slow rate of nerve regeneration.

Respiratory failure

Respiratory failure is defined as a PO_2 of less than 8 kPa or an inability of the lungs to adequately oxygenate arterial blood and/or clear CO_2.

There are four mechanisms of respiratory failure:

1. *shunting* (pneumonia, atelectasis, congenital heart disease)
2. *diffusion impairment* (pneumonia, interstitial lung disease)
3. *hypoventilation* (neuromuscular disease, drug overdose, chest wall compromise such as traumatic non-penetrating injury, diaphragm splinting, fatigue, wasting)
4. *ventilation–perfusion mismatch* (COPD, PE, pulmonary oedema, interstitial lung disease).

The type of respiratory failure is defined according to the arterial CO_2 concentration. *Type 1 respiratory failure* is hypoxia (PO_2 <8 kPa) in the presence of normocarbia. This can be considered to be a failure of oxygenation. This is often corrected with O_2 via a facemask but sometimes requires continuous positive airways pressure (CPAP) or invasive ventilation. Shunting and diffusion impairment are associated with type 1 respiratory failure. *Type 2 respiratory failure* is hypoxia (PO_2 <8 kPa) with associated hypercarbia (PCO_2 >6.5 kPa) and indicates a failure of ventilation. The presence of an acidosis suggests an acute deterioration. Metabolic compensation occurs in chronic type 2 respiratory failure, thus the pH is normalized but bicarbonate elevated. Although mechanical ventilation was previously the only option to manage such cases, bilevel non-invasive ventilation in which an inspiratory positive airways pressure inspiratory pressure (IPAP) is applied in addition to providing positive end expiratory pressure via a facial or nasal mask is now widely used, although the evidence base for its use in postoperative cases is limited. Non-invasive ventilation is indicated when there is type 2 respiratory failure in association with a pH <7.35.

Non-invasive ventilation

Non-invasive ventilation is generally applied in the setting of a high-dependency or intensive care unit, as this requires specialist staff and equipment. It is important to be aware that the raised intrathoracic pressures generated by non-invasive ventilation cause reduced venous return and thus cardiac output. Care is needed to ensure that the patient is intravascularly replete to avoid tissue hypoperfusion and hypotension, which in itself can worsen acidosis.

Non-invasive ventilation provides time to establish definitive treatment for the underlying condition and is not in itself a panacea for deterioration. Once non-invasive ventilation has been established it is essential to deduce the cause for the respiratory deterioration and instigate targeted medical therapy. Early recognition and treatment of atelectasis, bronchospasm, infection and hypoxia with nebulizers, antibiotics, chest physiotherapy and appropriate O_2 therapy can prevent the need for mechanical ventilation.

The contraindications to non-invasive ventilation include:

- reduced Glasgow Coma Scale score (<8)
- cardiac or respiratory arrest
- severe hypotension
- severe vomiting/haematemesis/excess bronchial secretions
- inability to protect own airway or preponderance to upper airway obstruction, including large head and neck tumours and anaphylaxis.

Preoperative assessment

Preoperative assessment of patients with respiratory disease aims to establish baseline function and optimize medication prior to surgery (Table 9.2). The patient's 'normal' exercise tolerance should be established. Establishment of predisposition to CO_2 retention is valuable preoperatively via arterial blood gas sampling. Useful information can be gained from the patient's response to previous surgical procedures and the time to recovery.

Table 9.2 Pulmonary function test patterns in respiratory disease

	Obstruction, e.g. COPD	**Intrapulmonary restriction, e.g. ILD**	**Extrapulmonary restriction, e.g. obesitypleural, chest wall and neuromuscular disorders**
FEV_1	↓↓	↓	↓
FVC	↓ or ↔	↓	↓
FEV_1/FVC ratio	↓	↑ or ↔	↑ or ↔
TLC	↑ or ↔	↓	↓
RV	↑	↓	↑
TLCO	↓	↓	↓ or ↔
KCO	↓	↓	↑ or ↔

↓, reduced, ↑, increased, ↔, normal. COPD, chronic obstructive pulmonary disease; FEV_1, forced expiratory volume in 1 second; FVC, forced vital capacity; ILD, interstitial lung disease; KCO, carbon monoxide gas transfer coefficient RV, residual volume; TLC, total lung capacity; TLCO, carbon monoxide gas transfer capacity.

Risk factors for postoperative respiratory complications include: underlying cardiorespiratory disease, older age, long anaesthetic time, smoking history, thoracic and abdominal surgery, obesity and poor functional baseline. Identification of risk factors and appropriate optimization with bronchodilators, antibiotics, steroids, pulmonary rehabilitation and non-invasive ventilation may improve postoperative recovery. Smoking cessation may reduce the risk of hospital-acquired infection and thus should be strongly encouraged preoperatively. Ideally this should occur at least 6 weeks prior to surgery.

Investigations in the preoperative assessment of cardiorespiratory patients include:

- O_2 saturation (if <95% on room air an O_2 assessment is required with arterial blood gases)
- chest radiograph
- spirometry [forced expiratory volume in 1 second (FEV_1), forced vital capacity (FVC), gas transfer] with reversibility studies
- 6 minute walk test
- consider cardiac comorbidity with ECG and echocardiogram
- cardiopulmonary exercise test.

Management of postoperative dyspnoea

Postoperative breathlessness is a common complication especially following thoracic and abdominal surgery. The main causes are pulmonary oedema, pneumonia, exacerbation of underlying lung disease and thromboembolic disease. The remainder of this chapter focuses on the recognition and management of respiratory disease in the context of the postoperative patient.

Investigations of postoperative dyspnoeic patient include:

- history and examination, including review of preoperative lung function tests
- observations of vital signs and O_2 saturation
- ECG
- blood tests: full blood count and C-reactive protein
- arterial blood gases
- chest radiograph
- consider CT thorax with/without CT pulmonary angiography (CTPA).

The common causes of postoperative dyspnoea are:

- Respiratory:
  - pneumonia
  - atelectasis
  - pleural effusion
  - pneumothorax
  - exacerbation of underlying lung disease (e.g. COPD)
  - PE.
- Cardiac:
  - left ventricular failure/pulmonary oedema
  - acute coronary syndrome.
- Others:
  - anaemia
  - iatrogenic phrenic nerve damage
  - fat embolism
  - anaesthetic/analgesic-related hypoventilation.

Pulmonary infection

Pneumonia is common, associated with significant morbidity and mortality and is responsible for prolonged hospital stay and cost. Those at increased risk include smokers, COPD patients, the elderly and immunosuppressed individuals.

Community-acquired pneumonia

This is most commonly caused by *Streptococcus pneumoniae*, *Haemophilus influenzae* or *Mycoplasma*. Treatment should be guided by local policy but is often with amoxicillin and clarithromycin for 7 days. Pre-existing community-acquired pneumonia (CAP) should be considered during admission clerking of all elective and emergency patients as it can complicate postoperative recovery if overlooked.

Hospital-acquired (nosocomial) pneumonia

This is defined as the presence of new radiographic infiltrates and sepsis occurring more than 48 hours following hospital admission and is associated with mortality rates between 20% and 50%. The causative pathogens include *Staphylococcus*, *Klebsiella* and *Pseudomonas aeruginosa* as well as those associated with CAP. Inadequate cough secondary to pain and muscular weakness leads to atelectasis, thus adequate analgesia, early mobilization and physiotherapy are important preventative measures. Treatment should be determined by local microbiology policies but is usually with broad-spectrum antibiotics providing anaerobic and Gram-negative cover such as piperacillin/tazobactam or second/third-generation cephalosporins.

Aspiration

Aspiration is a significant postoperative cause of nosocomial pneumonia. The risk of aspiration of oral secretions, food, fluid and medications is raised by impaired consciousness (sedatives, opiate analgesia, anaesthesia) and impaired protective cough/gag reflexes (postextubation, head, neck and facial surgery, nasogastric feeding). Aspiration should also be considered in trauma patients. Nasopharyngeal bleeding, loose teeth, alcohol/drug intoxication and brain injury should raise suspicion.

Clinical management

Clinical features include fever, cough, sputum, pleurisy, dyspnoea and confusion. Examination findings are tachycardia, tachypnoea, hypoxia and focal chest signs (bronchial breathing, crepitations, reduced air entry, increased vocal fremitus and decreased percussion note). Chest radiograph, sputum and blood cultures, arterial blood gas and blood tests (C-reactive protein, full blood count, renal and liver function tests) are necessary to guide diagnosis and management. Treatment with antibiotics should be guided by local policy and initiated immediately following the collection of microbiological samples. Antibiotic therapy can subsequently be rationalized when culture results become available. Adequate oxygenation ($PO_2 \geq 8$ kPa) and hydration should be maintained. Consideration should be given to chest physiotherapy, deep breathing and saline nebulizers to facilitate effective secretion clearance. Arterial blood gas sampling should be used to assess treatment response and severity. Failure to oxygenate above a PO_2 of 8 kPa with high-flow O_2 and the presence of a metabolic acidosis indicate severe disease and the need for escalation of care. Early identification of complications including shock, parapneumonic effusion, lobar collapse, abscess, empyema and ARDS is important and should prompt referral to respiratory or intensive care physicians.

Acute respiratory distress syndrome

ARDS is the development of acute lung inflammation and increased vascular permeability secondary to proinflammatory mediator release triggered by a variety of insults including sepsis, trauma, smoke inhalation, fat emboli, blood transfusion and pancreatitis. Mortality is greater than 50% and lung fibrosis common among survivors. Diagnosis requires the presence of sudden onset diffuse bilateral infiltrates on chest radiograph, a PaO_2/FiO_2 ratio of less than 200 mmHg and the absence of left ventricular failure (pulmonary wedge artery pressure <18 mmHg). Treatment of the underlying cause and supportive management are the mainstay. Mechanical ventilation is almost always required and evidence supports the use of low tidal volumes between 6 and 8 mL/kg and plateau pressures of <30 cmH_2O to minimize potential barotrauma. Other therapies that may be of benefit but that are not proven to be efficacious include inhaled nitric oxide (pulmonary vascular smooth muscle relaxant), methylprednisolone, fluid restriction, prone ventilation and extracorporeal membrane oxygenation (ECMO).

Exacerbation of airway disease: asthma/chronic obstructive pulmonary disease

Clinical management

Pre-existing airway obstruction may worsen peri- and postoperatively. It is important to optimize these patients preoperatively when there is an opportunity to do so in conjunction with respiratory physicians. Ensure that regular medication, and especially inhaled therapy such as inhaled corticosteroids, is continued throughout. Individuals with severe COPD (FEV_1 <30% or carbon monoxide gas transfer capacity <30% or on long-term O_2 therapy) are particularly at risk and need careful monitoring and also consideration of postoperative intensive or high-dependency care.

The use of nebulized β-agonists (such as salbutamol) and anticholinergics (such as ipratropium) needs to be considered if there is an exacerbation of underlying disease. In some cases it may be necessary to commence corticosteroids in addition to treating any infective component. Type 2 respiratory failure can occur especially in patients with pre-existing and severe COPD/emphysema.

Pulmonary embolism

Virchow's triad (venous stasis, vascular endothelial injury, hypercoagulability) explains the high incidence and mortality of venous thromboembolism (VTE) among postoperative patients. Most general surgical patients possess multiple risk factors for developing PE (Figure 9.2), such as major abdominal/pelvic surgery, immobility, dehydration, critical care admission, central venous access, malignancy, previous VTE, obesity, medical comorbidity and older age.

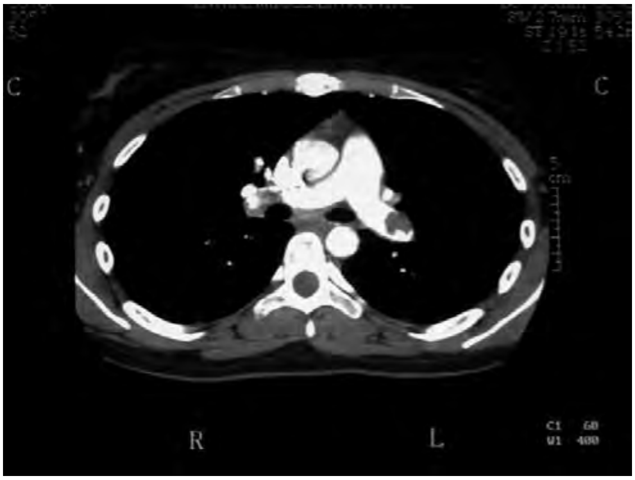

Figure 9.2 Acute pulmonary emboli in left main pulmonary artery.

Mechanical and pharmacological VTE prophylaxis are recommended for emergency admissions with inflammatory conditions and all surgical patients undergoing a procedure with an anaesthetic time of >90 minutes (>60 minutes if involving lower limbs or pelvis) or predicted prolonged immobility. Bleeding risk and contraindications to prophylaxis must be assessed on an individual basis. National guidance also suggests consideration of discontinuation of oral contraception or hormone replacement therapy 1 month preoperatively.

PE should be considered in patients with dyspnoea, pleuritic pain, haemoptysis, haemodynamic instability or collapse. Examination may be normal but tachycardia, new onset atrial fibrillation (AF) and tachypnoea are common. Other features include hypoxia, low-grade fever, hypotension, pleural rub, right heart failure and the presence of deep vein thrombosis. If there is high clinical suspicion and no contraindications, patients should receive treatment dose anticoagulant therapy immediately. An ECG may show sinus tachycardia, AF or right bundle branch block. The '$S_1Q_3T_3$' pattern is rare. Routine blood tests are helpful to exclude alternative causes; however, a D-dimer test is of no value in the surgical patient as this will be elevated postoperatively. An arterial blood gas often shows an increased A–a gradient and respiratory alkalosis (in response to the hypoxia, hyperventilation causes hypocarbia but is unable to increase oxygenation owing to the ventilation/perfusion mismatch) but can be normal. A chest radiograph may reveal an alternative pathology. Pleural effusions and wedge infarction may be seen with PE. A CTPA is diagnostic but a lower limb Doppler ultrasound can be useful in patients in whom a CTPA is contraindicated (contrast allergy, renal failure), as 70% of patients with PE will have an associated lower limb thrombus.

The management of PE is with O_2 and anticoagulant therapy. Low-molecular-weight or unfractionated heparin have equal efficacy. The total duration of anticoagulation following postoperative VTE is 4–6 weeks unless there is an underlying chronic risk factor (e.g. malignancy, previous idiopathic VTE, thrombophilia) and is usually with warfarin. In massive PE with collapse, thrombolysis should be considered. It is sometimes difficult to obtain a confirmatory CTPA in these circumstances and hence assessment of possible right ventricular strain or right-sided volume overload with echocardiography may be possible and in itself may identify intracardiac or intrapulmonary thrombus. Embolectomy is an alternative if life-threatening haemorrhage is likely as a result of anticoagulation. Inferior vena caval filters have not been proven to prevent fatal PE and these should not be used routinely.

Pleural effusion

Pleural effusions (Figure 9.3) are a common postoperative finding that occur for a wide variety of reasons (Table 9.3). Presentation of these can be gradual or sudden and is with dyspnoea, pleuritic chest pain or referred pain to the shoulder tip. Signs include reduced air entry, decreased percussion note, decreased vocal resonance/tactile fremitus, reduced expansion and bronchial breathing above the fluid level.

It is vital to establish the underlying cause of the effusion. All new pleural effusions should be sampled via ultrasound-guided thoracocentesis and sent for analysis of protein, albumin, lactate dehydrogenase, glucose and pH levels as well as microscopy, culture and cytology. Specialist tests include pleural fluid amylase and triglycerides, which can be raised in pancreatitis-associated effusions, oesophageal rupture and chylous effusions. The exception is when there is substantial risk of introducing infection such as after oesophagectomy or when there is overlying venous or skin grafting to the posterior thorax. In such cases pleural instrumentation should be avoided unless clinically indicated. Effusions are either transudative or exudative (Table 9.4) and the causes of each are given in Table 9.3.

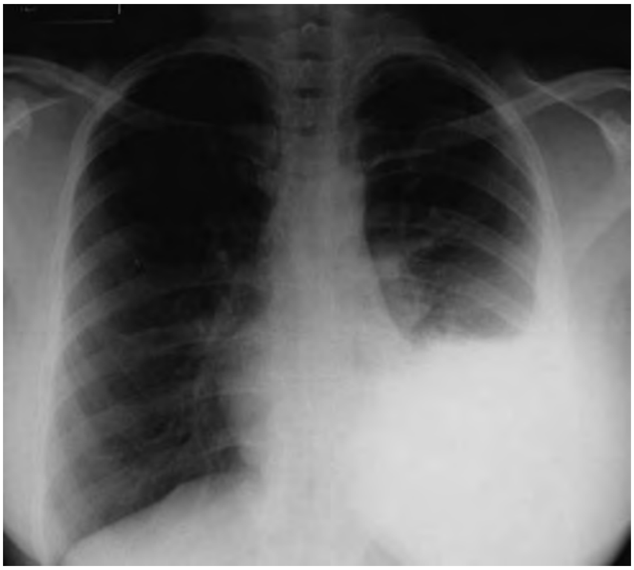

Figure 9.3 Left pleural effusion.

Table 9.3 Causes of pleural effusions

Causes of transudative effusion	Causes of exudative effusion
Increased venous pressure Left ventricular failure Constrictive pericarditis Fluid overload	Increased capillary permeability Infection (pneumonia, empyema, subphrenic collection, TB, oesophageal rupture) Inflammation (PE, rheumatoid arthritis, systemic lupus erythematosus, pancreatitis) Malignancy
Decreased oncotic pressure Hypoalbuminaemia (malnutrition, critical illness, malabsorption) Renal failure (nephrotic syndrome) Hepatic failure	Impaired lymphatic drainage Chylothorax (iatrogenic damage to thoracic duct, lymph invasion secondary to tumour)

PE, pulmonary embolism; TB, tuberculosis.

Table 9.4 Transudative versus exudative pleural effusions

	Transudates	Exudates
Pleural fluid protein/serum ratio	<0.5	>0.5
Pleural fluid LDH/serum ratio	<0.6	>0.6
Pleural fluid LDH level in relation to upper limit of normal for serum	<2/3	>2/3

LDH, lactate dehydrogenase.

Transudates infrequently require drainage as reaccumulation occurs too rapidly to be of benefit. In these cases treatment should focus on correction of the underlying condition, such as augmentation of nutrition in hypoalbuminaemia or treatment of cardiac failure/fluid overload. Exudates also require medical management of the underlying pathology but often require concurrent intercostal drainage and it is especially important to ensure that an empyema has not occurred (suspicion should be raised if there is evidence of ongoing sepsis), as this definitely requires drainage as antimicrobials are unable to penetrate and hence resolve this area of sepsis. Indicators of an empyema are aspirates of frank pustular material, presence of organisms on microscopy, polymorphonuclear cells and a pH <7.1.

Pneumothorax

Pneumothoraces (air within the pleural space) (Figure 9.4) can be either primary (occurring in normal lung) or secondary (underlying lung disease) and may occur spontaneously or following trauma. There is a strong association with smoking, males and small airways disease.

The classic presentation is with sudden onset breathlessness or pleuritic chest pain. Signs include tachycardia, tachypnoea, hypoxia and reduced expansion and breath sounds on the affected side. However, these features are frequently absent, especially in smaller pneumothoraces. A chest radiograph is usually diagnostic, but a CT thorax (Figure 9.5) is sometimes required to detect loculated pneumothoraces, to differentiate bullous lung disease from a pneumothorax and in trauma situations.

A 2 cm rim of air equates to a 50% lung collapse and it is at this volume that aspiration or drainage is required. In patients younger than 50 years with no underlying lung disease, aspiration should be attempted up to two times before drainage is considered. In patients with COPD, aspiration is rarely successful, thus drainage should be first-line management. Small bore Seldinger-type drains are usually sufficient.

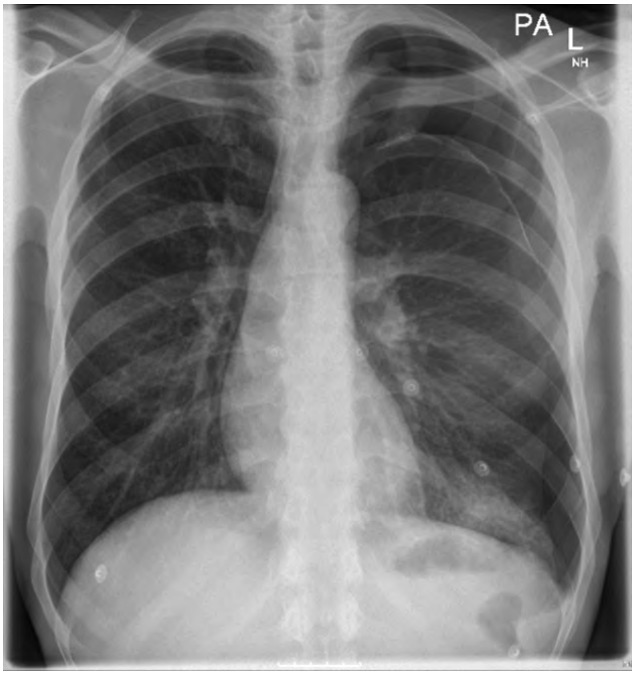

Figure 9.4 Left-sided pneumothorax.

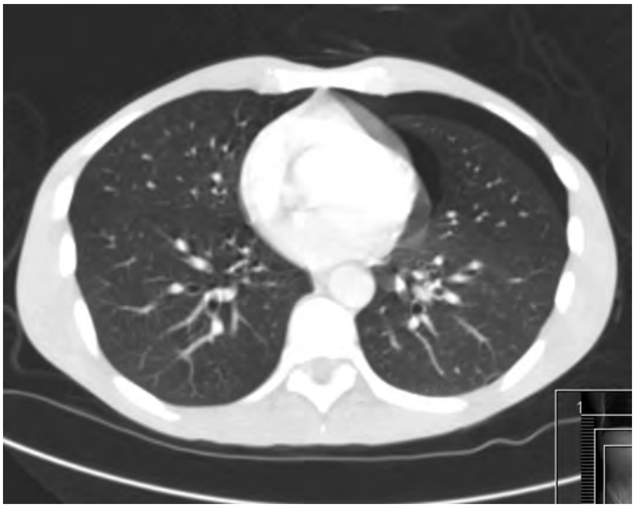

Figure 9.5 CT scan of left pneumothorax.

Traumatic pneumothoraces invariably require intercostal drainage and large bore Argyll-type drains are necessary. Small pneumothoraces (<2 cm rim of air) can be managed with observation alone. High-flow O_2 (unless contraindicated) is used to increase the rate of resorption of the pneumothorax and thus should be prescribed for all patients with pneumothorax. Advise patients that diving is contraindicated without a definitive surgical procedure and that air travel should be avoided for 7 days following confirmation of resolution with chest radiograph (the British Thoracic Society recommends a period of 2 weeks following a traumatic pneumothorax).

Haemothorax

Blood within the pleural cavity should be suspected if there is a pleural collection, especially following a thoracotomy or trauma and the patient becomes breathless, hypotensive and anaemic. As above, this should be aspirated diagnostically under ultrasound guidance. If a haemothorax is confirmed it is necessary to insert a large bore intercostal drain (minimum 28 G) with an underwater seal bottle to improve ventilation. Transfusion may also be required to correct the resulting anaemia and fluid resuscitation is important. In cases in which there is insufficient clearance, a significant clotted haemothorax or inability to re-expand the lungs, refer for a cardiothoracic review and decortication.

Re-expansion pulmonary oedema

This rare condition can occur following rapid re-expansion of a collapsed lung by drainage of pleural effusion or pneumothorax. It is associated with a significant mortality of up to 20%. Dyspnoea, increasing chest pain, hypoxia and the development of crepitations following intercostal drain insertion suggests the diagnosis. A chest radiograph usually demonstrates ipsilateral pulmonary infiltrates; however, re-expansion pulmonary oedema can occur bilaterally or contralaterally. Treatment is supportive with high-flow O_2 and CPAP or mechanical ventilation. Diuretics are contraindicated as this may worsen the condition. Risk factors include younger age, total lung collapse, mature pleural collections and rapid drainage. Controlled drainage of effusions (aim for maximum 1 litre per day) and avoidance of negative pressure suction in the first 48 hours of drainage reduces the risk.

CHAPTER 10

Renal insufficiency

NEILL DUNCAN AND RICHARD W. CORBETT

Introduction

The prime function of the kidney is to assist with the maintenance of the internal environment through the control of four broad physiological functions: (1) the selective control of the elimination or retention of water, (2) the selective control of the elimination or retention of electrolytes and other solutes, (3) maintenance of pH homeostasis and (4) hormone production. The first three of these functions occur through the combination of glomerular ultrafiltration, tubular reabsorption and active secretion along the length of the nephron, leading to the excretion of urine, whereas a number of hormonal processes, most notably erythropoietin (EPO) production and the activation of vitamin D, occur away from the glomerular and tubular apparatus.

Renal insufficiency relates to the inability of the kidneys to perform these functions in either the acute short term or the chronic long term, and damage may be reversible or permanent. The label of acute renal failure has been dropped in favour of acute kidney injury (AKI) as this terminology allows for states in which the kidney has not failed but may be at risk or injured, and in which early recognition and correct management may result in renal function being recovered. AKI, even at its earliest stages, carries an attributable risk of mortality. The physiological consequences of AKI can be managed by medical means in the earlier stages; it is only when organ failure has occurred that renal replacement therapy (RRT), for example haemodialysis or haemofiltration, is frequently required as a life-sustaining therapy. Although these treatments are effective and can approximate the basic physiological functions of the kidney, they are not without problems and associated morbidity; it is far more desirable to avoid progressive significant renal injury and to maintain native renal function.

In the surgical patient it is likely that renal insufficiency is encountered either as a pre-existing comorbidity as chronic kidney disease (CKD) or if AKI develops, because of either the surgical disease or an intervention. It is clearly possible for both of these states to coexist; indeed, a patient with pre-existing CKD is at greater risk of AKI.

This chapter will deal with AKI and CKD in turn but with a particular emphasis on AKI given its particular relevance to surgical disease and the critically unwell patient. Of particular clinical importance is the need to liaise closely with a nephrologist at an early stage in the care of patients who are receiving RRT with either chronic haemodialysis or renal transplantation. These two groups have particularly complex and differing needs, which are outside the scope of this chapter, but if they are not attended to diligently they can result in significant complications.

Acute kidney injury

Definition and epidemiology

AKI is characterized by a rapid deterioration in renal excretory function resulting from a wide range of causes. This is evidenced by oliguria and a rise in serum markers of excretory function, such as creatinine, over a period of hours to days. An important caveat is the time lag between the onset of renal injury and the rise in serum creatinine, which can be up to 36 hours, invalidating the use of calculations that estimate glomerular filtration rate (GFR) in this setting. The reciprocal correlation of serum creatinine with GFR, moreover, means that, by the time a rise in creatinine is seen to the upper limit of 'normal', up to 50% of renal function may have been lost.

Multiple definitions of AKI exist, although, in practice, these are not used to guide therapy but are descriptive of the risk of associated complications. The Acute Kidney Injury Network (AKIN) defines (Table 10.1) the stage of AKI either as an absolute increase or proportional increase in creatinine from baseline or as a change in urine output; for example, AKI stage 1 is defined as an

Table 10.1 The Acute Kidney Injury Network (AKIN) criteria for acute kidney injury

Stage	Serum creatinine criteria	Urine output criteria
1	Increase in serum creatinine of ≥0.3 mg/dL or increase to ≥150–200% from baseline	<0.5 mL/kg/h for >6 hours
2	Increase in serum creatinine to >200–300% from baseline	<0.5 mL/kg/h for >12 hours
3	Increase in serum creatinine to >300% from baseline or serum creatinine of ≥4 mg/dL; or receiving renal replacement therapy	<0.3 mL/kg/h for 24 hours or anuria for 12 hours

Table 10.2 The Risk, Injury, Failure, Loss and End-stage Kidney (RIFLE) criteria for acute kidney injury

Stage	GFR criteria	Urine output criteria
Risk	Increased serum creatinine ×1.5 baseline or GFR decrease >25%	<0.5 mL/kg/h for >6 hours
Injury	Increased serum creatinine ×2 baseline or GFR decrease >50%	<0.5 mL/kg/h for >12 hours
Failure	Increased serum creatinine ×3 baseline or GFR decrease >75% or serum creatinine ≥4 mg/dL with an acute increase of ≥0.5 mg/dL	<0.3 mL/kg/h for 24 hours or anuria 12 hours
Loss	Persistent acute kidney injury, i.e. complete loss of kidney function >4 weeks (i.e. dialysis dependence for 4 weeks)	
End-stage	End-stage kidney disease (i.e. dialysis dependent for >3 months)	

GFR, glomerular filtration rate. Note: 4 mg/dL is equivalent to 354 μmol/L; 0.5 mg/dL is equivalent to 44 μmol/L; 0.3 mg/dL is equivalent to 26 μmol/L.

increase in serum creatinine of >30 mmol/L, a 150–200% increase in creatinine from baseline or >6 hours of oliguria (<0.5 mL/kg/h) in patients who are adequately hydrated. The Risk, Injury, Failure, Loss and End-stage Kidney (RIFLE) classification criteria (Table 10.2) are based on patients admitted to an intensive care unit. The acronym mixes three grades of increasing severity of AKI based on similar criteria to those used in the AKIN definition (risk, injury, failure) but also includes two outcome variables (loss and end-stage renal disease). The entry criteria in both of these definitions may appear to be very low levels of renal impairment, but are strongly associated with evidence of poor outcomes and should act as a trigger for urgent investigation and corrective intervention.

Although some forms of surgery will entail a higher risk, AKI occurs in around 1% of all non-cardiac surgery patients who had normal preoperative renal function, with 0.1% requiring RRT. This accounts for between 20% and 50% of all hospital-associated AKI. Even in those patients with early stages of AKI there is an association with increased mortality, length of stay and use of resources in hospitalized patients. In cohort studies, stage 1 AKI is associated with a two- to fourfold increase in all hospital mortality. AKI not only occurs in association with failure of other organs but emerging evidence suggests that it also leads to dysfunction of other organs, possibly through upregulation of inflammatory mediators and endothelial injury.

The impact of renal impairment is not restricted to hospital admission; patients with initially normal renal function who recover after postoperative AKI will have an increased risk of death of 20% in the longer term compared with patients without AKI, as well as an increased risk of developing CKD. As might be expected, in those with pre-existing CKD the risks are greater, with a fivefold increased risk of prematurely requiring long-term RRT.

Prevention

In-hospital AKI arises frequently from a combination of insults: haemodynamic instability, loss of renal autoregulation, an inflammatory state and direct nephrotoxicity. Identifying the patient at risk and attempting to modify the factors that may lead to AKI are recommended given the evidence that adverse outcomes are associated with even minor levels of renal impairment. A variety of clinical features are known to be highly associated with an increased risk of AKI (Table 10.3); although it is possible to curtail the risk of AKI through the modification of some of these risk factors, many are unmodifiable and are associated with altered physiology leading to greater haemodynamic instability and impaired autoregulation.

Table 10.3 Features associated with increased risk of acute kidney injury

General	Perioperative
Age >60	Emergency surgery
Male	Intraperitoneal surgery
Congestive cardiac failure	Aortic cross-clamping
Liver cirrhosis	Massive blood transfusion
Hypertension	
Chronic kidney disease	
Diabetes mellitus (types 1 and 2)	
Active infection	

A clinical assessment of AKI risk should be made in all patients admitted to hospital as an emergency as well as in those undergoing significant elective procedures. Those identified as high risk should receive more intensive clinical and biochemical monitoring. Preoperative identification of high-risk patients, where possible, allows time for investigation of previously unidentified CKD, discontinuation of nephrotoxic agents and liaison with an anaesthetist and nephrologist. This is paramount for those with advanced renal impairment in whom significant interventions may precipitate the need for long-term RRT.

Minimizing haemodynamic instability

Kidneys receive around 20% of all cardiac output and they are particularly vulnerable to small reductions in blood flow. Maintaining renal perfusion is central to the prevention of AKI and most of the risk factors for AKI cause damage by potentiating hypoperfusion. An adequate blood pressure, although an element of treatment, is not the main goal of treatment by any means. The key to management is maintaining blood flow through the kidney by maintaining cardiac output with an appropriate circulating volume and vessel patency to the viscera.

Optimizing the circulating volume is difficult in AKI with surgery or trauma as there is reduced ability to excrete both sodium and water and increased risk of iatrogenic fluid and salt loading with the injudicious use of sodium-rich fluid with prescription of fluid replacement or drugs such as antibiotics or parenteral nutrition. The use of sodium-deplete fluids may lead to hyponatraemia. The tissue oedema that arises from aggressive use of any intravenous fluid is associated with poor wound healing, reduced mobility, venous stasis and thrombosis, pulmonary oedema and infection, and, ultimately, poorer outcome.

The choice and use of intravenous fluids remain a controversial area for the surgical patient but have recently been reviewed and summarized in UK consensus guidelines (British Consensus Guidelines on Intravenous Fluid Therapy for Adult Surgical Patients). These make a large number of recommendations, most notably encouraging in general the use of 'physiological' resuscitative or maintenance fluids such as Ringer's lactate/acetate or Hartmann's solution to avoid the large sodium and chloride loads associated with 0.9% 'normal' saline. There is some evidence that the use of hydroxyethyl starch (HES) preparations as colloid volume expanders may increase the risk of AKI in susceptible populations through direct tubular toxicity and are best avoided in this group of patients.

Those patients who are at greatest risk of hypovolaemia, such as those with significant intra-abdominal fluid losses (e.g. pancreatitis, bowel obstruction), extensive burns or kept nil by mouth for extended periods of time, need closer attention to their fluid requirements to ensure an adequate circulating volume. Patients with significant sepsis or cardiac dysfunction may require high-dependency care in order to maintain adequate renal and other organ perfusion through the use of vasopressors and inotropes.

There is no evidence that the use of 'low-dose' dopamine or fenoldopam (to preserve renal perfusion), mannitol (to force an osmotic diuresis) or the use of sodium bicarbonate fluid replacement have any benefit in preventing AKI.

Nephrotoxins

A wide variety of medications have nephrotoxic effects (Table 10.4) and are best avoided when possible or steps taken to limit the exposure when their use is unavoidable. Ideally they should be omitted 24–48 hours prior to surgery or other procedure (including contrast-mediated examinations) and recommenced once the risk of renal injury has passed.

Non-steroidal anti-inflammatory drugs (NSAIDs) can precipitate renal injury in a number of ways but predominantly do so by impairing renal autoregulation through the inhibition of cyclo-oxygenase, which mediates prostaglandin-induced vasodilatation of the afferent glomerular arteriole. Their beneficial analgesic effects need to be balanced against the risk of AKI; they are contraindicated in the high-risk population. Angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers are widely used in the management of CKD as they have strong prognostic benefits in the long term by reducing glomerular hypertension. However, in the acute setting their mechanism of action causing efferent arteriolar dilatation will exaggerate any haemodynamic insult by reducing the ability of the kidneys to autoregulate blood flow

Other hypertensive medications and diuretics are not in themselves nephrotoxic and may not need to be discontinued. In an acutely sick patient prone to hypotension their use needs to be reviewed on a frequent basis to reduce the risk of shock. Perioperatively advice should be sought from an anaesthetist. Metformin, equally, is not nephrotoxic, but can accumulate in renal impairment and is often stopped in a prophylactic manner to avoid an ensuing type B lactic acidosis should AKI occur.

Limiting contrast nephropathy

Contrast-mediated radiological examinations and interventional procedures are increasingly common, as are their complications. Ultimately, clinically mandated examinations or procedures should not be deferred but instead a careful assessment of risk made with preventative measures instituted to limit the kidney injury that arises from their use.

The exact mechanism of contrast-induced nephropathy is unclear but may relate to a combination of renal vasoconstriction and direct nephrotoxicity of the contrast agent. Conventional contrast agents are based upon a tri-iodinated ionized benzene ring and have a high osmolality (approximately five times greater than plasma), which along with their viscosity may contribute to the toxicity of these agents. Newer iso-osmolar non-ionic agents such as iodixanol appear to be less nephrotoxic but are considerably more expensive. The use of these newer agents in those at risk of AKI, along with the minimization of the volume required, is preferable.

The other risk factors for contrast-induced nephropathy are similar to those for the development of AKI and in general the actions taken to prevent all forms of AKI are also true for contrast examinations, including ensuring euvolaemia and discontinuing nephrotoxic drugs as well as metformin 48 hours prior to contrast exposure. Specifically evidence suggests that the use of approximately 1–2 litres of either isotonic sodium chloride or sodium bicarbonate solutions starting a few hours prior to the use of contrast and continuing for several hours afterwards is beneficial, although the studies are diverse in the timing and volume used. However, the evidence for other preventative measures such as *N*-acetylcysteine is conflicting and limited, and this is not generally advocated.

Table 10.4 Some examples of common nephrotoxic medications

Class of medication	Examples	Mechanism of action
Anaesthetic agent	Enflurane, methoxyflurane	Tubular toxicity
Angiotensin-converting enzyme inhibitor	Ramipril, perindopril	Afferent arteriolar vasoconstriction
Angiotensin II receptor blocker	Irbesartan, losartan, candesartan	Afferent arteriolar vasoconstriction
Antifungals	Amphotericin	Distal tubular toxicity
Aminoglycosides	Gentamicin, amikacin	Accumulate in proximal tubules
Antivirals	Aciclovir, foscarnet, indinavir	Intratubular crystal formation and toxicity
Chemotherapeutic	Cisplatin, ifosfamide	Tubular cell toxicity
Immunosuppressant	Ciclosporin, tacrolimus	Intrarenal vasoconstriction
Non-steroidal anti-inflammatory	Diclofenac, ibuprofen, naproxen	Vasoconstriction and acute interstitial nephritis
Radiocontrast media	Iopanoic acid, iothalamate	Multiple sites of action

Renovascular disease

As well as causing hypertension, renal artery stenosis can be associated with an ischaemic nephropathy. The most common cause for this is an atherosclerotic process that may involve either or both renal arteries. Perioperative hypotension may exacerbate renal hypoperfusion in those patients in whom the stenoses are flow limiting, leading to a profound AKI. There is limited and controversial evidence for angiographic treatment of renal artery stenosis with balloon angioplasty and stenting when significant surgery is contemplated – particularly major cardiac or vascular procedures. The possible benefits of prophylactic intervention should be discussed with a nephrologist. If the need for surgery is immediate then this should not be postponed in order to treat renal artery stenosis.

Investigating the patient with acute kidney injury

In a patient with surgical disease in whom AKI is recognized early, it is often an early indication of systemic physiological disturbance. The concern is that these patients may deteriorate further and that the AKI is associated with other organ dysfunction. All patients should have prompt assessment by an experienced clinician, as appropriate intervention with regular reassessment may limit further complications; in those with multiorgan dysfunction this may be best delivered in a critical care environment.

In the first stages of care it may not be clear whether an abnormal serum creatinine represents an AKI or relates to long-standing CKD. Ideally, corroborative biochemical results from either primary care or previous admissions can clarify this but if these are not available then 12 hourly serial creatinine monitoring should be performed along with measurement of urine output. Although small renal size, anaemia and hypocalcaemia are all associated with untreated CKD, they can be misleading; for example, diabetes, myeloma, amyloid and infiltrative lymphoproliferative disease may be causes of CKD with preserved renal size. If there is any doubt, it should be assumed that the renal impairment relates to reversible AKI.

Attempting to establish the aetiology of the injury is important as it allows perpetuating factors to be treated. Traditionally, the causes of AKI have been divided into prerenal, intrinsic and postrenal disease, although frequently more than one insult has led to AKI. This approach also lends itself to concurrent investigation and treatment.

Prerenal

A fall in renal perfusion leading to a decrease in GFR is a common cause of AKI. The kidneys can compensate for modest reductions in perfusion by autoregulation to maintain glomerular filtration through a combination of afferent arteriolar vasodilation and efferent arteriolar vasoconstriction. As discussed above, NSAIDs and drugs that block the angiotensin system directly inhibit the afferent and efferent vascular homeostatic mechanisms, respectively, and therefore will reduce GFR. More severe reductions in renal perfusion overwhelm autoregulation and lead to a rapid deterioration in GFR. If identified and treated promptly, even drastic falls in renal perfusion are reversible; however, delay in resuscitation may lead to intrarenal injury with ischaemic acute tubular necrosis (ATN).

A fall in renal perfusion may occur with any of the causes of systemic shock: hypovolaemia, cardiac failure and inappropriate vasodilatation (e.g. sepsis and anaphylaxis), although the relatively sensitive nature of the kidneys to physiological insults means that AKI may be evident before circulatory collapse ensues. Some common causes for all of these are listed in Box 10.1. Cardiac failure either may occur as a pre-existing problem (congestive cardiac failure) or may be acute. It may be difficult to identify patients with cardiac failure but it is very important as aggressive expansion of the intravascular compartment is associated with a paradoxical reduction in cardiac output owing to alterations in the intrinsic cardiac inotropy in such patients. The result of falling cardiac output is a further fall in renal perfusion and pulmonary oedema. Both sepsis and liver cirrhosis lead to inappropriate vasodilation of the peripheries, compromising renal perfusion. Cirrhosis also causes significant splanchnic vasodilation – a mechanism that is implicated in the hepatorenal syndrome. Hepatorenal syndrome is an uncommon form of AKI in those with advanced liver disease that requires careful consultation with a liver centre as the only definitive treatment is liver transplantation.

Clinical assessment, including a thorough history and examination, is vital in the assessment of the patient with AKI. The key management questions at this stage are whether there is adequate renal perfusion and is there intravascular hypovolaemia? Oliguria is not necessarily evidence of hypovolaemia and in the short term in the postoperative patient may represent a normal physiological response. Clinical signs reflecting intravascular hypovolaemia include reduced capillary refill, poor peripheral perfusion, low jugular (central) venous pressure, and a falling trend in blood pressure and rising trend in pulse. However, assessing the postoperative patient or those patients with significant comorbidities can be complex; for example, a patient with cor pulmonale will normally have high right heart filling pressures and a jugular venous pressure that is visible may occur

BOX 10.1 Causes of prerenal acute kidney injury

- Extracellular fluid volume depletion
  - Increased gastrointestinal losses (vomiting, diarrhoea)
  - Increased renal losses (diuretics, diabetes insipidus)
  - Sequestration (rhabdomyolysis, pancreatitis, ileus)
  - Increased dermal losses (burns, excessive sweating)
- Intravascular volume depletion
  - Haemorrhage
- Decreased cardiac output
  - Cardiac failure (longstanding congestive cardiac failure, recent myocardial infarction)
  - Cardiac tamponade (large pericardial effusion)
- Systemic arterial vasodilation
  - Sepsis
  - Liver cirrhosis
- Renal artery stenosis

in the setting of intravascular hypovolaemia. More invasive monitoring with the use of central venous catheters and urinary catheters may be useful but are not mandated, and may carry risk, particularly of infection; their use should be carefully considered before insertion and de-escalation with timely removal is vital.

There is no evidence for the use of any particular crystalloid or colloid in the resuscitation of the patient with AKI. However, Hartmann's solution, which contains potassium, should be avoided in the presence of hyperkalaemia, and potassium supplementation when serum potassium is in the normal range should be routinely avoided to avoid iatrogenically creating a clinical need for dialysis in a patient with progressive AKI. Solutions containing high-molecular-weight HES are contraindicated in AKI. Once the circulating volume has been corrected, if there is persisting evidence of impaired systemic perfusion then the use of vasopressors or other adjuncts to maintain renal and central organ perfusion should be considered early. In the anuric patient, repeated challenges of parenteral fluids run the risk of life-threatening pulmonary oedema.

Postrenal

Renal obstruction can occur at any level from the renal pelvis, through the ureters and bladder to the urethra and may result from either extrinsic or intraluminal factors. The former is often due to a compressive tumour, retroperitoneal fibrosis or occasionally inadvertent ureteric ligation (either bilateral or unilateral). Intraluminal obstruction usually results from blood clots, calculi or bladder outflow disease. The resulting intratubular pressure within the kidney opposes glomerular filtration pressure and reduces renal blood flow leading to a fall in GFR.

In any patient with AKI, the possibility of obstruction should be considered early as prompt relief of the obstruction can result in a rapid amelioration of renal function and carries a good prognosis. As such, radiological imaging, preferably ultrasonography, should be performed within 24 hours of the diagnosis of AKI in all patients; ultrasound has 90–95% sensitivity for obstruction. The ultrasound may be falsely reassuring, however, and show non-dilated pelvicalyceal systems and ureters in spite of obstruction in certain conditions, i.e. patients who may have infiltrative or inflammatory disease of the ureters and patients who have established oilgoanuria in whom insufficient urine is generated to dilate the renal tract. A high index of suspicion should lead to attempts to disobstruct with percutaneous nephrostomy tube insertion in such cases.

Importantly, when clinically assessing a patient with AKI it should be remembered that obstruction does not necessarily lead to anuria; acute unilateral ureteric obstruction may result in a rising serum creatinine without a significant change in urine output, hence the need to seek radiological imaging in all patients with AKI. The technique used for the relief of an acute obstruction will depend upon the level and nature of the obstruction, but timely disobstruction should be sought to prevent the irreversible kidney failure that results from delay. Disobstruction is mandatory if there is any suggestion of infection upstream of the obstruction with pyonephrosis.

Intrinsic renal injury

This is practically considered last as a diagnosis of exclusion made once the patient is euvolaemic and in the absence of obstruction. It includes a great diversity of different pathologies from the most common cause of AKI, i.e. ATN, through the range of renal-specific and systemic diseases that cause glomerular and tubulointerstitial pathology, and that are primarily the remit and interest of the nephrologist. Although a presumptive diagnosis of ATN is often made on clinical grounds, it is a histopathological diagnosis and what is described as ATN in a hospitalized patient may actually represent other intrinsic renal disease. In addition to ATN, this section will focus on a handful of other common specific presentations of AKI that are commonly associated with surgical disease.

Acute tubular necrosis

ATN is rarely a result of a prolonged hypoperfusion injury alone but in the unwell patient arises from a combination of ischaemia, sepsis and nephrotoxic insults. Cells within the proximal tubule and thick ascending limb of the kidney, which lie within the medulla of the kidney, appear most susceptible to injury as a result of a number of factors. First, the majority of renal blood flow is directed towards the cortex, wherein lie the glomeruli, such that even under normal physiological conditions the medulla is close to hypoxia. Second, the tubular cells are highly metabolically active as their predominant function is sodium reabsorption through the active generation of an ATP-dependent diffusion gradient. Third, there is increasing evidence for the role of inflammatory mediators leading to direct tubular toxicity through complement- and neutrophil-mediated mechanisms.

Despite the label, only a small number of cells actually undergo cell death, and even then many of them appear to undergo apoptosis rather than true necrosis. The tubular cells, unlike podocytes within the glomeruli, have the fortunate ability to regenerate. Recovery occurs with the restoration of tubular cell number, a process which can take from several days to months, although, in the absence of repeated insults, recovery predominantly has occurred by 2–3 weeks.

In those who have undergone oliguric ATN, the return of tubular function may replace a small volume muddy brown urine with a large volume diuresis; this polyuric state may take several days to resolve as the tubular concentrating mechanism is re-established. During this period it is important to ensure that a further hypovolaemic renal insult does not occur.

Nephrotoxins

A variety of nephrotoxic medications (some of which are included in Table 10.4) are associated with intrinsic AKI, although the mechanisms by which they act are equally varied. NSAIDs, ACE inhibitors and angiotensin receptor blockers, as well as radiological contrast which causes a tubular necrosis, have already been discussed.

Aminoglycosides, such as gentamicin, are renally excreted and exert a direct cytotoxic effect on tubular epithelial cells, where they accumulate. Classically, a non-oliguric AKI occurs, and is related not only to the cumulative dose but also to the dosing regimen and duration of therapy. Aminoglycosides may be a contributory factor in AKI even after they have been discontinued because of drug accumulation. The risk of AKI can be reduced by the use of careful therapeutic drug monitoring. High-dose single daily dosing should be avoided in those at risk or with established AKI. Their use in patients with advanced renal impairment risks ototoxicity. Glycopeptide antibiotics have occasionally at high dosages been reported to cause nephrotoxicity; however, when used in conjunction with aminoglycosides they have a synergistic adverse effect and caution should be exercised in the use of these two classes concomitantly.

Other antibiotics, particularly penicillins and rifampicin, along with diuretics, proton pump inhibitors and NSAIDs are among a long list of potential drugs that can cause an acute inflammatory interstitial nephritis. This is a reversible hypersensitivity reaction to a drug or occasionally an infectious agent, which occurs 7 days to weeks after exposure. Clinically it may be associated with any combination of eosinophilia, arthralgia and a maculopapular rash and is treated by removal of the offending drug if it can be reliably identified; steroids are sometimes used. However, the incidence should not be overstated and should not preclude the use of these drugs in patients with AKI unless there are specific features of concern. Acute interstitial nephritis is unlikely to be the cause of AKI within 7 days of the start of the potentially offending drug.

Amphotericin, an antifungal agent, has a direct cytotoxic mechanism that leads not only to a decrease in GFR but also to profound hypokalaemia and hypomagnesaemia through renal losses into the urine. The effectiveness of this drug and also its toxicity relate to the cumulative dose. The introduction of liposomal formulations of amphotericin have reduced its organ toxicity, but at greater cost.

Sodium phosphate bowel preparations for colonoscopy have been implicated in a condition labelled phosphate nephropathy, which predominantly seems to occur in those patients with pre-existing CKD. The injury that occurs is not always reversible and this drug should be avoided in this group of patients.

Ironically, the immunosuppressant calcineurin inhibitors ciclosporin and tacrolimus, which are widely used for renal transplantation among other solid organ transplantations, can also be nephrotoxic. At high plasma concentrations they cause afferent arteriolar vasoconstriction and reduced GFR. Toxicity is commonly associated with hyperkalaemia. These effects can be reversed by dose reduction, but this should only be done after liaison with the responsible transplant team.

Rhabdomyolysis

Breakdown of muscle leads to a release of potentially nephrotoxic contents, and the inflamed muscle sequesters fluid causing volume depletion. Myoglobin is freely filtered at the glomerulus and free radical-mediated injury to the tubular cells is caused by the haem–porphyrin ring and obstruction through precipitation of myoglobin within the distal tubules. A wide number of aetiologies may lead to rhabdomyolysis, including muscle injury, drugs, toxins and infectious agents. However, in surgical disease it is often seen in the context of major trauma (particularly entrapment and burns), limb ischaemia and with an increasing frequency following surgery. Prolonged bariatric surgery in which there is high risk of pressure necrosis and also vascular surgery with prolonged use of tourniquet are implicated.

A clinical diagnosis can be made on the basis of characteristic dark 'tea-coloured' urine, as well as a plasma creatinine kinase level that is markedly elevated by several orders of magnitude. If an established oligoanuric AKI has developed then treatment can be difficult; however, if identified early, therapy is directed at maintaining a good diuresis. Large quantities of iso-osmolar saline are used, although the accumulation of oedema in muscle may result in greater quantities of infused fluid than is diuresed; volumes of >10 L/day are frequently required. Theoretically, myoglobin precipitates more easily at acidic urinary pH and intravenous sodium bicarbonate infusion keeping the urine pH >6.5 may reduce tubular precipitation. Hypocalcaemia results from calcium sequestration within damaged muscle; if, in addition, the patient is alkalinized by intravenous sodium bicarbonate, plasma ionized calcium levels may fall resulting in tetany, and the patient should be monitored carefully with this in mind. A forced diuresis is continued for several days and discontinued once creatinine kinase levels appear to be falling significantly.

Cholesterol embolization

Those patients with a high burden of atherosclerotic disease, usually the elderly, may develop an irreversible embolic AKI following vascular surgery, angiography, thrombolysis or occasionally spontaneously. Disrupted arterial plaque results in distal embolization that leads to vaso-occlusion and inflammation in the kidneys, the lower limbs, the brain and eyes and occasionally the gut. Characteristically, there is a rapid development of AKI following a procedure, associated with proteinuria and an eosinophilia and purpuric cutaneous infarcts over the lower limbs, particularly in the digits (described as 'trash feet'). There is no evidence that anticoagulation has either a primary or secondary preventative effect and may, if anything, increase the risk of the embolization of unstable plaque. Whereas contrast nephropathy and cholesterol embolization may supervene concomitantly and cause AKI following endovascular injury and intervention, the former normally resolves by 14 days, the latter persists and is a rare a cause of end-stage renal failure.

Multiple myeloma

Myeloma can cause renal impairment in a multitude of ways; however, it can occasionally present as an acute injury in the context of comorbid disease in the elderly. Volume depletion may lead to the precipitation of even modest levels of circulating paraprotein, which form insoluble casts within the renal tubules. The presence of anaemia and a detectable serum paraprotein are helpful in the diagnosis.

Oxalate nephropathy

Hyperoxaluria is associated with the formation of oxalate stones and also oxalate nephropathy, a progressive irreversible cause of renal impairment. Oxalate is found in a large number of plant-derived foodstuffs and, within the gut, it usually complexes with calcium, forming an insoluble precipitate that is egested in faeces. However, in the setting of malabsorption, free fatty acids saponify calcium and inhibit the formation of calcium oxalate complexes; free oxalate is then absorbed within the colon, resulting in hyperoxalaemia and hyperoxaluria. This is recognized to occur in conditions that are associated with fat or bile acid malabsorption such as inflammatory bowel disease, pancreatic insufficiency, bowel resection and blind loop syndrome as well as jejunoileal and Roux-en-Y bypass.

As well as forming macroscopic stones, less frequently a clinical picture similar to that seen in the rare congenital condition primary hyperoxaluria occurs, with renal tubular crystalline deposits of calcium oxalate leading to tubulitis, fibrosis and progressive renal impairment. The timing of oxalate nephropathy is less acute than other pathologies described here, but is an increasingly recognized complication of upper gastrointestinal surgery in which it may present as early as 4 months postoperatively. Following bariatric surgery, up to 25% of patients may have urinary oxalate levels sufficient to be associated with subsequent renal impairment. The clinical determinants of nephropathy remain unclear, but those undergoing bariatric surgery may be predisposed as a result of comorbidities of diabetes, hypertension and obesity in this group of patients.

Attempts to limit dietary oxalate may have some benefit; however, once renal impairment has developed there is often a rapid progression to end-stage renal failure. The role for early surgical reversal, when possible, of bypass procedures in delaying the progression of the disease is unclear.

Vasculitis

Systemic or renal limited vasculitis with an associated glomerulonephritis are uncommon causes of AKI but should be suspected in the setting of a clinical history of constitutional ill-health with weight loss and fevers, and organ-specific symptoms such as small joint arthralgia, haemoptysis, epistaxis, rash, serositis and neuropathy. The first presentation of a systemic vasculitis may occasionally be with abdominal pain and gastrointestinal haemorrhage. Regardless of the type of vasculitis, if a glomerulonephritis is present there will be evidence of renal inflammation on urinalysis with visible 'Coca-Cola' urine or microscopic haematuria, proteinuria and red cell casts on microscopic examination. Concern about AKI in the setting of vasculitis necessitates urgent discussion with a nephrologist about urgent specific immunosuppressive treatment.

Differentiating prerenal and intrinsic renal disease

A number of clinical and biochemical clues may be available to differentiate whether an unobstructed patient with AKI has prerenal or intrinsic renal disease, although, in practice, this is usually differentiated by the timing of the clinical course, with prerenal AKI responding rapidly to restoration of euvolaemia whereas an absent or prolonged response suggests intrinsic disease. Loss of urinary concentrating ability is an early sign of intrinsic disease with urine osmolality (U_{Osm}) below 350 mosmol/kg diagnostic, whereas a level greater than 500 mosmol/kg in the absence of diuretics demonstrates an appropriate concentrating response seen in prerenal AKI. The fractional excretion of sodium (EF_{Na}) is generally <1% in prerenal and >1% in intrinsic disease but correlates poorly in those patients on diuretics with CKD and may not hold true for contrast-induced AKI.

The early involvement of a nephrologist is important in intrinsic renal disease, particularly when there is a history and clinical evidence of renal inflammation, features of a multiorgan systemic disease and prolonged presumptive ATN. A renal biopsy will help determine the cause of an intrinsic AKI but in practice is reserved only for those in whom assessment suggests that there may be a response to disease-specific therapy as in acute interstitial nephritis or glomerulonephritis.

Care of the patient with acute kidney injury

Promoting recovery from acute kidney injury

The initial steps in management of AKI are to ensure restoration of renal perfusion with fluid resuscitation and vasopressors or inotropes when needed, discontinuing nephrotoxic medications, while excluding obstruction and considering other causes of renal impairment. Currently, there is no evidence for the use of any drugs to promote recovery of AKI.

Furosemide and other loop diuretics are widely used in advanced AKI, with the intention of converting oliguric to non-oliguric AKI. This may be perceived to be beneficial in selected patients as fluid balance becomes easier to manage but ultimately RRT may be indicated for other reasons. Furosemide exerts its action on active sodium pumps from the luminal side of the tubular cell, it is therefore important to increase the prescribed dose in patients with reduced GFR to ensure that there is a sufficient concentration of filtered drug in the tubular lumen. Furosemide reduces the metabolic demand of tubular cells and therefore may reduce cell injury when perfusion is poor. However, at least one meta-analysis has demonstrated no difference in outcomes relating to patient survival or need for dialysis. Furosemide is not without risks, most notably ototoxicity when used in large doses as is required in oliguric AKI.

Dopamine at low doses (up to 5 μg/kg/min) binds to the D_1 receptor, causing vasodilatation and increased blood flow to the renal, coronary and mesenteric arteries. Unfortunately, there is no evidence that it affects AKI outcome or mortality, but, similarly to the use of loop diuretics, it is associated with a diuresis. There is some evidence that atrial natriuretic peptide may be of some benefit but larger studies are required to demonstrate a consistent benefit.

General complications of acute kidney injury

The subsequent aspects of management of AKI are broadly to ensure appropriate clinical monitoring to allow prompt attention to complications of renal impairment, many of which are treated similarly if they arise from CKD. Monitoring should include daily, if not more frequently, assessment of circulating volume and weight and blood tests (renal function, haemoglobin, bicarbonate, calcium and phosphate).

Sepsis needs to be identified early and inflammatory responses examined for infective cause and treated aggressively. The anorexic and catabolic nature of renal impairment is often poorly matched by dietary intake and this needs to be addressed.

A variety of drugs will need modification in both delivery and dosing, especially those which are renally excreted. Of particular note in the surgical patient are analgesics and anticoagulants; gabapentin and all opioids may accumulate easily causing narcosis, equally heparins (including low-molecular-weight heparins) need to be dose reduced substantially. In those on dialysis and with advanced CKD there is no evidence for beneficial use of low-molecular-weight heparins for thromboprophylaxis and the risk of haemorrhage is increased by other uraemic factors such as gastrointestinal ulceration, angiodysplasia, anaemia and platelet dysfunction. Metformin and sulphonylureas can accumulate and should be stopped with AKI or advanced CKD. Rarely, penicillin-based and carbapenem antibiotics may also accumulate leading to neurotoxicity, with confusion, agitation and fitting.

Renal complications of acute kidney injury

Fluid overload is probably the most common problem associated with established AKI. In patients with positive fluid balance, large fluid intake and inadequate urine output, steps should be taken to limit fluid intake while avoiding intravascular volume depletion. Life-threatening pulmonary oedema is a particular risk in the oligoanuric patient in this setting; urgent treatment with topical or intravenous nitrates, non-invasive ventilation and occasionally loop diuretics may allow time for commencement of RRT. Pulmonary oedema is more likely in inflamed patients with increased capillary wall permeability and low intravascular oncotic pressure.

Rising serum potassium levels >5.5 mmol/L should prompt a removal of sources of oral or intravenous potassium supplementation. Overt hyperkalaemia >6.0 mmol/L may be associated with cardiac conduction defects and requires urgent treatment with intravenous calcium to stabilize the heart. Intravenous insulin with dextrose, sodium bicarbonate and nebulized salbutamol will all shift potassium to the intracellular space but have a duration of action of only hours and the clinician should be aware of the possibility of rebound hyperkalaemia. Hypertonic intravenous fluids may cause tissue necrosis with extravasation, and reliable venous vascular access should be used ideally via a central venous catheter. To avoid precipitation of calcium salts intravenous calcium and bicarbonate should never be administered via the same vascular access. Oral calcium-based resins that bind potassium are poorly tolerated and provide no benefit in acute hyperkalaemia and little benefit in the prevention of chronic hyperkalaemia by reducing dietary potassium absorption. Refractory hyperkalaemia >6.5 mmol/L in the setting of AKI is an indication for urgent dialysis.

The use of intravenous sodium bicarbonate in the treatment of persistent metabolic acidosis is contentious. It can be used in those patients with a modest acidosis that relates to AKI alone and is particularly useful in controlling hyperkalaemia. When AKI coexists with a lactate or ketoacidosis its use may lead to a paradoxical worsening of any acidosis. Progressive acidosis and uraemia are further indications for acute RRT.

Renal replacement therapy in acute kidney injury

A variety of dialytic modalities are available for supportive care in AKI. Local practice will determine whether they are delivered in a critical care setting or a nephrology unit; in those with multiorgan dysfunction, it is likely to be the former. Acute peritoneal dialysis is only very rarely used outside of resource-poor settings and will not be discussed further. The main divisions are between intermittent haemodialysis (iHD), continuous RRT (CRRT) and sustained low-efficiency dialysis (SLED). There is no strong evidence supporting the use of one therapy in preference to the others, apart from limitations of each technique in certain settings.

iHD differs little from standard haemodialysis offered in end-stage renal failure; it offers excellent solute clearance and fluid removal over a short timescale. This makes it ideal for stable patients with isolated AKI. However, the high ultrafiltration rates that are required can exacerbate haemodynamic instability and this precludes its use in a large number of patients with AKI. In reality, those patients requiring circulatory support with inotropes, vasopressors or intra-aortic balloon pumps tolerate iHD poorly.

CRRT encompasses a large number of techniques that utilize slow ultrafiltration rates. The major benefit is improved haemodynamic stability arising from slower blood flow rates. The disadvantage is poor solute clearance – these techniques need to be used for up to 24 hours a day to render them effective; also, interruptions due to clotted circuits or time off the machine can lead to a significant reduction in the delivered dose of renal replacement. One of the more widely used techniques is continuous venovenous haemofiltration (CVVHF), which uses, as does iHD, a semipermeable membrane across which a hydrostatic pressure is generated so that solute and fluid are removed by ultrafiltration. All the ultrafiltrate is discarded and a sterile replacement fluid is added to blood before returning to the patient in CVVHF. This is in contrast with iHD, which uses a countercurrent exchange mechanism to control the removal of fluids and solutes, such that the majority of fluid processed returns to the patient and no replacement fluid is required.

SLED lies as an intermediary technique between these two, utilizing the slow ultrafiltration rates of CRRT, coupled with the excellent solute clearance offered by iHD. The technique is gaining in popularity but is not widely available.

All forms of RRT require some form of vascular access; this is usually an uncuffed, temporary dual-lumen catheter placed in a femoral, subclavian or jugular vein. Both lumens need to be of large bore to allow the high flows of at least 250 mL/min required by these techniques. The major complications of catheters relate to problems at the time of insertion, and subsequent risk of infection and central venous thrombosis and stenosis, the latter is more common with the subclavian approach and has implications for patients who survive with end-stage renal disease requiring long-term

RRT when permanent vascular access may be compromised. Infection risk can be reduced by the use of tunnelled lines in those patients who may require ongoing RRT. The use of arteriovenous shunts has gone out of practice because of the high rate of arterial vascular complications.

Another practical consideration is the need for anticoagulation to prevent clotting within the extracorporeal circuit. The preference would be for an effective regional anticoagulant that was active only within the circuit; sodium citrate, heparin and prostacyclin (a short-acting potent platelet inhibitor) can all be used but invariably may have systemic effects if overused and result in clotting of the circuit if underused.

Future advances in acute kidney injury

Given that a rise in serum creatinine is a delayed marker of AKI and can have poor specificity, there are a number of novel biomarkers that are being investigated that not only may allow a more rapid identification of AKI but also be predictive of the severity of injury. More, specific markers of the nature of injury may allow the development of targeted therapies. Two such potential markers are neutrophil gelatinase-associated lipocalin, which appears early after AKI in both urine and serum, and cystatin C, which may have a role in identifying chronic as well as acute kidney disease. It is likely, however, that future developments may also rely on the profile of several markers to generate a 'profile' rather than relying on a single biomarker.

In the patient undergoing surgery and identified to be at high risk for AKI, remote ischaemic preconditioning may potentially have a protective role. Remote ischaemic preconditioning describes the phenomenon in which transient non-lethal ischaemia and reperfusion applied to one organ or tissue protects another organ or tissue from a subsequent episode of lethal ischaemia and reperfusion. This currently involves the use of a blood pressure cuff inflated to 200 mmHg for several minutes on an upper or lower limb either in the hours prior to surgery or after anaesthetic induction. There is some evidence from early small trials that it may reduce the incidence and severity of AKI in selected patients.

Chronic kidney disease

When the CKD staging is applied to data from the general population it is estimated that 10% of people have significantly advanced CKD. Therefore, this will commonly be the case in hospitalized surgical patients and, as has been outlined, increases a patient's risk of surgical mortality and morbidity including AKI. The following sections briefly outline the definition, associated complications and implications for surgical management.

Definition and epidemiology

Despite the nomenclature, CKD is not a single pathological process but represents a large number of pathologies that result in irreversible loss of kidney function. The term covers a spectrum within the population including early asymptomatic renal damage to patients with end-stage renal failure undergoing RRT.

A common staging system has been adopted worldwide in an attempt to aid both primary and secondary healthcare in the identification and prioritization of patients with early renal damage in order to target interventions that may delay the progression to end-stage renal failure and deal with the complications associated with CKD. For most patients, GFR is estimated (eGFR) by the use of formulae such as the Modification of Diet in Renal Disease (MDRD) formula, which incorporates serum creatinine and age, sex and ethnicity among others. The staging of CKD is based primarily on eGFR, with secondary determinants being the presence of significant proteinuria or structural kidney abnormalities with eGFR >60 mL/min/1.73m^2, when the formula is not so predictive of true GFR; Table 10.5 outlines the National Institute for Health and Clinical Excellence CKD classification.

Creatinine is an end-product of muscle catabolism that is released into the circulation at a constant rate and is freely filtered at the glomerulus as well as being secreted by the renal tubules. However, there is significant interpatient variability that relates to differences in muscle mass; the use of eGFR attempts to overcome these limitations. It is important to note that the 'normal range' for serum creatinine in laboratory results needs to be interpreted with caution: it is possible for a large, young black man with high muscle mass to have an 'abnormal' high creatinine with a normal GFR, while a small, elderly non-black woman may have a 'normal' creatinine yet have significant renal impairment.

CKD may be a progressive condition and it is generally accepted that patients will on average have a decline in eGFR by 1–2 mL/min/year. A number of factors are recognized to accelerate this decline, most notably diabetes, poorly controlled hypertension and proteinuria; the presence of these together can result in a deterioration of up to 15–20 mL/min/year. However, with good management, focusing on aggressive blood pressure control (<130/80 mmHg in a high-risk group), along with glycaemic control, smoking cessation and avoidance of nephrotoxic drugs, progression can be slowed.

Proteinuria is included as a secondary measure of CKD stage as it is the strongest single predictor of GFR decline in both the

Table 10.5 Kidney Disease Outcomes Quality Initiative (KDOQI) classification of chronic kidney disease

Stage*	GFR (mL/min/1.73m^2)	Description
1	≥90	Normal kidney function but urine or other abnormalities point to kidney disease
2	60–89	Mildly reduced kidney function; urine or other abnormalities point to kidney disease
3	30–59	Moderately reduced kidney function
4	15–29	Severely reduced kidney function
5	<15	Very severe or end-stage kidney failure

*The suffix (p) may be used to denote the presence of significant proteinuria.

diabetic and non-diabetic population. In the healthy glomerulus, protein is not filtered and remains within the capillary, although some low levels of protein are actively secreted in the tubules such as Tamm–Horsfall protein (uromodulin). Progressive renal damage is associated with glomerular scarring and an increase in protein leak at this site; proteinuria may itself perpetuate further renal damage. Large trials have demonstrated that the reduction of proteinuria by the use of drugs such as angiotensin receptor blockers and ACE inhibitors predict a better outcome. These drugs are therefore widely used in CKD not only for their beneficial effect on blood pressure but also for their renoprotective effect.

Proteinuria is defined as a urinary protein excretion of >500 mg/24 h; however, owing to their lack of reliability, the use of 24 hour urinary collections has been superseded by the use of either urine albumin–creatinine (ACR) or protein–creatinine (PCR) ratios. Using these methods, significant proteinuria is considered to be present when a urinary ACR >30 mg/mmol or PCR >50 mg/mmol or more is present. PCR >100 mg/mmol may indicate a glomerular pathology as opposed to or in addition to a tubular pathology. PCR >300 mg/mmol is considered to be in the 'nephrotic range', and may be associated with nephrotic syndrome, which may be due to membranous nephropathy and have an underlying surgical pathology such as a solid organ tumour. Nephrotic syndrome is also associated with a hypercoaguable state and risk of venous thromboembolism – highly relevant perioperatively.

Complications of chronic kidney disease

Sodium, potassium and water retention

At modest reductions in eGFR, the kidney is able to maintain sodium homeostasis but this is lost in almost all patients as renal function declines, resulting in sodium retention and extracellular volume expansion. This presents clinically with pulmonary and peripheral oedema, requiring the use of loop diuretics and sodium restriction to control. The relative insensitivity of the renal tubule to diuretics in advanced CKD means that high doses (up to 500 mg/day furosemide) may be required. Loop diuretics are also helpful in aiding potassium excretion, although the mainstay of therapy is dietary restriction. Avoidance of excessive volumes of parenteral fluids, particularly those containing significant quantities of potassium, is important in these patients perioperatively. Anaesthetic muscle relaxants such as suxamethonium and the catabolic status of the perioperative patient both predispose to hyperkalaemia. Postoperative assessment of potassium levels is strongly advocated in patients with advanced CKD.

Metabolic acidosis

Failure to adequately excrete hydrogen ions, while also losing the ability to prevent tubular bicarbonate loss, manifests as a metabolic acidosis, which further impairs potassium excretion. Symptomatic dyspnoea is unusual outside of advanced CKD, but oral sodium bicarbonate is used at earlier stages of renal impairment to correct the acidosis, which may aid in the management of hyperkalaemia, slow progression of CKD and reduce demineralization of bones.

Haematological

CKD is usually associated with reduced levels of erythropoietin (EPO), which is produced by interstitial fibroblasts within the renal cortex in response to hypoxia. EPO controls production of red blood cells within the bone marrow and the inadequate levels in CKD results in a normochromic normocytic anaemia. This is treated with the use of recombinant human EPO, while supplementary intravenous iron is usually also required to support erythropoiesis – inadequate gastrointestinal absorption hinders adequate oral supplementation.

Advanced renal dysfunction is associated with a coagulopathy that is not characterized by conventional laboratory techniques. In part this is related to platelet dysfunction, but there is also evidence of other coagulation factor anomalies. Apart from dialysis in those with advanced renal impairment, there are few specific treatments, although there is some evidence for the use of desmopressin but it is of limited efficacy. The surgeon should therefore anticipate that the patient with CKD will bleed, and certainly for planned surgery in patients who are dialysis dependent adequate preoperative heparin-free dialysis and optimization of haematocrit through blood transfusion may be desirable. Liaison with the nephrologist is valuable.

Cardiovascular

There is a close association between worsening eGFR and risk of cardiovascular events; even from the earliest stages of CKD, cardiac disease is the leading cause of mortality in end-stage renal failure. Furthermore, the presence of proteinuria is also independently associated with cardiovascular risk, and reduction of proteinuria in clinical trials reduces cardiovascular risk. Some of the increased cardiovascular risk with CKD is attributable to traditional vascular risk factors; however, there are a number of novel risk factors including endothelial dysfunction, anaemia and vascular calcification which are peculiarly important in renal patients. Renal patients have increased frequency of adverse cardiac events, left ventricular hypertrophy, stroke and peripheral vascular disease. Preoperative appreciation of these risks is important in deciding on intervention; however, quantitative assessment is extremely difficult. Patients should not be prejudiced from effective surgical treatment and involvement of the nephrologist in perioperative management is welcomed.

Immunity

After cardiac disease, the second most frequent cause of death among those patients with end-stage renal failure is infection. CKD is a chronic immunosuppressed state in which there is increased susceptibility not only to standard bacterial infections but also to reactivation of mycobacteria and a failure to clear chronic viral infections such as hepatitis B. There is *in vitro* evidence of impaired cellular and humoral responses in these patients. Poor nutrition is a common cofactor, and healing is impaired. Infection therefore needs to be avoided by timely removal of prosthetic materials; for example, urinary catheters and central venous catheters and infection should be treated aggressively and promptly with antibiotics.

Chronic kidney disease: metabolic bone disease

Metabolic bone disease is initiated by a reduction in phosphate excretion in the kidney and failure of 1a-hydroxylase in the kidney to produce circulating 1,25-dihydroxyvitamin D; these drive hyperparathyroidism. The consequences include osteodystrophy, a failure to buffer serum calcium levels and, importantly, soft-tissue calcification within the vasacalature. As a result patients with CKD have an increased fracture risk. Calcific arteriosclerosis leads to high rates of cardiac events, stroke and peripheral vascular disease. Stiffened vessels are less adaptive to haemodynamic insult and the consequences of shock are more profound. All these elements are important to take into account when assessing and managing surgical patients with renal disease.

Treatment of CKD metabolic bone disease in the earliest stage involves limiting phosphate intake both by dietary restriction and also by the use of phosphate binders – drugs that complex with phosphate in the gastrointestinal tract and prevent its absorption. Correction of metabolic acidosis and the use of activated vitamin D and calcimimetics have a role. At a later stage, described as tertiary hyperparathyroidism, when parathyroid adenomas have evolved from the hyperplastic glands of secondary hyperparathyroidism, control can be obtained only by surgical parathyroidectomy. Rarely, the latter is required as an emergency procedure for the treatment of calciphylaxis, a calcific vasculitis-associated tissue necrosis in hyperparathyroidism that carries a mortality of >50% if untreated. Patients with cutaneous ulcers associated with this condition may present to the plastic surgeon, and lack of recognition with local treatment in the absence of parathyroidectomy is futile.

Renal replacement therapy

Despite efforts to minimize the progression of CKD, many patients will progress to end-stage renal failure. Some patients' first presentation to a renal physician may be at end-stage, particularly if they have been relatively asymptomatic, not had contact with medical providers or CKD has not been identified. In those with end-stage renal failure, there are a variety of potential forms of treatment, the choice of which is a combination of patient preference and clinical indication. RRT may involve modalities of haemodialysis, peritoneal dialysis and transplantation; indeed, many patients will experience more than one of these modalities and sometimes all of these during their lifetime. However, supportive care with the choice not to initiate RRT or to discontinue established RRT may be recommended for those patients for whom it will not improve their overall quality of life and may even worsen it. In those who opt for RRT, there is no evidence for commencing dialysis on the basis of eGFR; practice varies but the indications include symptomatic uraemia, as well as hyperkalaemia and fluid management refractory to medical therapy. In those for whom transplantation is an option, pre-emptive transplantation prior to the requirement for a dialytic therapy is preferable.

Peritoneal dialysis

Peritoneal dialysis utilizes the patient's peritoneum as the dialytic membrane. Sterile fluid of volumes up to 2.5 litres is instilled by the patient or carer into the peritoneal space through a cuffed catheter sited on the anterior abdominal wall. This is then left for a variable period of time, during which solutes and fluid diffuse across the peritoneal membrane. The waste fluid is then drained out before a new bag is instilled. This is performed either as continuous ambulatory peritoneal dialysis, when three or four exchanges occur across the day, with an exchange left to dwell overnight, or as automated peritoneal dialysis when a machine cycles a number of exchanges overnight and a further exchange may be used during the day. The cuffed catheter can be inserted under local anaesthetic and may remain in position for many years. In general, dialysis is not started for several weeks until the breach in the peritoneum has healed and there is no evidence of a leak; the latter may present with perineal swelling, for example in the scrotum. Abdominal hernias require surgical attention, as the increased peritoneal pressure can rapidly exacerbate the size of the sac.

As a dialytic therapy it is used globally and has the advantage that it can be performed by the patient at home, at their place of work or while travelling, as long as they have an available supply of peritoneal dialysis fluid. The major complication is peritonitis, through the inoculation of bacteria or fungus into the peritoneum. The presentation is often of abdominal pain and is associated with cloudy waste drainage fluid, which demonstrates a leucocytosis on microscopy. Dialysis can usually continue while it is treated with intraperitoneal antibiotics. A more devastating but rare complication is encapsulating peritoneal sclerosis, a progressive fibrotic condition characterized by the coexistence of peritoneal sclerosis and features of bowel encapsulation with obstruction or altered function and is associated with a high mortality. The exact causation is unknown, but risk factors include length of time on peritoneal dialysis and episodes of bacterial peritonitis. Treatment is primarily conservative with the use of home parenteral nutrition if necessary. Peritonectomy is a surgical solution advocated in specialist centres for some patients with beneficial results.

Haemodialysis

In the stable patient, haemodialysis or haemodiafiltration utilizes a combination of diffusion and convection across an artificial extracorporeal membrane to remove waste fluid and solutes. This is performed traditionally on an intermittent three times a week basis in an outpatient dialysis unit but there is a resurgence in home haemodialysis, performed by the patient up to six times week. The length of each session varies between patients but is usually between 3 and 5 hours.

The success of haemodialysis is heavily dependent upon vascular access to allow blood flows of >350 mL/min required for effective dialysis. This can be achieved by the use of an arteriovenous fistula or an arteriovenous graft, which are then needled at each dialysis session or via an indwelling central venous catheter. Fistulas are the preferred form of dialysis access and are formed by the surgical anastomosis of an artery and vein, usually in the arm: radiocephalic and brachiocephalic and brachiobasilic. The native fistula requires a period of 4–6 weeks to mature, and failure of formation to function rates vary from 20% to 50%. A synthetic graft may be formed when there is unsatisfactory vasculature to form a fistula by interposing a synthetic tube graft that can be needled immediately; however, these are complicated by a high thrombosis and infection rate. Steal syndromes from distal tissues are occasionally seen with both fistulas and grafts. If dialysis is required as an emergency without other forms of access available, then a non-tunnelled central venous catheter may be placed; ideally, this should be converted to a tunnelled catheter at the first opportunity. The tunnelled catheter is typically placed in the internal jugular vein and is then tunnelled under the skin on the ipsilateral side; a profibrotic cuff over the external catheter tube secures it in place. While there is a risk of bacteraemia with a fistula, indwelling tunnelled catheters carry a greater risk of infection mitigated somewhat by the tunnel. The traumatic effect of the catheter on the endothelium of the central veins may also predispose in the long term to the development of a central venous stenosis.

Renal transplantation

For those patients in whom it is feasible, transplantation remains the pre-eminent from of RRT, with clear evidence of improved survival over dialysis in age-matched populations. Ideally, these patients are best served by a pre-emptive live donation as allograft survival from a living donor surpasses that seen with a well-matched deceased donor organ. A well-functioning transplant offers some protection against many of the complications of CKD and provides a more effective form of solute and fluid clearance than dialysis, as well as approximating far better the other physiological roles of the kidney. Moreover, there is a profound symptomatic benefit in those who undergo transplantation following dialysis, over and above the freedom from alternate daily or even more frequent medical interventions. However, the effect of CKD on cardiovascular risk and impaired immunity is not obviated by transplantation, and morbidity from these two groups of conditions remains high.

Patients with insulin-requiring diabetes mellitus may be considered for associated pancreas transplantation, predominantly type 1 diabetic patients with a smaller number of type 2 patients for whom islet failure has developed and insulin resistance is not overwhelming. The technique was pioneered through simultaneous pancreas–kidney transplantation, but there may be reasons for considering pancreas after kidney transplantation; for example, after live kidney donation. The relative benefits of whole organ pancreas and islet cell transplantation remains controversial.

CHAPTER 11

Surgical infections and infestations

SIR ALFRED CUSCHIERI

Introduction

The biological factors involved in infection (infestation in the case of parasites) are:

- the virulence of the invading microbe
- the size of the infecting inoculum
- the state of the host's defence system.

At its most basic level, infection represents an adverse shift of balance in favour of microbial invasion that overwhelms the host defence system. In immunologically competent individuals the invasion is determined by the product of the virulence and the size of the inoculum of the pathogenic organisms. In immunocompromised patients low-virulence organisms and even commensals that are not normally considered pathogenic can obtain a foothold and cause serious infections.

Classification and consequences of infections

From a practical standpoint infections in surgical patients are best categorized as:

- community-acquired infections
- nosocomial (hospital)-acquired infections that cover (1) common postoperative infections and (2) infections in critically ill patients, usually in intensive care units (ICUs).

This distinction is important for various reasons, e.g. varying spectrum of infectious disease within the two settings, frequent presence of immune deficiency in hospital patients and significantly higher prevalence of infections by antibiotic-resistant organisms in hospital-acquired infections.

Nosocomial (hospital-acquired) infections afflict 3–5% of patients and are the most important contributors to prolonged hospital stay, increased costs and death after surgical treatment. On average, a postoperative wound infection increases the costs of an operation by 300–400%. Infections that arise following discharge from hospital are not reported consistently and probably account for half of the infections after surgical treatment. These postdischarge infections have assumed greater importance to the overall assessment of surgical morbidity and costs with the significant increase in ambulatory and short-stay surgical care. A minimum of 45 days of follow-up is necessary to obtain a valid assessment of wound infection rates.

Community-acquired infections cover a wide range, with some being primarily medical in the first instance, e.g. respiratory infections, meningitis, acquired immunodeficiency syndrome (AIDS) and viral hepatitis, and others surgical, e.g. abscesses, appendicitis and peritonitis. Thus, surgical community-acquired infections require emergency surgical treatment.

Consequences of nosocomial infections

The importance of nosocomial infections is highlighted by the statistic that they are the sixth leading cause of death in the USA, and hospital surveys indicate a rising incidence in most Western countries, with many being caused by antibiotic-resistant bacteria. In addition, nosocomial infections incur added costs and increase the discomfort and disability experienced by patients following elective operations. For patients who sustain serious injury and those who require critical care, infection is frequently lethal. The onset of bacterial or fungal infection contributes, as an independent causative factor, to the development of multiple organ systems failure.

Postoperative surgical infections

Infections following surgical operations fall into three categories:

1. systemic: including postoperative chest and urinary infections
2. surgical site: infection at the operative site (usually abscess formation)
3. wound infection.

It is important to stress that around 70% of postoperative infections present in the community after discharge from hospital.

Postoperative pyrexia

Pyrexia is a common feature of postoperative infections, although it may be absent in immunologically compromised patients. Its important features are:

- time of onset
- degree of pyrexia and type (persistent, intermittent)
- accompaniments, particularly rigors (shivering) and haemodynamic change.

Most early postoperative fevers are due to non-infectious causes, particularly pulmonary collapse. Early wound infections (occurring within 18–24 hours) tend to be of a serious nature (see below). Rigors indicate bacteraemia or viraemia and always necessitate blood culture in addition to physical examination. A flushed appearance with a hyperdynamic circulation is also indicative of bacteraemia and usually signifies the early stages of septic shock. Intermittent pyrexia is indicative of an abscess.

If a patient develops a high temperature in the postoperative period, the following are necessary in all patients: physical examination of the lungs, wound, calves and urine. In addition, most would advise a chest radiograph. Leucocytosis is a feature of the early postoperative period when cultures are usually negative. Thus, these laboratory tests (white blood cell count, total and differential) and culture screen (sputum, urine, blood and wound) are undertaken on a selective basis and in response to specific clinical findings:

- fever that persists beyond the first 24 hours
- fever that recurs after a period without fever (intermittent)
- fever that arises after the first 24 hours
- fever accompanied by rigors, haemodynamic change or chest/abdominal signs.

Procurement of material for culture

This is an important practical aspect of management as it ensures valid culture results and aids recovery of organisms that are difficult to culture. The first principle is to retrieve an uncontaminated specimen in a sterile container that does not contain air if anaerobes are thought to be involved in the infection. Thus, material from intra-abdominal abscesses that often contains anaerobic organisms should be aspirated into a sterile syringe and all the air expelled. The specimen should then be transferred to an anaerobic transfer container or left in the syringe for direct inoculation into culture medium in the bacteriology department.

Gram staining of the infected material provides an important immediate evaluation while the results of culture are awaited. The request form accompanying the specimen should give sufficient details and, in particular, indicate the pathogens suspected whenever possible. Blood cultures should be obtained in duplicate, 20–30 mL per set obtained from different sites in adults. The skin overlying the venepuncture site should be scrubbed with antiseptic (povidone iodine) for 2 minutes beforehand and sterile gloves worn to prevent contamination. The wound surface should be cleaned with sterile water (not bacteriostatic saline) before obtaining the specimen, which is best obtained by scraping. Sometimes a small biopsy is needed for culture. Swabs of wounds or fluids are undependable, as they may not represent the fluid content of the wound accurately. Bullous lesions are aspirated after gentle surface cleaning. Body fluids (ascites, pleural effusions) are aspirated into a syringe after disinfection of the wound surface with povidone iodine. In some situations, quantitative cultures are needed, e.g. clean catch specimens of urine and burn sepsis.

Common postoperative infections

The common postoperative infections include:

- wound infections
- pneumonia
- urinary tract infections
- central venous line infections
- intra-abdominal abscess
- infection of implanted material.

Urinary tract infections

These are most commonly associated with catheterization of the bladder (indwelling and 'in and out'). Symptoms include dysuria and frequency and, sometimes, the onset of incontinence. Loin pain and tenderness are only found in patients with severe upper urinary tract infections. The specific diagnosis of urinary infection is made with the recovery of more than 10^5 organisms per millilitre of urine. The most common organisms cultured in nosocomial urinary infections are *Escherichia coli, Pseudomonas aeruginosa* and coagulase-negative *Staphylococcus* spp.

Central venous line infection

This is encountered in 3–5% of patients who have monitoring lines in place and those receiving parenteral nutrition. Fever in such patients is an indication for inspection of the puncture site for signs of inflammation and for changing the line. For temporary lines, removal and replacement to another site are indicated. Replacement over a guide wire may permit preservation of a valuable access site. Permanent lines may occasionally be salvaged, temporarily, by a course of systemic antibiotics. However, if signs of infection have not resolved completely within 48 hours, the catheter should be removed. The tip of all removed catheters should be cultured. *The presence of more than 15 colonies is indicative of line infection*. Episodes of line sepsis can be prevented by meticulous attention to cleanliness of nutrition support lines.

Intra-abdominal abscess

Intra-abdominal abscess can arise in:

- Patients undergoing a major operation involving the alimentary tract. The abscess results either from contamination at the time of surgery or from suture line leakage.
- Critically ill patients from failure of intraperitoneal host defences and the gut barrier function with translocation of intraluminal bacteria into the peritoneal cavity (sometimes referred to as tertiary peritonitis).
- Patients with acute abdominal conditions requiring emergency operations, e.g. trauma, perforated viscus or severe gangrenous perforated appendicitis. These patients have a 6–10% risk of developing intra-abdominal abscesses.

Signs and symptoms of postoperative abdominal abscess usually arise between the fifth and 10th postoperative day and include intermittent fever, localized tenderness and absent bowel sounds. In some instances the abscess is palpable abdominally or rectally (pelvic collection). Persistent drainage from an abdominal wound infection that has been opened indicates that this is being fed from an intra-abdominal site. Patients with intra-abdominal abscess may develop signs of sepsis such as hypotension, hyperdynamic circulation, respiratory distress and other features of the multiple organ failure/systemic inflammatory response syndrome (SIRS).

Plain radiology may show an elevated immobile hemidiaphragm in patients with subphrenic abscess and visible gas may be seen, especially in patients who have sustained anastomotic dehiscence or have developed a pancreatic abscess, but diagnosis is nowadays based on ultrasound scanning and especially CT. Both are usually performed, one after the other. CT provides more detailed information on the precise location and anatomy of the abscess cavity. CT-guided drainage is now used as the first line of treatment in these patients, with surgery being reserved for large multiloculated abscesses containing a large amount of slough. Systemic antibiotics are indicated to forestall the systemic effects of bacteraemia that may occur before, during or after the abscess drainage.

The key issue relates to the role of laparotomy in septic patients with SIRS and multiorgan failure. In the past, this was recommended in all these patients on the premise that the detection and evacuation of abscesses was followed by improvement or reversal in 50% of patients. This view is now not generally accepted, as the majority of patients with SIRS do not have an intra-abdominal focus of infection. The current consensus is that laparotomy is used selectively in patients who are in the early stages of the disease, especially those in whom the organ failure was precipitated by intra-abdominal infection in the first instance, i.e. detection of residual collections. Laparotomy is not indicated in patients in the late hypodynamic decompensated stage of the disease unless there are specific signs of intra-abdominal infection.

Infection of implanted prosthetic material

Infection is an ever-present risk when prosthetic material or implants are used; whether this is simple mesh for hernia repair or a more complex implant, e.g. joint prosthesis, vascular grafts, cardiac valves or pacemaker devices. The clinical evidence of infection of implanted materials ranges from subtle to catastrophic. Thus, implanted intravenous lines may exhibit only fever and local erythema at the puncture sites, whereas infected aortic grafts may present with life-threatening haemorrhage due to anastomotic disruption or acute aortoenteric fistula.

In nearly all instances, removal of the implant is necessary to control infection. Removal and replacement of implanted devices such as pacemakers to another site with systemic antibiotic cover is needed. For infected vascular grafts removal with a new prosthesis tunnelled through uncontaminated tissue (extra-anatomical bypass) is usually performed, e.g. axillobifemoral grafts for infected abdominal aortic grafts. In some patients, the threat to life or anticipated disability may prohibit removal of the implant, e.g. infected thoracic aortic graft. Irrigation of the infected area with antibiotic solutions in addition to systemic antibiotics may buy time but does not provide permanent control of the infection.

A growing percentage of nosocomial infections are associated with medical devices. One solution to this problem is to coat the device with anti-infective coating. Antibiotic coating has been used especially for vascular grafts. In this instance the polymer is impregnated with gelatin, which then binds antibiotics such as rifampicin. This approach has a number of limitations. In the first instance, each antibiotic is effective only against certain bacteria. Second, there is the problem of bacterial resistance and, third, antibiotic coating tends to be effective for only short periods (days to weeks). A more recent technology involves *oligodynamic iontophoresis*. This is an electrochemical process whereby minute amounts of silver ions are released from the device into the surrounding tissue fluid, thereby preventing bacterial colonization and infection of the implant. Oligodynamic iontophoresis-enhanced materials are polymers impregnated with silver, platinum and carbon particles. These components, following implantation of the device, set up an electrochemical reaction once in contact with the crystalloid tissue fluid, with the silver and platinum particles acting as the electrodes of a battery. The result of this reaction is the release of bactericidal silver ions that lasts for several months. Currently, oligodynamic iontophoresis-enhanced central line catheters are being evaluated in randomized trials.

Principles of antibiotic therapy

Antibiotics are rarely used as the sole agents to eradicate surgical infections; in most instances they constitute adjuvant treatment to surgical and radiological interventional procedures, e.g. excision of the infecting focus drainage of abscesses, debridement or lavage of infected serous cavities. They are certainly no substitute for effective surgical management of these disorders. The use of antibiotics as prophylactic agents to cover certain operations is well established and of proven value. *The adverse effects of antibiotics, particularly the emergence of resistant strains of organisms, limit their overall usefulness, especially in critically ill patients.*

Antimicrobial resistance

Over the past 20 years antimicrobial resistance (AMR) has become a major worldwide health problem with adverse effects on the treatment of a wide spectrum of infectious disease from tuberculosis to malaria and both community- and hospital-acquired infections. In certain countries such as the UK, meticillin-resistant *Staphylococcus aureus* (MRSA) and vancomycin-resistant *Clostridium difficile* infections have reached epidemic proportions with regular outbreaks resulting in ward closures. In the European Union (EU) countries, 25 000 patients die each year from infections caused by drug-resistant bacteria with related costs exceeding €1.5 billion in healthcare expenses and productivity losses. Both the World Health Organization (WHO) and the European Commission have issued comprehensive action plans needed to address the problem of increasing AMR.

The EU Action Plan covers seven areas where measures are most necessary:

1. making sure antimicrobials are used appropriately in both humans and animals
2. preventing microbial infections and their spread
3. developing new effective antimicrobials or alternatives for treatment
4. co-operating with international partners to contain the risks of AMR
5. improving monitoring and surveillance in human and animal medicine
6. research and innovation
7. communication, education and training.

The mechanisms underlying AMR are complex and incompletely understood but in the final analysis the problem relates to the misuse or inappropriate use of antibiotics, which are grossly overprescribed in both primary and hospital healthcare. AMR is caused by mutation in plasmid (transferable) or chromosomal genes. Mutations remain at a low level in the population of bacteria under natural conditions but increase with stress induced by antibiotic exposure. Resistance genes can be transmitted between bacteria by transformation or conjugation. Resistance can occur to a single antibiotic or to several.

Enzymes

β-Lactam resistance in bacteria is the result of the expression of several classes of β-lactamase enzymes. This accounts for resistance to many β-lactams, including the third-generation cephalosporins (cefotaxime and ceftazidime) by several species of Enterobacteriaceae and *P. aeruginosa*. New plasmid-mediated β-lactamases, extended-spectrum β-lactamases, confer resistance to most β-lactams antibiotics except cephamycins and carbapenems. The genetic information encoding the β-lactamase can be transferred between many Gram-negative and Gram-positive bacteria.

Altered target site

Fluoroquinolone antibiotics exert their antibacterial effect by inhibition of DNA gyrase (bacterial topoisomerase II) and topoisomerase. Mutation in *gyrA* (encodes A subunit of gyrase) occurs predominantly in Gram-negative bacteria, whereas mutation in *grlA* (topoisomerase IV subunit A) occurs predominantly in Gram-positive bacteria. Double or multiple mutations within *gyrA* confers high-level resistance to fluoroquinolone antibiotics.

Diminished uptake and efflux of antibiotic

The concentration of antibiotic in bacteria can be reduced by decreasing the penetration (uptake) or by increasing efflux of antibiotic from the bacterial cell. It is thought that the major route through the bacterial cell membrane for hydrophilic antibiotics (fluoroquinolones, chloramphenicol, tetracycline and some β-lactams) is through water-filled protein pores called porins mediated through a protein OmpF, complete loss of which gives rise to cross-resistance to a number of antibiotics.

Increased efflux is another recognized mechanism of antibiotic resistance. This efflux is mediated by several export proteins, including the Bmr from *Bacillus subtilis* and the Tet efflux proteins and *NorA* gene of *S. aureus*. Bmr mediates the efflux of chloramphenicol and fluoroquinolones.

Transformation

This mechanism involves the uptake of naked DNA by bacteria from the environment. The most studied species include *Streptococcus pneumoniae*, *Haemophilus influenzae* and *Neisseria* spp. Most naturally transformable bacteria usually take up DNA from a closely related bacterium, usually from DNA released by bacterial lysis.

Conjugation

This requires contact between two bacterial cells, thus enabling bacterial gene transfer. The genes are transferred either as plasmids or a conjugative transposon (designated Tn plus a number). Conjugation is thought to be the main mode of transfer of antibiotic resistance genes between bacteria. Large plasmids bearing several individual genes that each confer resistance to a different antibiotic are well documented, especially during prolonged antibiotic therapy.

Antibiotic policy

Certain principles governing antibiotic therapy in hospital practice are agreed and in general usage:

- Each hospital has its own drug formulary that includes an antibiotic policy (first-line antibiotics to be used for specific conditions) based on cost, efficacy, the pharmacokinetic properties and the hospital's known resistant species. This policy covers both the treatment of established infections and the use of specific antibiotics for prophylaxis of infection in patients undergoing surgery. By agreement, certain antibiotics are kept in reserve for serious infections.
- For established infections, the sensitivity of the organisms cultured to antibiotics is performed routinely and the first-line antibiotic regimen used may need to be changed accordingly.
- For certain antibiotics, therapeutic drug monitoring is necessary to (1) establish adequate serum concentrations and (2) identify potentially lethal concentrations. This applies particularly to aminoglycosides

(gentamicin, netilmicin, tobramycin and vancomycin) and flucytosine. The desirable levels of aminoglycosides vary according to the nature and severity of the infection. Dose adjustment is essential in patients with renal impairment, when advice should be sought from the clinical pharmacist. The volume of distribution of aminoglycosides is increased in critically ill patients and, for this reason, suboptimal dosing is common.

- In some infections synergistic combinations of antibiotics are indicated. Antimicrobial synergy occurs, for example, when an aminoglycoside is combined with penicillin for treatment of certain staphylococcal or enterococcal infections, and with ticarcillin for enhanced activity against *Pseudomonas* spp. For surgical patients, the traditional treatment of potentially life-threatening infections, e.g. pneumonia, suppurative cholangitis, peritonitis and burn sepsis, has been with combinations of aminoglycosides and other drugs such as cephalosporins, clindamycin and metronidazole.
- Infected collections negate antibiotic activity owing to changes in tissue pH, oxygen tension, levels of magnesium and calcium, and the production by various organisms of substances that inactivate antibiotics, such as β-lactamase, which inactivates penicillin. Thus, drainage and debridement will improve antibiotic effectiveness as well as reduce the bacterial inoculum.
- In serious infections in critically ill patients, discussion with and advice from the hospital clinical bacteriologist is essential.
- Special nursing measures and isolation of patients with MRSA infections are necessary.

Additional measures for enhancing antibiotic action include:

- altering body fluid pH, e.g. urine
- delaying excretion of the drug, e.g. use of probenecid with penicillin
- changing the route of administration, e.g. intravenous from oral
- increasing the dose of antibiotic (effective in cephalosporins); this can be achieved by increasing the absolute dose or the total dose (increase duration of therapy), or by reducing the dosing interval
- using substances that block bacteria-inactivating enzymes, e.g. clavulanic acid.

Types of antibiotic

Penicillins

The use of penicillins has been eclipsed by other antibiotics because of the emergence of resistant organisms that produce penicillinase, as well as the emergence of MRSA. Penicillins as a group are effective against Gram-positive organisms and *Neisseria gonorrhoea*. The aminopenicillin group (ampicillin, amoxicillin) also has limited Gram-negative activity. Penicillinase-resistant penicillins are useful against resistant staphylococci.

More recent penicillin classes include the carboxypenicillins (carbenicillin, ticarcillin) and ureidopenicillins (mezlocillin, azlocillin and piperacillin). The main advantage of carboxypenicillins is their effectiveness in *Pseudomonas* spp. and *Proteus* spp. infections. Ureidopenicillins are effective against *Pseudomonas* and *Klebsiella* spp. Resistance of β-lactamase-producing *Staphylococcus* spp. and *H. influenzae* is common. Reports of decreasing activity of ureidopenicillins with increasing inoculum size are important.

As a group, penicillins may produce allergic reactions that range from rashes (relatively common) to anaphylaxis (rare). Ampicillin is associated with diarrhoea. Haemolytic anaemia, drug fever, granulocytopenia and hepatitis are unusual but important side effects.

Cephalosporins

These were first introduced in the 1950s and are usually classified into three generations:

- *first-generation cephalosporins*: cefadroxil, cephalexin, cephradine, cefazolin, cephalothin, cephapirin
- *second-generation cephalosporins*: cefaclor, cefamandole, cefonicid, ceforanide, cefotetan, cefoxitin, cefuroxime
- *third-generation cephalosporins:* cefoperazone, cefotaxime, ceftazidime, ceftizoxime, ceftriaxone.

First-generation drugs are available in both oral and parenteral forms. Cefazolin has been used widely as a prophylactic drug in high-risk elective operations. Only one second-generation cephalosporin is available for oral use (cefaclor); this is active against *H. influenzae.*

The major advantage of second-generation cephalosporins is improved activity against Gram-negative organisms such as *E. coli* and *Proteus* spp. Activity against *S. pneumoniae* and *Streptococcus pyogenes* is equal to the first-generation drugs. Cefoxitin is a useful drug for surgical patients because of its activity against *Bacteroides fragilis* and persistent high tissue levels lasting for 3–4 hours. The level of activity against anaerobes is shared by cefotetan. Cefoxitin is useful as a primary drug directed against suspected mixed infections within the peritoneal cavity and is commonly used in trauma patients.

Third-generation cephalosporins have improved activity against Gram-negative organisms. Thus, some of the drugs in this category have been suggested as primary single-drug therapy for difficult infections such as nosocomial pneumonia and peritonitis. The major advantage of these drugs over combinations of aminoglycosides with earlier generations of cephalosporins for nosocomial infections is the lack of toxicity and lack of need to monitor drug levels. However, clinical studies have not documented a superior outcome in pneumonia or peritonitis when third-generation cephalosporins are compared with combination therapy with aminoglycosides. Toxic side effects of third-generation cephalosporins are unusual. Moxalactam is associated with prolongation of the prothrombin time.

Aminoglycosides

This group has a wide spectrum of activity against a large number of organisms and has consistently been shown to be useful in many difficult clinical infections, particularly pneumonia and peritonitis. Toxicity is the major drawback, involving renal damage and ototoxicity, the latter producing deafness and vestibular dysfunction. Gentamicin, tobramycin and amikacin are most often used. The drugs are given parenterally because of poor intestinal absorption.

Serum drug-level monitoring is essential to determine effective tissue levels of the drug. Timing of the blood-level assay is important. One level should be drawn within 30 minutes of beginning an infusion of drug, with the second (peak) level being drawn 30 minutes after the end of the infusion. Peak levels above 5 μg/mL are associated with improved survival from serious infections. With pneumonia, higher levels in the range of 10 μg/mL may be required.

Clindamycin

This antibiotic is useful in infections caused by *B. fragilis.* The drug suppresses protein synthesis by bacterial ribosomes and binds to the same subcellular site as chloramphenicol. Thus, simultaneous use of these two drugs is highly inadvisable. Clindamycin-associated diarrhoea, rarely progressing to pseudomembranous colitis (PMC), is an adverse side effect.

Vancomycin

This has assumed major importance in the treatment of surgical infections due to resistant micro-organisms, particularly MRSA and *Staphylococcus epidermidis* and *Corynebacterium diphtheriae.* In MRSA infections, the addition of aminoglycosides or rifampicin may be necessary (sometimes all three). Vancomycin should be administered over a 1 hour period to avoid hypotension and a red rash over the upper body (red man syndrome). Vancomycin is also used in the treatment of PMC caused by *C. difficile.* Resistance to vancomycin is now well documented among nosocomial infections.

Carbapenems

This group, which is related to the penicillins, is active against a variety of Gram-negative organisms and anaerobes. The most commonly used antibiotic of this group is imipenem–cilastatin. Cilastatin is a toxicity-free additive that inhibits the dehydropeptidase enzyme that catalyses the reaction leading to rapid excretion of imipenem by the kidney. Another member of the group is meropenem. These antibiotics are valuable in the treatment of serious abdominal and pulmonary infections caused by Gram-negative bacteria.

Monobactams

The only member of this group that is used clinically is aztreonam, which exhibits marked activity against aerobic Gram-negative organisms. Studies have confirmed outcomes equivalent to combination therapy with aminoglycosides in infections due to *E. coli, Klebsiella pneumoniae, Streptococcus marcescens, P. aeruginosa, Enterobacter* spp., *Proteus* spp. and *Providencia* spp. Combined with clindamycin, this drug has been effective in the treatment of aspiration pneumonia.

β-Lactamase inhibitors

The binding of the β-lactamase inhibitor clavulanic acid to certain antibiotics, e.g. ticarcillin, enhances their activity. Co-amoxiclav (amoxicillin + clavulanic acid) is effective against aspiration and postoperative pneumonia and peritonitis.

Quinolones

This group includes ciprofloxacin and norfloxacin. These drugs have a wide spectrum of activity against Enterobacteriaceae and may be administered orally and parenterally. Occasional nausea, vomiting and diarrhoea represent the most common side effects.

Metronidazole

Originally introduced for the treatment of protozoal infections (*Trichomonas vaginalis, Giardia lamblia, Entamoeba histolytica*), this is the most effective agent against anaerobic Gram-negative infections, *Bacteroides* and *B. fragilis,* and is often used in combination with cephalosporins and aminoglycosides for mixed infections. Metronidazole is also effective in PMC caused by *C. difficile.*

Infections in critically ill intensive care unit patients

Patients in ICUs are two to five times more likely to develop nosocomial infections than the general hospital population (where 5% prevalence is regarded as the norm). The acknowledged risk factors include:

- age >70 years
- shock
- steroids
- chemotherapy
- ICU stay >3 days
- previous antibiotics
- mechanical ventilation
- invasive monitoring
- indwelling urinary catheter >10 days
- acute renal failure
- surgical versus medical patient.

Invasive monitoring poses a real dilemma and the value of the widespread use of the pulmonary flotation catheters has been questioned recently. Selective use only in patients who require this invasive cardiac monitoring is a sensible option. The consequences of infection in ICU patients are always serious, with an established association with multiple organ systems failure and a fatal outcome.

Detection of infection in intensive care unit patients

Evaluation of the critically ill patient for infection is often difficult. The two problems are (1) differentiation between colonization and invasive infection and (2) localization of the site of infection. In the search for infection, a systematic head-to-toe approach is needed. The prior condition of the patient is also taken into consideration, i.e. pre-existing medical diseases and the surgical procedures that have been performed. Frequently, the occurrence of infection in ICU patients is closely associated with complications of surgical interventions. In this context, the nature of the operation is important, e.g. anastomotic dehiscence and intra-abdominal abscesses after gastrointestinal surgery, mediastinitis after cardiac surgery. Other hospital-acquired infections must also be excluded:

- *head and neck*: sinusitis, meningitis, ventriculitis, etc.
- *chest*: aspiration, pneumonia, lung abscess, empyema
- *abdomen*: *C. difficile* PMC, urinary tract infection
- *catheter-related infections*: arterial catheters, central venous catheters, Swan–Ganz catheters.

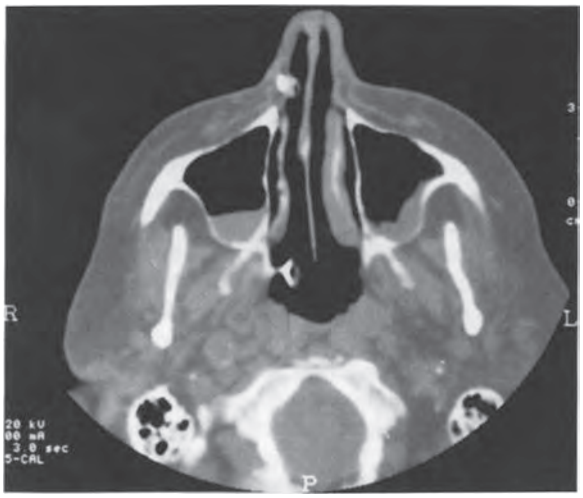

Figure 11.1 CT scan of the head in a patient who was septic from sinusitis. Note the air–fluid levels in the maxillary sinuses.

Sinusitis is most commonly associated with nasotracheal intubation but may also complicate indwelling nasogastric tubes. The overall reported incidence in ICU patients is 2%. Facial trauma is a predisposing factor. The maxillary sinuses are involved in 50–75% of cases. The mechanism by which the sinusitis occurs is usually obstruction of the sinus ostia by the tube; hence, the sinus involved is almost always on the same side as the nasal tube. The diagnosis, once suspected, is established by a CT scan (Figure 11.1). The bacteria involved are usually Gram-negative bacilli, *S. aureus* or anaerobes. Treatment includes removal of the nasal tube, decongestant sprays, antibiotics and drainage of the sinus.

Meningitis and ventriculitis are most commonly related to intracranial surgery, head trauma or the placement of intracranial pressure monitors. The most common organisms causing these infections are Gram-negative bacilli, *Staphylococcus* spp. and *Streptococcus* spp. The use of prophylactic antibiotics in patients with intracranial monitoring devices remains controversial.

Chest infections in intensive care unit patients

These are very common and include pneumonia, lung abscess, empyema and mediastinitis (after cardiac surgery). Pneumonia is by far the most common. Lung abscess usually arises against a background of pneumonia, and empyema is most commonly encountered in trauma patients with chest tube drainage and oesophageal perforation or leaks. The majority of ICU-acquired pneumonias reflect the ICU's bacterial flora. Within a short time of arriving in the ICU, the patient's own bacterial flora is replaced by the ICU flora, which often contains antibiotic-resistant strains. The risk factors for pneumonia are:

- age
- aspiration
- head injury
- smoking
- intubation and mechanical ventilation
- lung injury: acute respiratory distress syndrome (ARDS) and pulmonary contusion
- prior use of antibiotics
- prolonged preoperative hospital stay
- pulmonary oedema
- use of H_2 blockers and proton-pump inhibitors
- upper abdominal and chest incision.

Patients on mechanical ventilation are particularly at risk as normal protective mechanisms such as the mucociliary clearance mechanism and coughing are breached. The mechanism by which pneumonia occurs in ICU patients is thought to be by aspiration of upper airway and oropharyngeal secretions in most instances, as evidenced by the bacteriology. Thus, approximately 70–75% are caused by aerobic Gram-negative bacilli, 15–20% by *S. aureus* and 5–15% by *Candida*. Only 2–15% of normal humans have Gram-negative bacilli colonizing their upper airways, but, in critically ill patients, the colonization of the upper airway occurs within the first few days of ICU stay in 55–75% of patients.

The diagnosis of pneumonia in critically ill patients may be difficult. Chest radiograph may not be helpful as many of these patients already have pulmonary infiltrates from other causes, e.g. ARDS or pulmonary contusion (trauma patients). Thus, diagnosis is based on (1) quantity and quality of sputum, (2) Gram staining and (3) sputum culture. The presence of copious purulent sputum containing leucocytes and intracellular bacteria on Gram staining is enough to make a diagnosis pending the results of culture. Initial therapy is based on sputum Gram staining as follows:

- *Gram-negative bacilli*: third-generation cephalosporin, extended spectrum penicillin, monobactam, aminoglycoside
- *Gram-negative bacilli with suspicion of* Pseudomonas: imipenem or cilastatin, penicillin + aminoglycoside, third-generation cephalosporin + aminoglycoside
- *Gram-positive cocci in clumps:* nafcillin, vancomycin for MRSA
- *Gram-positive cocci in chains*: penicillin G
- *yeast:* amphotericin B, fluconazole.

The results of sputum culture may not be representative of the infection because of contamination by oral flora. To overcome this, samples may be obtained by transtracheal aspiration through the cricothyroid membrane via an Angiocath (in non-intubated patients) or via a flexible bronchoscope with a protected brush technique for sputum sampling.

Catheter-related infections

Patients in the ICU are more likely to develop catheter-related sepsis than those in hospital wards. However, it is unclear whether this is due to the patient's underlying illness or to the fact that these patients tend to have catheters that are often inserted under emergency conditions, are *in situ* for long periods and are frequently manipulated. Catheter-related bacteraemia is encountered when the number of colony-forming units cultured from the tip is 15 or more. The changing of catheters to prevent this bacteraemia and sepsis remains controversial, with several regimens being recommended:

- change catheter to a different site every 3–7 days
- change the catheter over a guide wire every 3–7 days
- do not change unless there is a problem.

In practice, no advantage has been documented to favour any one of these policies and the most important factor in the protection against catheter-related sepsis is the adoption of a strict aseptic technique when placing and caring for catheters. Several adjunctive techniques have been used to minimize the incidence of catheter-related sepsis: bonding antibiotics and silver compounds to the catheters, sterile protective plastic sleeves, silver ion-impregnated collagen cuffs, etc. Especially in ICU patients, catheter-related sepsis may have potentially lethal consequences, such as subacute bacterial endocarditis and suppurative thrombophlebitis.

The algorithm for management of catheters in critically ill patients is shown in Figure 11.2.

Fungal infections

These are important in ICU patients for two reasons:

1. Disseminated fungal infections constitute a grave prognostic marker of critical illness.
2. Despite newer fungal agents, the mortality (usually from multisystem organ failure) remains high, ranging from 33% to 75%. By far the most common organism responsible in ICU patients is *Candida albicans*. Much less commonly, other fungi, e.g. *Aspergillus* spp., *Torulopsis glabrata*, *Mucor* spp., are responsible.

The risk factors for colonization and invasive infections are:

- multiple antibiotic usage over a prolonged period
- immune depression
- steroid therapy
- parenteral nutrition
- concomitant bacteraemia.

Specific bacterial infections of surgical importance

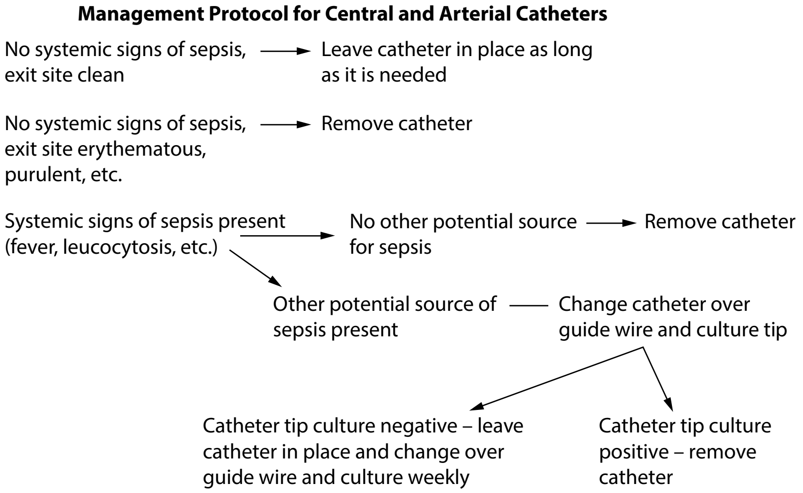
Gas gangrene

Gas gangrene is extremely rare in civilian practice (0.1/100 000 per annum). The essential factor required for spore germination and production of illness is reduced oxygen tension. This may result from severe contusion and laceration with necrotic tissue, devitalization of a wound by compression, impaired blood supply, or foreign bodies implanted in the depths of a punctured wound, e.g. shrapnel or pieces of clothing and soil, which induces tissue necrosis as a result of its high ionized calcium salts and silicic acid. The oxygen tension of a wound may be further lowered by coexisting infection with pyogenic organisms. Gas gangrene has been reported following injection of epinephrine (adrenaline) into the buttocks where the skin is often contaminated by clostridial spores from the patient's faeces.

Bacteriology and pathology

Gas gangrene is a mixed clostridial infection by saccharolytic (pathogenic) and proteolytic (saprophytic) organisms. The true pathogens are *Clostridium perfringens* (*C. welchii*), *Clostridium novyi* (*C. oedematiens*) and *Clostridium septicum*. Type A *C. perfringens* is the most important human pathogen. It produces α-toxin, which is a lecithinase and breaks down the phospholipid constituents of red cells with the production of haemolysis. Other exotoxins produced by some strains of *C. perfringens* include haemolysin, collagenase, hyaluronidase and deoxyribonuclease.

These exotoxins produce a cellulitis and a progressive myonecrosis. They ferment the muscle carbohydrate, with the production of lactic acid and gas (H_2, CO_2). The discharge from the wound is initially odourless. Spread of the necrosis occurs as a result of exotoxin release and ischaemia from pressure by gas and exudate within tight muscle compartments. The affected area becomes tense, oedematous and crepitant. At first, the dead muscle is odourless and brick red in colour. Progressive putrefaction by saprophytic clostridia (*Clostridium sporogenes, Clostridium histolyticum*)



Management Protocol for Central and Arterial Catheters
No systemic signs of sepsis, exit site clean
Leave catheter in place as long as it is needed
No systemic signs of sepsis, exit site erythematous, purulent, etc.
Remove catheter
Systemic signs of sepsis present (fever, leucocytosis, etc.)
No other potential source for sepsis
Remove catheter
Other potential source of sepsis present
Change catheter over guide wire and culture tip
Catheter tip culture negative – leave catheter in place and change over guide wire and culture weekly
Catheter tip culture positive – remove catheter

Figure 11.2 Algorithm for the routine care of intravascular catheters.

of the dead muscle completes the pathological process with the production of the characteristic fishy odour and the greenish-black appearance of the established disease.

The profound toxaemia is due to the circulating exotoxins and results in shock, haemolytic anaemia, renal failure and jaundice. The organisms themselves do not invade the bloodstream except as an agonal event, and this accounts for the foamy liver and gas bubbles found in other organs at necropsy.

Clinical features

The majority of gas gangrene infections are exogenous and result from contamination of large wounds as occurs in agriculture tractor injuries, severe comminuted compound fractures sustained in road traffic accidents and battle casualties. An appreciable number of cases in civilian practice are, however, endogenous in origin from contamination by bowel organisms. In the West, endogenous gas gangrene is most commonly encountered following amputation for peripheral vascular disease. Risk factors in this group include diabetes and incontinence. Other instances of gas gangrene may result from criminal abortion and infections following intestinal and, less commonly, biliary operations.

The incubation period between the initiating incident and the onset of the clostridial infection varies from 1 day to 4 weeks. Its duration carries an inverse relationship with the severity of the illness and the mortality. The demonstration of gas (Figure 11.3) is not essential for the diagnosis as non-gas-forming clostridial infections of wounds are well documented. Indeed, the most useful clinical classification is into gas-forming and non-gas-forming clostridial infections. *The most important factor that determines whether the infection remains localized and non-crepitant, or becomes invasive with severe toxaemia and gas formation is the presence of dead muscle.*

Non-gas-forming infections

The disease is mild and, apart from pyrexia, there is minimal toxicity. The wound is oedematous and erythematous, and may develop a brownish discoloration. Crepitus is absent; pain and tenderness are not severe and the mortality due to the clostridial infection is negligible.

Gas-forming infections

The incubation period is usually less than 3 days and the onset acute. The condition declares itself by severe pain in the region of the wound and rapid development of toxaemia, drowsiness, fever and tachycardia. The affected area becomes swollen, tense, oedematous and extremely tender. The discharge may be serous or blood stained. It is variable in amount and initially odourless but subsequently becomes sweet to foul smelling. Gas is detected by crepitus and radiological examination. The overlying skin goes through a series of changes from intense white to inflammatory erythema with ecchymosis, bullae formation and frank greenish-black gangrene (Figure 11.4). In severe cases, jaundice, haemolysis and renal failure develop and contribute to the death of the patient. The overall mortality is 40%, but the mortality due to overwhelming clostridial infection is 10–15%.

Treatment

The treatment consists of general resuscitative measures for shock and specific therapy, i.e. antibiotics, antitoxin, surgical treatment and, when available, hyperbaric oxygen.

Antibiotic therapy

This is used both in the prophylaxis and in the treatment of established disease. For prophylaxis, the antibiotic therapy must be started immediately before the operation, e.g. amputation for peripheral vascular disease or soon after the injury, and should be continued until the healing is complete if the risk is high. The benefit of antibiotic therapy in established disease remains doubtful, largely because of poor antibiotic penetration into ischaemic tissue. Nonetheless, it constitutes part of the orthodox therapy. Antibiotic treatment should provide wide coverage to include Gram-positive

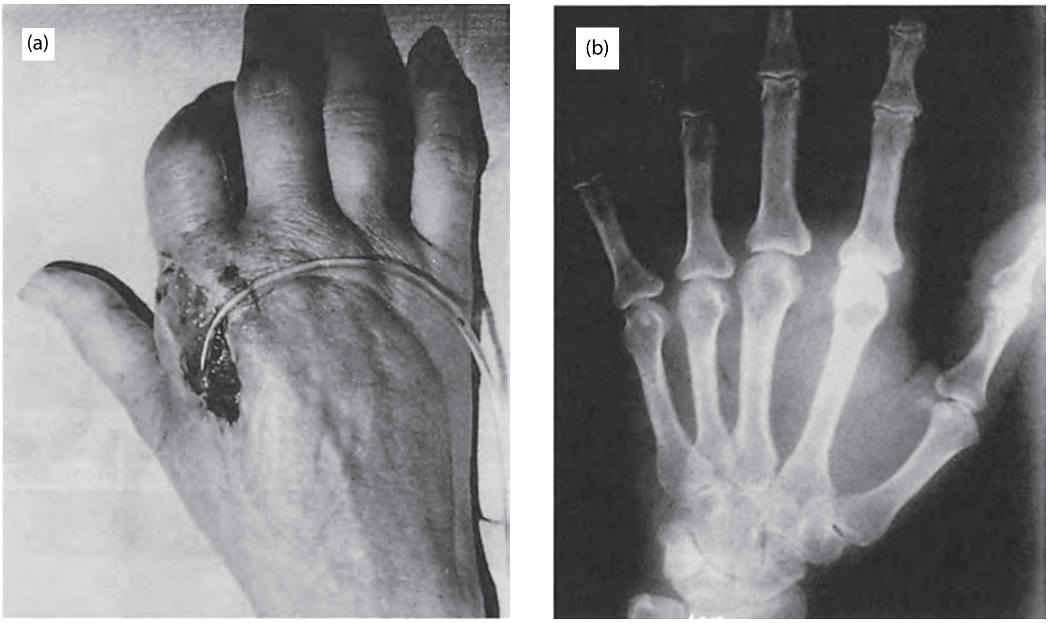


Figure 11.3 (a) Gas gangrene of the hand; (b) radiograph of the same hand showing gas in the soft tissues.

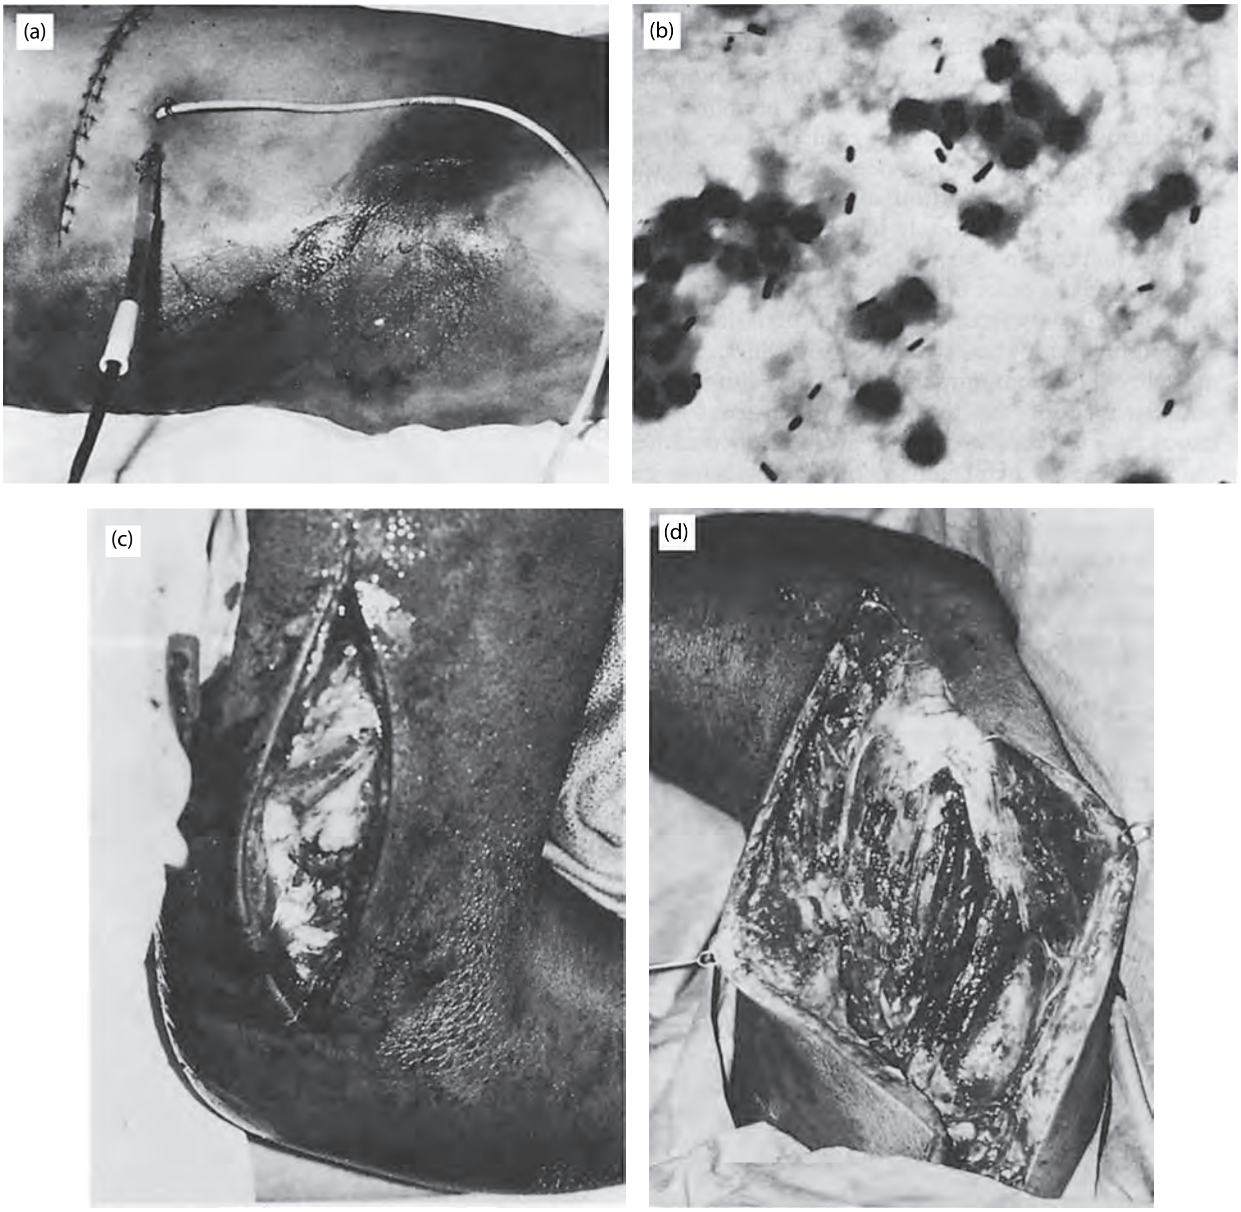

Figure 11.4 Gas gangrene: (a) abdominal wall after common bile duct exploration for ductal calculi; (b) microscopy of the needle aspirate from the same patient showing clostridial organisms; (c) gas gangrene of the upper arm: note bulging of oedematous tissues after incision of the skin; (d) same patient: extensive necrosis of upper arm muscles.

(penicillin or cephalosporin), Gram-negative (aminoglycoside, third-generation cephalosporin or ciprofloxacin) and anaerobic bacteria (clindamycin or metronidazole). In addition, vancomycin or linezolid should be considered in those at risk for MRSA. Tetracycline and erythromycin exhibit moderate activity against most clostridial species but rapid development of drug resistance is a problem. The treatment is continued for a minimum of 7 days and the antibiotic regimen may need to be changed, depending on the bacteriology and sensitivity tests.

Surgical treatment

Surgical treatment must be carried out immediately after resuscitation and commencement of antibiotic therapy and is delayed only if facilities for hyperbaric oxygen therapy are available (see below), when operative intervention is postponed until completion of the first hyperbaric treatment. The aim of surgical treatment is the excision of all necrotic tissue regardless of anatomical defects thus produced. Pus is evacuated and the completely debrided wound is irrigated with hydrogen peroxide solution. *The complete excision of all dead and infected tissue at the first operation is crucial to the survival of the patient.* In limb infections, this may necessitate amputation. No attempt is made to provide skin cover and the wound is packed with gauze soaked in isotonic saline solution. The patient is returned to the operating theatre 24–48 hours later for a dressing change under general anaesthesia. Any residual necrotic areas are excised down to bleeding tissues, after which the wound is dressed as before. Reconstructive surgery and skin grafting are delayed until the infection has been totally eradicated.

Hyperbaric oxygen therapy benefits patients with pure clostridial infections, and may result in rapid improvement in the clinical condition and in limb salvage. Hyperbaric oxygen therapy is started soon after the initial resuscitation and before surgical intervention. It consists of repeated treatments of 1.5–2 hours at a pressure of 250 kPa (2.5 atm).

Mortality

The reported mortality from traumatic gas gangrene is greater than 25% but that associated with non-traumatic gas gangrene caused by *C. septicum* is much higher, with reported mortality rates varying from 67% to 100%.

Clostridial enterocolitis and pseudomembranous colitis

This results from the ingestion of improperly cooked food contaminated by *C. perfringens*. The disease is usually self-limiting and causes severe colicky abdominal pain and diarrhoea. The organism is present in the stool in high counts. Occasionally, the condition is more severe and leads to widespread necrosis of the bowel (primarily of the small intestine) and is then referred to as enteritis necrotica. In addition to severe abdominal pain, vomiting and diarrhoea, the patient exhibits signs of peritonitis with profound toxaemia and shock. The condition carries a very high mortality.

Enterocolitis caused by *C. perfringens* has to be distinguished from PMC, which develops as a complication of antibiotic therapy in about 1 out of every 15 000 people treated with an antibiotic and is caused by *C. difficile*. The incidence of PMC is rising in many countries and approximately 30 000 people die each year from PMC in the USA. The risk factors for PMC include:

- old age
- AIDS
- suppression of gastric acid secretion
- antibiotic use
- chemotherapy
- Crohn disease
- enemas
- previous PMC infection
- prolonged hospitalization
- recent surgery
- tube feedings
- ulcerative colitis.

The symptoms of PMC colitis include diarrhoea that contains green or yellow mucus and blood in the stool, tenesmus, anorexia and nausea, cramping abdominal pain, vomiting, fever and rigors and weight loss. When suspected, stool cultures and stool test for *C. difficile* are mandatory in addition to other tests such as colonoscopy. Treatment is with rehydration and antibiotic therapy with any of the following depending on sensitivity: fidaxomicin, metronidazole, vancomycin or rifaximin (see Chapter 30).

Infective non-clostridial gangrene

Various clinical syndromes have been described as infective non-clostridial gangrene. The most common causative organisms are anaerobic streptococci, but necrotizing infections with *E. coli* and *Bacteroides* are well documented. The most common member of the *Bacteroides* species responsible for infective gangrene is *Fusiformis fusiformis,* which is often accompanied by *Borrelia vincentii,* although it is doubtful whether the latter plays any part in the disease process.

These gangrenous conditions usually arise against a background of debility, atherosclerosis and diabetes mellitus. The causative anaerobes often act in association with *S. pyogenes*, staphylococci and coliform bacilli. However, in some well-documented cases, a causative organism cannot be identified. In some cases a precipitating factor, e.g. trauma, operation or viral infection, initiates the condition; in others, particularly in diabetic patients, the morbid process arises spontaneously. A commonly favoured pathological classification is into:

- cutaneous gangrene (progressive bacterial gangrene)
- subcutaneous gangrene (necrotizing fasciitis)
- subfascial infective gangrene.

In cutaneous gangrene, the necrosis is limited to the skin only and systemic signs are usually minimal, although the disease may extend to the deeper tissues. In subcutaneous gangrene, the necrotic process primarily involves the subcutaneous fat and/or the deep fascia, usually sparing the underlying muscle layer. Necrosis of the skin is secondary to the development of thrombosis of the perforating vessels as they course through the necrotic infected deeper layers. Subcutaneous gangrene is a serious, rapidly spreading disease, which is accompanied by toxaemia and may prove fatal. Subfascial infections consist of myositis and myonecrosis.

The above classification, although useful in outlining the pathology and prognosis in the majority of these infections, does not cover the entire spectrum of these infections, some of which cannot be readily placed in either of these categories. In addition, a cutaneous infection may spread to involve the subcutaneous and subfascial compartments. Thus, a more comprehensive clinical classification of infective non-clostridial gangrene is:

- cutaneous gangrene (Meleney's progressive bacterial gangrene)
- subcutaneous gangrene: necrotizing fasciitis and Meleney's undermining ulcer
- infected vascular gangrene
- cancrum oris and noma vulva: protein calorie malnutrition
- streptococcal myositis
- human bite infections.

Cutaneous gangrene (Meleney's progressive bacterial gangrene)

This is usually a synergistic infection with two microbial species that differ in their requirements for oxygen. In classic cases, the micro-organisms involved are microaerophilic streptococci and aerobic staphylococci, although *Bacteroides* and a variety of Gram-negative aerobic bacteria can be involved. Bacterial inoculation most frequently follows minor trauma, or a postoperative consequence of a surgical drain or mass closure with deep tension sutures. It often follows drainage of abscesses, particularly in patients with diabetes mellitus and severe atherosclerosis. In most instances, 1–2 weeks elapse before the onset of clinical manifestations. At that time, the skin surrounding the wound becomes red, oedematous and very tender. As the cutaneous infection extends outwards, the central area becomes necrotic, turning to eschar that ulcerates (Figure 11.5). A thin, foul-smelling discharge simulating dishwater emanates from the ulcer. At this stage, the patient becomes systemically toxic. Broad-spectrum antibiotics and surgical excision are necessary for survival. The most favoured first-line antibiotic combination is benzyl penicillin, metronidazole and gentamicin. At operation, the infected necrosis is found to be limited to the skin and subcutaneous fat, but the fascia and underlying muscle are spared except for in advanced cases. Following complete excision, the wound is left open and packed with gauze soaked in a bactericidal agent. Debridement may have to be repeated. Secondary wound closure or skin cover by grafting is only attempted after the infection has been completely eradicated and healthy granulation tissue has formed.

Subcutaneous gangrene

The most important example of this is necrotizing fasciitis, also known as haemolytic streptococcal gangrene, hospital gangrene and gangrenous erysipelas. It includes conditions such as perineal phlegmon (Figure 11.6) and Fournier's scrotal gangrene (Figure 11.7). It is caused by haemolytic streptococci and, less commonly, haemolytic staphylococci. Various other organisms have been identified in some of these infections, including coliforms, *Bacteroides*, diphtheroids and *Pseudomonas.* Most commonly, the condition arises following surgery or trauma. Spontaneous cases have been described, although, in some of these patients, the preceding trauma may have been so slight as to be ignored by the patient. The most commonly affected sites are the extremities, followed by the lower trunk, including the external genitalia and the perineum. The exact mechanism for the subcutaneous necrosis is unknown but appears to be related to the binding of the mucopeptide fraction of the bacterial cell wall with dermal collagen. The necrosis does not involve the muscle layer and skin involvement is secondary to thrombosis of the perforating vessels coursing through the infected necrotic area.

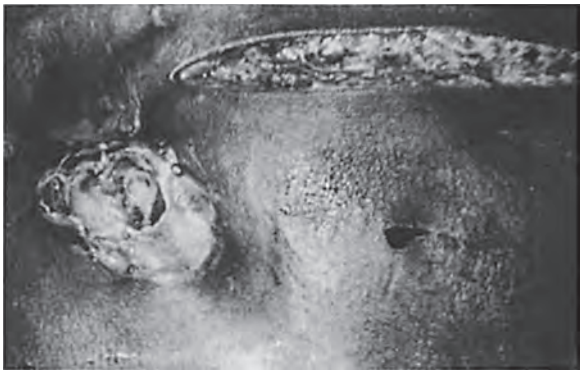

Figure 11.5 Meleney's progressive bacterial gangrene. Culture revealed *Staphylococcus aureus* and a microaerophilic *Streptococcus.*

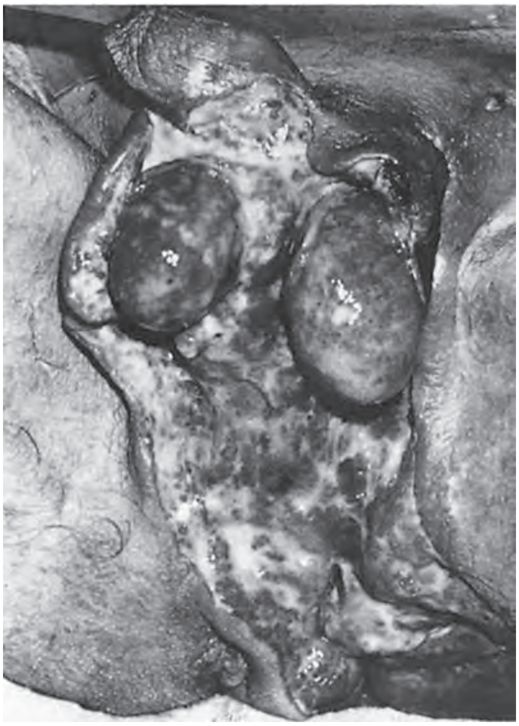

Figure 11.6 Extensive perineal phlegmon involving the skin of the scrotum and penile shaft.

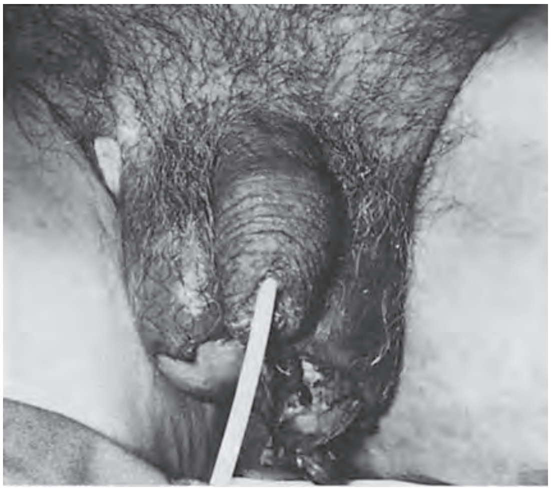

Figure 11.7 Fournier's gangrene with necrosis of scrotal skin.

The disease is always serious and carries a definite mortality. The affected part is initially very painful but then becomes numb owing to the involvement of sensory nerve fibres. The process spreads rapidly through the subcutaneous fatty/fascial plane with reddish discoloration, inflammatory oedema (sometimes bullous), necrosis and eventual sloughing of the overlying skin (Figure 11.8). Systemic manifestations are always present and the toxaemia may be severe with pyrexia, tachycardia and shock. Blood cultures should always be taken in these patients. Treatment includes resuscitation with crystalloids and blood, antibiotics using a triple regimen (benzyl penicillin, metronidazole and aminoglycoside), and early wide surgical excision and drainage with delayed skin cover.

Meleney's chronic undermining ulcer results from infection by a microaerophilic *Streptococcus* and usually develops after surgery on the intestinal and genital tracts. The infection and necrosis start in the subcutaneous tissues (Figure 11.9) but the disease progressively affects the deeper tissues to involve the pelvis. Treatment is with a combination of benzyl penicillin and metronidazole, together with surgical excision and delayed skin cover.

Infected vascular gangrene

A significant proportion of these necrotic infections occur in diabetic patients. Infected vascular gangrene has a gradual onset. The affected part (usually the foot) becomes painful, swollen, black and foul smelling. Radiographs show extensive gas formation in the tissues of the involved foot. The infection is a mixed one with faecal organisms, most commonly *B. fragilis* and *Peptostreptococcus.* The severity of the toxaemia is variable.

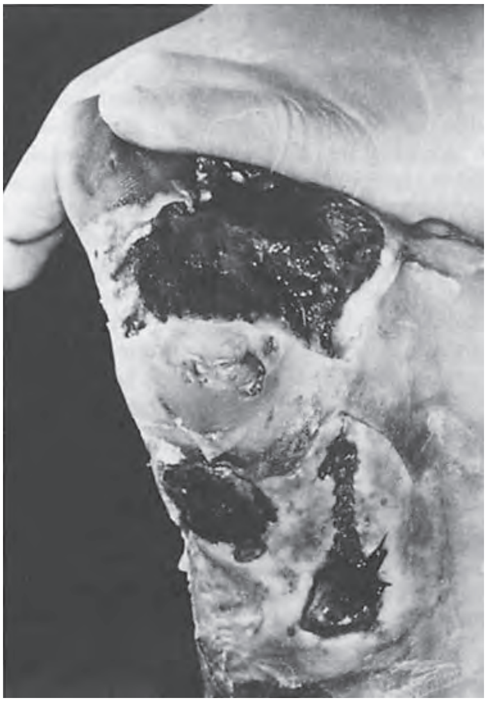

Figure 11.8 Necrotizing fasciitis of the sole of the foot.

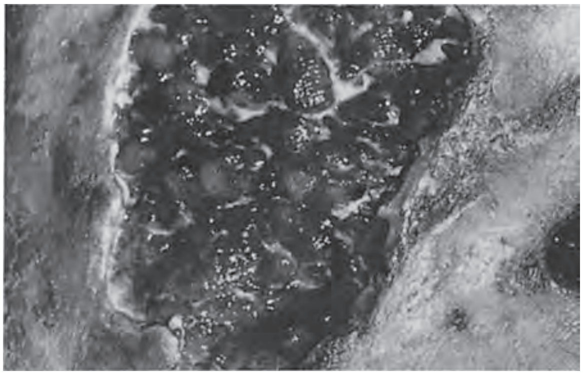

Figure 11.9 Meleney's chronic undermining ulcer in the right iliac fossa in a renal transplant patient.

Streptococcal myositis

This represents a unique infection that can usually be distinguished from clostridial infections by the presence of pronounced skin reaction: cyanotic discoloration, blebs containing foul-smelling fluid teeming with Gram-positive cocci, and islands of frankly gangrenous skin. After instituting supportive care and antibiotics, treatment is with a generous incision, exploration and drainage of all the infected muscle groups, aptly termed the 'fillet' procedure. Only occasionally is myonecrosis present and this requires excision. The wound is kept open and packed with saline gauze. Prognosis is surprisingly good if the infection is managed before the onset of myonecrosis.

Cancrum oris and noma vulvae

These are instances of mucocutaneous gangrene affecting the mouth (cancrum oris) or the vulva (noma vulvae). Both arise against a background of malnutrition in children and are usually preceded by an infectious illness, such as measles. The infection is often a mixed one, but the protagonists are either anaerobic streptococci or members of the *Bacteroides* species. The disease results in slow but relentless necrosis of the perioral or vulval tissues, and in cancrum oris death may result from inhalation pneumonia. Correction of the underlying malnutrition is essential, in addition to antibiotic therapy. Skin cover and plastic reconstruction are delayed until the infection has been cleared and the patient's nutritional status has improved.

Human bite infections

The anaerobic infections caused by human bites can be particularly virulent and cause marked tissue destruction. The infection is usually a mixed one, the causative organisms being a combination of two or more of the following: *Bacteroides melaninogenicus*, *Fusobacterium* spp., anaerobic cocci and spirochaetes. The first-line antibiotic is penicillin, which is administered in high doses. The importance of tetanus prophylaxis in these patients must not be forgotten.

Tetanus

In the vast majority of cases, tetanus is an exogenous infection, although rare instances of endogenous infections are documented after septic abortions and operations on the gastrointestinal tract. The conditions governing the germination of spores of *Clostridium tetani* are identical to those of gas gangrene and necessitate local hypoxia. The most common portal of entry worldwide is the umbilical stump following the application of dung to this region in newborn babies that is practised in some developing countries. Elsewhere, the lower limbs constitute the most common portal of entry. Usually, the wound is a minor one but it is always penetrating in nature. *In some 25% of cases in the West, the portal of entry is not evident at the time of diagnosis.*

Other sources of infection include piercing of the ear lobes; tattooing; burns; parenteral injections including vaccination; skin lesions, especially leg ulcers; nasal foreign bodies; and ear infections. The disease is well recognized in drug addicts.

C. tetani (Figure 11.10) produces two exotoxins. The most important is a neurotoxin called tetanospasmin that is responsible for the disease. A haemolytic toxin called tetanolysin acts on the peripheral neuromuscular junctions but does not play a significant role in the disease. Tetanospasmin reaches the central nervous system (CNS) along the axons of motor trunks, probably in the tissue spaces between the nerve fibres, and acts by blocking the inhibitory impulses at the motor synapses. This results in two forms of contractions of striated muscles: tonic (spasm), characteristic of the early disease, and clonic (convulsions), indicating severe established disease.

The overall mortality of tetanus is 10–15%. Adverse factors include extremes of age, short incubation period, type of injury and severity of the illness. Thus, whereas mild to moderate tetanus carries a small mortality, death from the disease occurs in 30–40% of patients with severe tetanus. Death usually results from asphyxia from involvement of the muscles of respiration and from cardiovascular complications resulting from sympathetic overactivity.

Clinical features

Neonatal tetanus is by far the most common type in developing countries, where it accounts for 70% of cases. It is best considered separately from the disease in children and adults.

Neonatal tetanus

The clinical picture is characteristic and the disease usually becomes manifest on the eighth day, hence the popular name 'eighth-day disease'. It starts with failure to suckle on the third day. This is followed quickly by spasm of the facial muscles (risus sardonicus) and masseter (lockjaw), and progression to generalized clonic spasms with flexion of the arms, clenched fists, extension of the lower limbs and plantarflexion of the toes.

Children and adults

The majority of patients (95%) who develop tetanus have not been previously immunized. The incubation period ranges from 4 to 10 days, and the shorter the interval the more severe the disease. The progress of the disease (the time from the first symptom to the onset of tetanus) varies according to the severity of the disease but the full-blown picture is reached by the third day in 70% of cases. The condition declares itself by stiffness, twitching and cramps limited to the same spinal segment as the area of infection (local tetanus). Other early symptoms and signs include muscle pains, headaches, irritability, restlessness, constipation, sweating and tachycardia. This is followed by the development of spasm of the masseter muscles, facial musculature and muscles of deglutition (dysphagia). In the full-blown picture, there are generalized clonic convulsions that may be triggered by mild external stimuli (sound, movement of personnel, etc.). As the extensor muscles are more powerful than the flexor muscles, the patient classically assumes a position of opisthotonos. It is characteristic of tetanus that the muscles do not relax between convulsive attacks, and this distinguishes tetanic convulsions from those caused by strychnine poisoning.

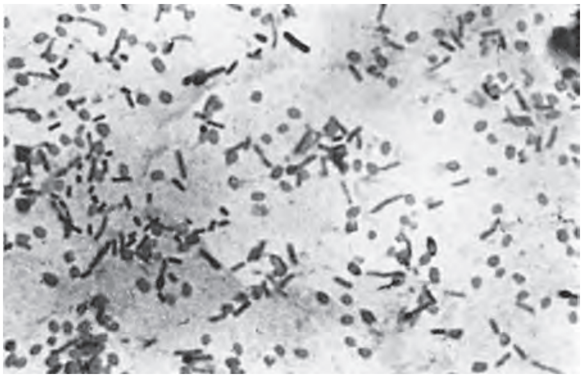

Figure 11.10 *Clostridium tetani* organisms.

Tetanus is classified into:

- mild: no dysphagia or respiratory distress
- moderate: presence of dysphagia and respiratory distress
- severe: gross spasticity and major spasms.

Treatment

Prophylaxis

The best method of prevention is by active immunization with tetanus toxoid (a formolized preparation of the exotoxin adsorbed on aluminium hydroxide or phosphate). Three injections are administered, with the second injection 6 weeks after the first, and the third injection 6–12 months later. A booster injection is given at 10 year intervals and at times of wounding. Booster toxoid injections are not necessary if a patient sustains a wound within 5 years of completion of an active immunization course or booster dose. However, if the period since the last toxoid injection exceeds 5 years, but is less than 10 years, a booster dose should be administered. In the absence of a history of active immunization, or if the period since the last toxoid injection exceeds 10 years, passive immunization with human tetanus immunoglobulin [tetanus immune globulin (TIG)] in a dose of 250 units intramuscularly is indicated. This single dose provides immunity for about 4 weeks. If the wound has not healed by this time, a second dose is administered. Active immunization with toxoid should be started at the same time (using a different limb) in those not previously immunized, or a single booster dose is administered to those patients who had allowed their active immunization to lapse for more than 10 years. The use of equine antitetanic serum is no longer practised because of the risk of anaphylactic reactions. Active immunization with tetanus toxoid of the pregnant female will protect the infant from neonatal tetanus.

Treatment of established disease

Specific measures include surgical attention to the wound if present with excision and open packing with antibiotic or hydrogen peroxide-soaked gauze. Benzyl penicillin is administered in a dose of 2 MU every 4 hours for 7 days, and TIG is given in a dose of 2000–4000 U intramuscularly. Metronidazole (500 mg orally every 6 hours or 1.0 g rectally 8 hourly) may be used instead of penicillin and is reported to be more effective. In neonatal tetanus, good results have been obtained with intrathecal TIG and prednisolone. Doxycycline is another effective antibiotic. Supportive measures include intravenous fluids, control of pain and sedation. Diazepam alone, compared with other sedatives such as phenobarbitone, appears to more effective in treating tetanus, and adding other drugs to diazepam does not appear beneficial and may be harmful.

For mild tetanus, the patient only requires sedation with diazepam. Tracheostomy and sedation are necessary for patients with moderate tetanus. In severe disease, the patient has to be treated with neuromuscular blockade and positive-pressure ventilation. The very severe cases with sympathetic overactivity and cardiovascular complications (tachycardia, labile hypertension, vasoconstriction, myocardial instability) require general anaesthesia, mechanical ventilation and adrenergic blockade.

Chronic bacterial infections

These are produced by the species of the order Actinomycetales, so named because the bacterial cells may branch to form hyphae. With some species, e.g. *Actinomyces israelii,* this branching tendency is marked and simulates the appearance of a fungal growth (*actino*, radial; *myces*, fungus). The composition of the order Actinomycetales is shown in Table 11.1.

Streptomycetaceae are not pathogenic to humans. The genus *Streptomyces* is, however, of medical importance as it contains many species valuable for the production of antibiotics (streptomycin, tetramycin, etc.). Most species of *Nocardia* are harmless and live on decaying organic matter in the soil. A few species, e.g. *Nocardia asteroides*, can cause infection of the lung that is often fatal and may be mistaken for tuberculosis. Other species (*Nocardia madurae, Nocardia brasiliensis*) are known to produce a chronic disease of the hands or feet similar to actinomycosis.

Tuberculosis

In conjunction with all of the mycobacteria, the tubercle bacilli are non-sporing, immobile, aerobic and Gram positive. Differential staining methods are used to identify the mycobacteria since, after heat staining with carbol fuchsin, these bacteria, with the exception of *Nocardia* spp., are unique in resisting decolouration after treatment with strong acids and alcohol, i.e. are acid fast.

There are several strains of non-pathogenic saprophytes in the soil and on plants (e.g. *Mycobacterium phlei*) and on the human skin (*Mycobacterium smegmatis*). The pathogenic status of several other species is variable but some are often found in tuberculosis-like disorders or in association with established tuberculosis, especially in immune-suppressed individuals. They are referred to variously as atypical, environmental, anonymous or MOTT (mycobacteria other than typical tubercle) to differentiate them from the established pathogens, i.e. *Mycobacterium tuberculosis* and *Mycobacterium bovis.* The precise differentiation of the various mycobacteria is important. Culture is usually performed on Lowenstein–Jensen medium and requires 6 weeks, although faster growth can be obtained in Dubois medium. No single test is said to be reliable in the identification of *M. tuberculosis* and *M. bovis*, although tests for virulence in guinea-pigs (*M. tuberculosis*) and rabbits (*M. bovis*) are among the most reliable of the diagnostic tests. *Mycobacterium tuberculosis* is the only species known to produce niacin on culture.

Table 11.1 The Actinomycetales

Order	Family	Genus	Pathogenic species
Actinomycetales	Mycobacteriaceae	*Mycobacterium*	*M. tuberculosis*
			M. leprae
	Actinomycetaceae	*Actinomyces*	*A. israelii*
		Nocardia	*N. asteroides*
			N. madurae
	Streptomycetaceae	*Streptomyces*	–

Following the eradication of tuberculous herds and the introduction of pasteurized milk, bovine tuberculosis is rarely encountered in the West, and most of the reported cases are pulmonary infections. The vast majority of cases in these countries are caused by *M. tuberculosis*, usually as a result of inhalation of organisms present in fresh droplets or dust contaminated with dried sputum by a patient with open pulmonary tuberculosis. Both bovine and human infections are still common in economically deprived areas, such as parts of the African continent, Latin America and India. The global increase in tuberculosis that occurred during the 1980s and 1990s was associated with a re-emergence of resistance to antituberculous drugs (isoniazid and multidrug).

Pathology

It has been estimated that 90% of all tuberculous infections involve the lungs, but the infection may affect practically any organ or tissue. The most commonly recognized extrapulmonary infections include tuberculosis of the skin, lymph nodes, bones and joints, genitourinary tract, abdomen and intestines, and CNS.

Tuberculous lesions assume one of two forms:

- proliferative: the tubercle follicle
- exudative.

The most common proliferative lesion that is usually encountered in the lungs and solid organs is the tubercle follicle. This consists of an area of coagulative necrosis (caseation) due primarily to hypersensitivity to the tuberculoprotein, surrounded by epithelioid and Langerhans giant cells (both derived from macrophages), and an outer zone of small, round cells consisting mainly of lymphocytes and fibroblasts.

The exudative form of tuberculosis is typically encountered in infections of the serous cavities, e.g. tuberculous pleurisy/peritonitis, and epithelial surfaces (sterile pyuria in renal tuberculosis). It results in the formation of a cellular exudate rich in fibrin, together with a dense infiltration of the tissues with lymphocytes.

Childhood tuberculosis is characterized by marked involvement of the regional lymph nodes, as exemplified by the primary complex (Ghon focus at the periphery of the lung mid-zone and hilar lymphadenopathy) and tabes mesenterica, where a small focus in the intestine is associated with marked enlargement of the mesenteric lymph nodes, which at times rupture causing tuberculous peritonitis. By contrast, in the adult, lymph node enlargement is not marked and the disease either heals by fibrosis or extends locally by caseation, liquefaction and cavitation, with little tendency to bloodstream dissemination. This altered tissue response in the adult appears to be the result of tissue maturation.

Softening and liquefaction of the caseous material underlies the development of tuberculous 'cold' abscesses. The liquefied debris may track along fascial planes, as in the psoas abscess originating from spinal tuberculosis (Figure 11.11), or point to the surface with the eventual formation of tuberculous sinuses, e.g. collar-stud abscess in the neck from tuberculous lymphadenitis and scrotal sinuses from tuberculous epididymitis.

Involvement of a pulmonary vein by a tuberculous focus in the lung may lead to bloodstream dissemination and miliary tuberculosis, especially if the resistance is lowered by poor nutrition, debility, old age or immune deficiency from any cause. If the bloodstream inoculum is small, the bacilli may be destroyed by the cells of the monocyte–macrophage system. Failing this, they may either produce metastatic disease immediately or remain quiescent with reactivation some years later. These lesions are referred to as local metastatic tuberculosis or secondary tuberculosis and account for the majority of tuberculous infections encountered in surgical practice.

Clinical features

The general symptoms of active tuberculous infections include malaise, asthenia, weight loss, mild fever and night sweats. The symptomatology is, however, extremely varied and the disease may simulate many other disorders. The specific symptoms relate to the organ involved in the disease. Tuberculosis is a disease of malnutrition and overcrowding. Other predisposing factors include poor general health, chronic disease, silicosis and diabetes. Certain ethnic groups, such as the Australian Aborigines, black Africans and native Americans, are particularly susceptible.

Allergy (hypersensitivity) and acquired immunity

Tuberculous infection, subclinical or otherwise, results in the development of a cell-mediated allergy (delayed hypersensitivity) to tuberculoprotein that causes caseation and an accelerated macrophage response. This hypersensitivity, which indicates present or past infection, can be determined by the tuberculin skin reaction, which consists of the intracutaneous injection of purified protein derivative that is derived from and has replaced Koch's old tuberculin. The delayed hypersensitivity, although closely related, is not the mechanism of the acquired immunity to tuberculosis. This immunity, which is only partial, is cell mediated by sensitized lymphocytes. Active immunization with bacille Calmette–Guérin (BCG) is generally recommended for tuberculin-negative individuals. Complications of BCG vaccination are rare and include local abscess formation, regional lymphadenitis and, rarely, systemic infection with progressive pulmonary disease. The last has been reported following immunotherapy with BCG in patients with malignant disease.

Treatment

Effective modern chemotherapy is followed by a high cure rate without the necessity for long-term follow-up unless disease is caused by resistant organisms. It has eliminated the need for sanatorium management. The drugs available include streptomycin, para-aminosalicylic acid, isoniazid, rifampicin, pyrazinamide and ethambutol. *Mycobacterium bovis* is intrinsically resistant to pyrazinamide. The resistance to isoniazid in the UK now averages 5.5% and multidrug resistance 1.35%. Both

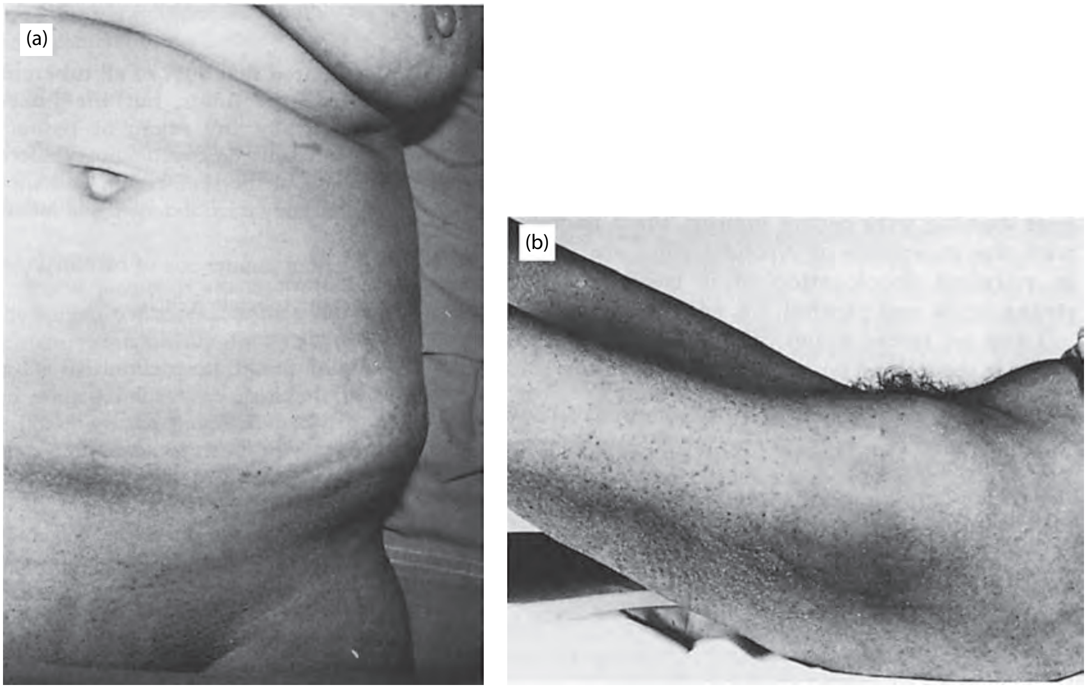

Figure 11.11 Tuberculous abscess: (a) left iliac fossa; (b) femoral triangle: infrainguinal extension of psoas abscess resulting from spinal disease.

isoniazid and multidrug resistance rates are higher in patients known to be infected with human immunodeficiency virus (HIV) (13.5% isoniazid and 6.1% multidrug).

Leprosy

It is estimated that 15 million people in the world have leprosy, which is common throughout most of Africa, southern Asia, the Far East, and South and Central America. There are about 400 active cases registered in the UK. However, no case of indigenously contracted leprosy has been reported in Britain.

Mycobacterium leprae, the causative organism, is a slender and acid-fast rod, occurring singly or in clusters (globi) in the reticuloendothelial (macrophage) cells. This slowly multiplying organism has been grown in the footpads of mice and the armadillo but not in an artificial culture medium. The infectivity of leprosy is a function of the concentration of leprosy bacilli in the body of the patient, and the chances of bacteria emerging and remaining viable and pathogenic to susceptible contacts. Leprosy is not a very contagious disease. It is frequently contracted in childhood or adolescence, revealing itself in symptoms and signs some years later. This silent period is commonly 2–5 years and often longer. Bacilli-laden nasal discharge is probably the main source of infection, but bacilliferous ulcerations, sweaty hairy skin and maternal milk may contain viable bacilli. Infection may be acquired by inhalation or through abrasions in the skin.

Pathology

The pathological lesions depend on the type and extent of the immune response. If cell-mediated immunity is strong, *tuberculoid* lesions form. The reaction consists of non-specific accumulation of giant cells, epithelioid cells, histiocytes and lymphocytes. Lymphocytic infiltrations are observed around and within nerve bundles. Bacilli are scanty *(paucibacillary disease)* and the lepromin test is positive.

When cell-mediated immunity is depressed, *lepromatous* leprosy (multibacillary disease) results. The whole dermis is replaced by highly bacilliferous tissue that invades the adnexa and eventually destroys superficial nerves, pigment-forming cells, sweat and sebaceous glands and hair follicles. The target tissues are the Schwann cells, endothelial cells and muscle cells. Bacilli may also be found in the liver, bone marrow, spleen, kidneys and lungs. Acute vasculitis caused by immune complexes may give rise to erythema nodosum leprosum, or other manifestations such as iritis, neuritis, orchitis, lymphadenitis and myositis. Longstanding lepromatous leprosy can result in chronic nephritis and amyloidosis.

Clinical features

Leprosy encompasses a whole spectrum of disease between the two main types, lepromatous and tuberculoid. The earlier manifestation, which is qualified as indeterminate, consists of a small hypopigmented macule, 2–5 cm, appearing anywhere in the body and often healing spontaneously. Determinate lesions that progress to clinical disease may arise out of indeterminate ones or *de novo*. Their subsequent features will depend on whether the disease is predominantly tuberculoid or lepromatous in nature.

Tuberculoid leprosy

In this type (Figure 11.12), there are a few or solitary skin lesions measuring 2–5 cm in diameter, often with a raised edge. The lesions are dry, hairless and anaesthetic. They are hypopigmented in dark-skinned and coppery in white-skinned individuals. Local or distant cutaneous nerve thickening occurs. The most common nerves involved are the ulnar nerve at the elbow, the median nerve at the wrist, the common peroneal in the popliteal fossa, the posterior tibial around the medial malleolus and the greater auricular nerve over the sternomastoid muscle. Sensory, motor and autonomic nerve trunks are affected. Nerve damage occurs early in tuberculoid leprosy.

Lepromatous leprosy

This presents as a widespread symmetrical macular rash, slightly hypopigmented or erythematous, affecting the face, extensor surface of the limbs and the upper trunk. The midline of the back, the axillae, groin and scalp are usually spared. There is congestion and discharge from the nose, the mucosa of which is thickened and yellow. Iritis may occur.

As the disease progresses, the skin, especially of the face, becomes thickened and nodular with thinning or loss of the eyebrows (Figure 11.13). Symmetrical enlargement of the peripheral nerves occurs, with widespread peripheral anaesthesia and muscular weakness. Painless neuropathic ulceration, absorption of the extremities of the digits, wrist drop, foot drop and claw hand occur (Figure 11.14). Nerve damage is observed late in lepromatous leprosy. Although acute exacerbations are found in all kinds of leprosy, they are most serious in the lepromatous type. An acute relapse is often heralded by an attack of erythema nodosum leprosum, and manifests widespread sensitivity phenomena in the skin, uveal tract, nerves, lymph nodes and joints.

Borderline leprosy

The presenting features are not typical of either tuberculoid or lepromatous leprosy. The disease may be arrested at this stage or progress in either direction. In borderline tuberculoid leprosy, the lesions are more numerous and varied than in the pure tuberculoid disease. The peripheral nerves are thickened and sensation is impaired. It is a common presentation in Africans. Asians and Europeans usually present with borderline lepromatous leprosy. Symmetry of the skin lesions is less

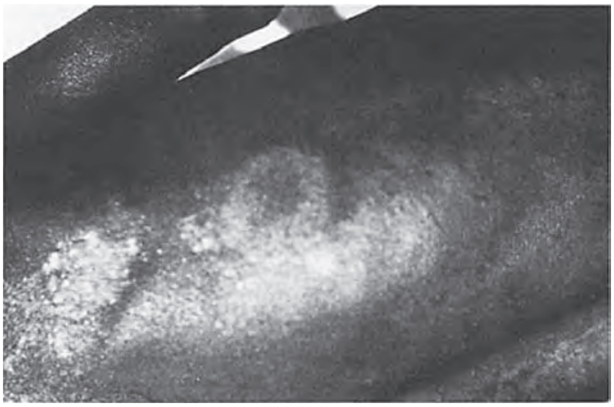

Figure 11.12 Tuberculoid leprosy.

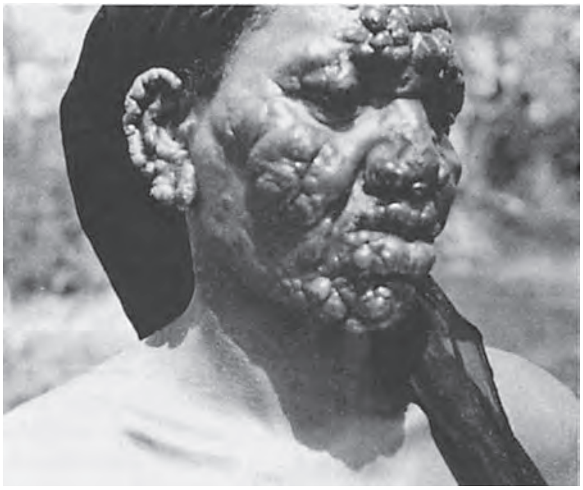

Figure 11.13 Lepromatous leprosy.

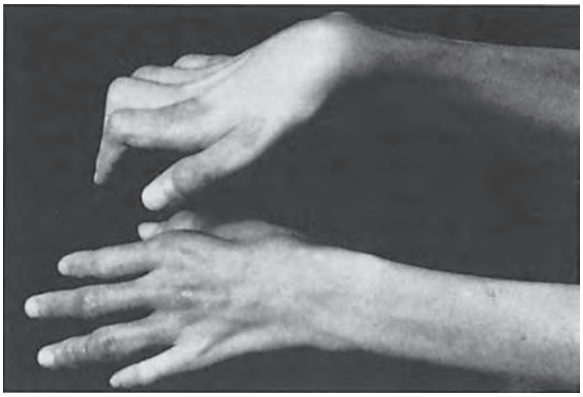

Figure 11.14 Claw hand in advanced lepromatous leprosy. With early treatment this lesion should never be seen.

constant, while the nodules are often discrete, red and fleshy. Nerve damage occurs early.

Diagnosis

Examination of dermal material obtained by the slit–scrape method reveals numerous bacilli in lepromatous and borderline lepromatous leprosy, while in paucibacillary disease (tuberculoid and borderline tuberculoid) bacteria are scanty and difficult to demonstrate. The dermal fluid is placed on a slide, dried and stained with a modified Ziehl–Neelsen method. Bacilli are also found in the nasal discharge. Histological examination of biopsies confirms the diagnosis.

Treatment

Multibacillary disease

The treatment of lepromatous and borderline lepromatous leprosy is by a combination of (1) rifampicin 600 mg once monthly, (2) dapsone 100 mg daily and (3) clofazimine 50 mg daily with an additional monthly dose of 300 mg. Where clofazimine is unacceptable because of its effects on skin colour, it is replaced with ethionamide 250 mg. This triple drug therapy is given for a minimum of 2 years, preferably until such time as the patient has achieved skin smear negativity. Acute exacerbations of multibacillary disease require hospitalization with complete physical and mental rest. If the symptoms are not relieved by aspirin 0.6 g three times a day, chlorpromazine is administered for 5 days. Patients with severe symptoms or those who develop erythema nodosum leprosum lesions require treatment with prednisolone or clofazimine or thalidomide.

Paucibacillary disease

Tuberculoid and borderline tuberculoid leprosy are treated with (1) rifampicin 600 mg once monthly and (2) dapsone 100 mg daily for 6 months.

Actinomycosis

This is a rare chronic infection caused by *A. israelii,* most commonly in the region of the lower jaw (cervicofacial). Actinomycosis occurs worldwide and is commoner in areas with low socioeconomic status and poor dental hygiene. The disease is characterized by the formation of loculated abscesses with marked induration and sinus formation (Figure 11.15).

Pathology

Actinomyces israelii occurs as a normal commensal in the human mouth. The organism is anaerobic and Gram positive but not acid fast. Although the precise conditions that result in the development of this endogenous infection are not known, the disease often follows trauma such as extraction of a carious tooth. The traumatic implantation of the organism in sufficient numbers appears necessary for the establishment of the disease, and cases following human bites or penetrating hand injuries resulting from violent contact with human teeth (punch actinomycosis) are well documented. The disease starts as an area of acute suppurative inflammation that persists as a chronic process with the formation of multiple loculated abscess cavities surrounded with dense fibrosis. Colonies of the organism occur in the pus as small greyish-yellow granules (sulphur granules), and consist of a densely felted mass of filaments surrounded by radially disposed club-shaped excrescences (Figure 11.16).

The disease spreads mainly by direct contact, with considerable destruction of tissue and multiple sinus formation. Blood-borne spread is important, as exemplified by the spread of ileocaecal actinomycosis via the portal vein to the liver, with the development of multiple intercommunicating liver abscesses (honeycomb liver). Pulmonary infection may also disseminate via the bloodstream to other organs such as bones, kidneys and

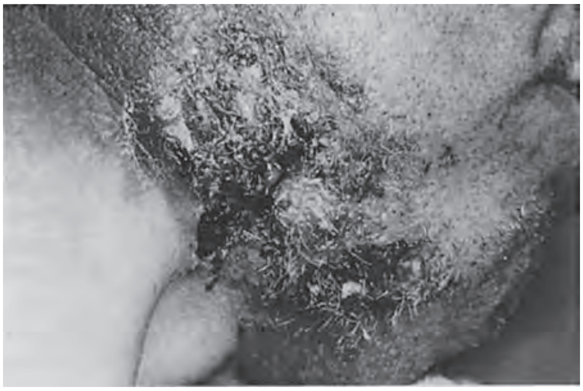

Figure 11.15 Cervicofacial actinomycosis.

CNS. In most instances, actinomycosis starts in the cervicofacial region (70%). In other instances, the primary infection occurs in the ileocaecal region (20%) or lungs (10%). For unknown reasons, actinomycosis is more common in men than in women (male–female ratio, 3:1), with the exception of pelvic actinomycosis.

The infection can affect all ages, but most cases are reported in young to middle-aged adults (aged 20–50 years). Nowadays, mortality is low because of the efficacy of antibiotic therapy. Preliminary diagnosis can be made by examining sulphur granules. The granules are squashed between two slides and stained with 1% methylene blue before microscopic inspection. Diagnosis is confirmed by culture (aerobic and anaerobic). A Gram-stained smear of the specimen may demonstrate the presence of beaded, branched, Gram-positive filamentous rods, suggesting the diagnosis. Cultures should be incubated for 48 hours or longer; the isolation and definitive identification of actinomycetes may require 2–3 weeks. Nucleic acid probes and polymerase chain reaction (PCR) methods have been developed for more rapid identification. Antimicrobial susceptibility testing is not needed as actinomycetes are invariably sensitive to penicillin, although the copathogens may not be.

Treatment

The organism has a wide spectrum of sensitivity to commonly used antibiotics such as penicillin and lincomycin. Prognosis is good following prolonged antibiotic treatment.

High-dose penicillin administered over a prolonged period (6 months to 1 year) is the established treatment. More recently, shorter courses of penicillin therapy (<6 months have been reported as sufficient especially in cervicofacial actinomycosis. However, the duration of penicillin therapy should be tailored to the individual patient based on clinical and radiographic response. The risk of actinomycetes developing penicillin resistance is minimal. Lack of a clinical response to penicillin is due to the presence of resistant companion bacteria, which may require modification of the antibiotic regimen, i.e. addition of an antibiotic active against these copathogens.

In patients who are allergic to penicillin, the following antibiotics may be used:

- *lincosamide*: lacks activity against some companion bacteria
- *amoxicillin/clavulanic acid (Augmentin)*: covers both pathogenic actinomycetes and companion bacteria, which frequently are resistant to penicillin
- *ceftriaxone*: covers both pathogenic actinomycetes and companion bacteria; used in cervicofacial and thoracic actinomycosis
- *imipenem/cilastatin*: covers both pathogenic actinomycetes and companion bacteria, which frequently are resistant to penicillin; used in abdominal and pelvic actinomycosis. See also Chapter 29.

Syphilis

This venereal disease is caused by *Treponema pallidum* and is transmitted by sexual intercourse. The most common portal of entry is the genital region, followed by the mouth or lips. Transmission by fomites is rare since the organisms are destroyed by rapid drying, but can occur. Placental transmission of *T. pallidum* is well documented with prenatal infection. In addition, infants may acquire extragenital infection during delivery from a mother with acute syphilis. Infants with congenital syphilis have lesions at birth or acquire them soon afterwards.

Pathology and clinical course

Following penetration of the skin or mucous membrane, the spirochaetes spread along the lymphatics and lymph nodes to reach the bloodstream within hours of exposure. The primary lesion, which appears some 2–4 weeks later, is known as the chancre, and is found most often in the genitalia, lips and mouth. It consists of a painless, indurated papule that breaks down to form a typically flat hard ulcer (Figure 11.17) and heals completely even without treatment. The associated regional lymphadenopathy is also painless.

The disease becomes generalized (*secondary syphilis*) within 2–3 months of infection. A widespread skin eruption (papular, vesicular or bullous) develops predominantly on the face, palms and soles. In addition, other lesions such as condylomata lata, mucous patches and serpiginous ulcers occur, usually at mucocutaneous junctions. Constitutional symptoms include low-grade fever, sore throat, headaches, joint and muscle pain, generalized lymphadenopathy, iridocyclitis and anaemia. The disease remains highly infective during this stage. All secondary lesions heal spontaneously.

Tertiary syphilis is characterized by destructive lesions of a localized or diffuse nature that probably result from hypersensitivity to the spirochaetal antigens. The classic localized lesion is the gumma, which consists of an area of coagulative necrosis surrounded by a zone of lymphocytes, plasma cells and macrophages. Adjacent arteries exhibit marked endarteritis

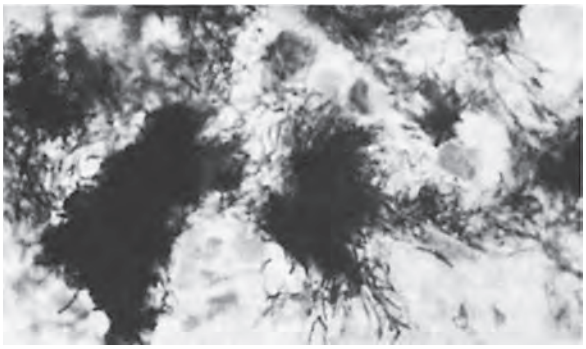

Figure 11.16 Microscopy of the sulphur granules from a patient with cervicofacial actinomycosis.

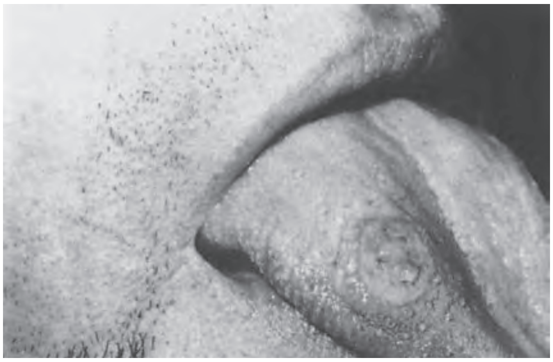

Figure 11.17 Syphilitic ulcer of the tongue: primary lesion.

obliterans. The most common sites of gumma include the testes, liver and bones (nose, palate, skull, clavicle, ulna and tibia). The bony lesions account for the deformities of tertiary syphilis, e.g. saddle nose (Figure 11.18). The diffuse tertiary lesions of syphilis include syphilitic aortitis and vasculitis, cerebral syphilis (meningovascular and parenchymatous) and diffuse syphilitic osteitis. The vascular lesions lead to weakening of the media with aneurysm formation and, in the case of the ascending aorta, with aortic regurgitation.

Meningovascular syphilis is characterized by focal meningitis, vascular episodes due to endarteritis and isolated cranial nerve palsies. Parenchymatous neurosyphilis comprises tabes dorsalis and general paralysis of the insane. In the former, there is degenerative demyelination and gliosis affecting the posterior columns of the spinal cord and posterior spinal nerve roots, resulting in the characteristic high-stepping gait. General paralysis of the insane is a chronic syphilitic meningoencephalitis. The disease affects the frontal lobes most severely.

Diffuse syphilitic inflammation of bones in tertiary syphilis is exemplified by the sabre tibia (Figure 11.19), in which the apparent bowing is due to the deposition of new periosteal bone, and the worm-eaten appearance of the skull that results from the combined effects of destruction and new bone formation.

Diagnostic tests

Treponema pallidum cannot be cultured. The organism can be identified from the exudate of primary and secondary lesions by dark-ground illumination after fluorescent antibody staining. Serological tests are based on either the Wasserman or the treponemal antibodies. The former include the Kahn and Venereal Disease Research Laboratories flocculation tests, and the latter the Reiter protein complement-fixation test, the *T. pallidum* immobilization test and the fluorescent treponemal antibody test. The serological tests using the treponemal antibody are more specific (fewer false-positive reactions).

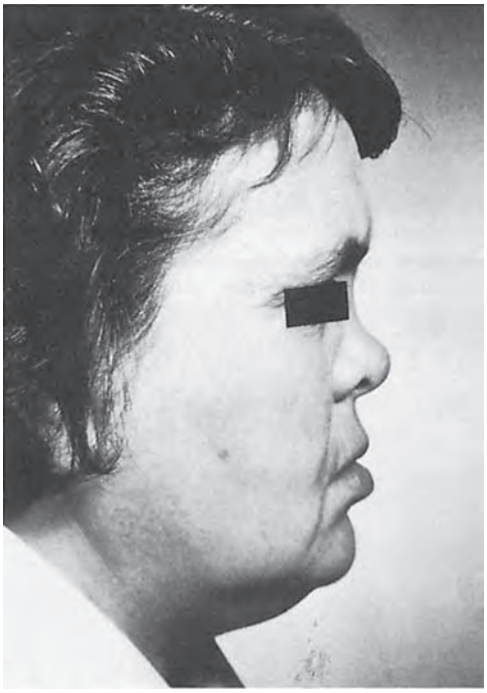

Figure 11.18 Saddle nose deformity in tertiary syphilis.

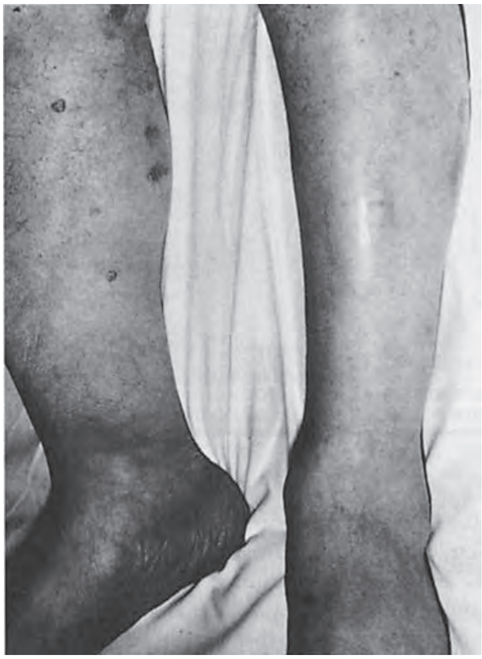

Figure 11.19 Diffuse syphilitic osteitis resulting in a sabre tibia.

Treatment

Both primary and secondary syphilis respond readily to adequate treatment, which is usually by intramuscular penicillin.

Gonorrhoea

This is caused by *N. gonorrhoea* and, in the vast majority of cases, transmission is by sexual intercourse.

Clinical features

In the female, the disease causes an acute purulent inflammation of the vulva, cervix, uterus and adnexa. Presentation with acute pelvic peritonitis and tubo-ovarian abscess is common. Secondary involvement of the rectum (proctitis) is found in 50% of females. Rarely, the rectum is the primary site of infection. In adult life the vagina is relatively resistant to gonococcal infection. This is not so in prepubertal girls, probably because of the immature and non-keratinized vaginal epithelium. Thus, gonococcal vaginitis and vulvovaginitis may occur in this age group. However, most cases of vulvovaginitis in prepubertal girls are not venereal in origin but result from endogenous infection with *Neisseria* spp. (*Neisseria sicca*, *Neisseria flava*, etc.) from the upper respiratory tract, the organisms being introduced into the vagina by dirty hands, towels, clothing, etc. Vulvovaginitis in both children and adults can be caused by *C. albicans* and *T. vaginalis.*

In the male, infection with *N. gonorrhoea* results in inflammation of the urethra but often also involves the epididymis, seminal vesicles, bladder and prostate. The untreated urethral inflammation may lead to stricture formation of the bulbar or spongy urethra.

In both sexes the disease may result in infertility owing to stricture of the fallopian tubes in the female and vas deferens in the male. One of the disastrous consequences of gonococcal infection in the female used to be infection of the eyeballs of the neonate during delivery (gonococcal ophthalmia neonatorum), which led to blindness in infancy. This is rarely encountered nowadays, with the advent of effective chemotherapy and routine instillation of silver nitrate or other antiseptic into the eyes of the newborn.

Treatment

Gonococcal infections are usually sensitive to penicillin. Tetracyclines are used for resistant infections, which account for 25% of cases.

Lymphogranuloma venereum

Lymphogranuloma venereum (LGV), also known as tropical bubo, is caused by *Chlamydia trachomatis.* Chlamydiae are obligate intracellular parasites and for this reason used to be considered as viruses. However, they have all the characteristics of bacteria, including a complex cell wall, but lack the metabolic enzymes necessary for an independent existence. *Chlamydia trachomatis* has three serotypes that cause LGV and others that are responsible for oculogenital infections.

LGV is common in tropical countries and is contracted by sexual intercourse, the reservoir of infection being the cervix in the asymptomatic female and the rectal mucosa in the asymptomatic homosexual male. It produces a papular, ulcerative or bullous lesion in the genital region that is not often painful and which heals spontaneously. This is followed within 1–6 weeks by gross lymphadenopathy (buboes). The enlarged lymph nodes in the ilioinguinal region suppurate and subsequently ulcerate, discharging seropurulent material. The disease may involve the pelvic organs and rectum in the female. It often becomes chronic with extensive scarring leading to elephantiasis and fibrous strictures of the rectum, vagina and urethra. Sulphonamide therapy (5 g daily for 7 days) gives good results in early cases. Tetracyclines are indicated for resistant cases. Surgical treatment should only be undertaken after an adequate course of chemotherapy. Abscesses should be aspirated and incision avoided.

Granuloma inguinale

This is found in certain tropical countries and the southern USA. It is an infection with Donovan bodies (donovania granulomatosis). Although infection is generally acquired by sexual intercourse, extragenital inoculation may occur. The primary lesion is a papule that ulcerates subsequently. In the male, it is usually found on the penis but other sites are well documented in both sexes. However, the majority of primary lesions occur in the genital, perineal, perianal or pubic regions. A 5 day course of streptomycin (4 g daily) is curative in most instances. Chlortetracycline, tetracycline and chloramphenicol are also effective.

Chancroid (soft chancre)

This is caused by *Haemophilus ducreyi* and is transmitted by sexual contact. The infection is more common and more severe in males. The disease starts as a soft macule, usually in the foreskin, 3–10 days after exposure. The lesion subsequently becomes necrotic and produces a ragged ulcer that may result in substantial penile destruction. These ulcers may be multiple and vary considerably in size. In the female, ulcerative lesions are found in the vulva and vagina. The inguinal lymph nodes become enlarged and painful and may suppurate. Treatment is by sulphonamides and tetracycline in the first instance. Resistant cases respond to cephalothin.

Condylomata acuminata

The term 'condylomata acuminata' (genital warts) is used to differentiate these pointed warts from the flat condylomata lata of syphilis. Genital warts result from infection with the human papillomavirus (HPV) and occur in the genital, perineal and perianal regions (Figure 11.20), and may be followed by the appearance of warts elsewhere in the body. Treatment is by the application of 10% podophyllin or excision. See HPV later in this chapter.

Viral infections of surgical importance

The important infections in surgical practice are the Herpetoviridae, HPV, viral hepatitis and AIDS.

Herpetoviridae infections

This family comprises a large number of viruses but only four are pathogenic to humans. These are the herpes simplex virus (HSV), varicella zoster virus (VZV), cytomegalovirus (CMV) and Epstein–Barr virus (EBV). They are important because of their common and ubiquitous occurrence, and because of their association in some instances with the development of certain neoplastic conditions.

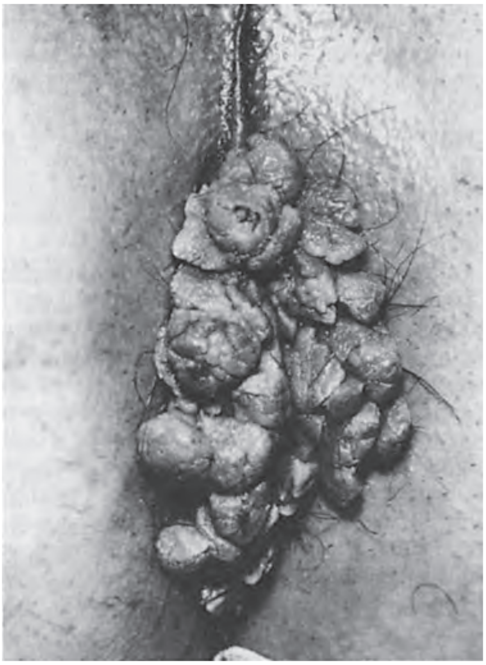

Figure 11.20 Condylomata acuminata of the perianal region.

Moreover, they can cause serious and at times fatal infections in debilitated and immunocompromised patients.

These viral infections cause an initial, often mild and inconsequential, primary infection, following which the virus remains dormant in a non-infectious state (latent) at certain sites, e.g. sensory ganglia in HSV and probably in VZV. From time to time, reactivation of the virus with occurrence of clinical manifestations, such as cold sores or shingles, may follow a febrile illness, operation, menstruation, radiotherapy, etc. The latency site for the EBV genome is thought to be the B-lymphocytes, whereas the CMV genome appears to persist in the renal tubules, leucocytes (particularly polymorphs), parotid gland and cervix.

Herpes simplex infections

There are two recognized strains: HSV-1, which is responsible for the majority of non-genital infections, and HSV-2, which accounts for most of the ocular and genital infections. HSV infections are widespread and prevalence rates range from 50% to 100% depending on socioeconomic status. The infection is acquired in the first instance by close personal contact, and genital herpes is now one of the well-recognized venereal diseases in the West, with a rising incidence such that in the UK genital herpes is twice as common as syphilis.

Labial herpes

This is the most common type of infection caused by HSV-1. The portal of entry is the mouth, and vesicular lesions occur most commonly on the lips, as cold sores, but may be severe, especially in the neonate, debilitated and immunocompromised, in whom they may cause extensive gingivostomatitis with intraoral/pharyngeal ulceration, fever and cervical lymphadenopathy. Rarely, the infection may disseminate to the brain, liver and adrenals, and is then usually fatal. Labial herpes is the most common recurrent type. Precipitating factors include fever, exposure to sunlight and menstruation. Each crop of labial vesicles is preceded by a burning sensation in the skin of the affected site.

Cutaneous herpes

Although HSV does not penetrate intact healthy skin, infections may occur in patients with skin disorders and in the presence of burns and lacerations leading to an extensive vesicular eruption (eczema herpeticum). In burn patients, the infection may become widely disseminated and lead to severe and often fatal pneumonia.

Ocular herpes

Most of these infections are due to HSV-1 except for those acquired in the neonatal period from an infected mother. The eye lesions include follicular conjunctivitis that may progress to corneal involvement with the formation of dendritic ulcers and corneal opacities. Corticosteroids enhance the eye damage caused by the virus and should be avoided in these infections.

Central nervous system infections

HSV infections may cause encephalitis, radiculitis, myelitis and meningitis. The encephalitis is usually the result of reactivation of latent infection.

Genital herpes

Although the majority of genital herpes infections are due to HSV-2, some are caused by HSV-1. The disease, which is usually sexually transmitted, has an incubation period of 2–20 days with an average of 6 days. The primary infection is followed by recurrent attacks that are usually less severe with intervening periods of latency during which the patient feels well and has no clinical manifestations. The risk of transmission of the disease is highest during an acute attack but asymptomatic individuals may pass on the disease to their sexual partners. There is strong evidence linking herpes simplex infection of the cervix with the development of cervical cancer and a fourfold increased risk is encountered in females with genital herpes. An association between cancer of the vulva and genital herpes has also been suggested, although the evidence linking the two conditions is inconclusive at present.

A primary attack is heralded by systemic symptoms due to the viraemia: malaise, fever and myalgia. The lesions are found on the penis and perianal region in the male, and labia, clitoris, vagina, cervix, perineum and perianal region in the female. They consist of painful vesicles that ulcerate, then crust and heal spontaneously. Neuralgia is often present. The severe pain during an attack may precipitate acute retention of urine.

Treatment of herpes simplex virus infections

As the virus is metabolically inactive during a latency period, treatment is futile at this stage. Effective therapy with the antiviral agent aciclovir is possible provided it is started early during a first or recurrent attack. There is a preferential uptake of the drug by the infected (virally colonized) cells, where it is activated by a virus-specific thymidine kinase forming aciclovir triphosphate, which inhibits the viral DNA polymerase.

Varicella zoster virus infections

The painful clinical condition known as zoster (formerly herpes zoster) is always the result of a reactivation of the same virus that causes chickenpox. Although in some instances no apparent cause for this activation is clinically obvious, in others a state of depressed cell-mediated immunity is present due to trauma, malignancy and immunosuppressive drugs, particularly in transplant patients. In severely immunocompromised patients, the infection may be systemic, with the development of pneumonia and involvement of other organs such as the liver, CNS, adrenals and pancreas. The systemic disease carries a very high mortality.

In the more usual condition, an exanthematous rash develops over a dermatome supplied by a specific dorsal nerve root or extramedullary nerve ganglion. The dermatomes supplied by the third dorsal to the second lumbar segment of the spinal cord are the ones most commonly affected, followed by that supplied by the fifth cranial nerve. Pain and paraesthesiae often predate the development of the vesicular rash. The most distressing feature of the disease is the development of neuralgia (St Anthony's fire), which may persist for several weeks and require specialist treatment.

Cytomegalovirus infections

The pattern of infection with CMV varies with the socioeconomic state of the country. In poor, developing countries with overcrowding and poor sanitation, the disease is acquired early in life and, by the age of 5 years, the vast majority of children become seropositive for the virus. In the West neonatal infection is rare and most primary infections are acquired in adolescence, mainly from kissing and sexual intercourse, such that the prevalence of seropositive individuals rises to 60–70% by the age of 60 years. The disease can be transmitted by the transfusion of blood products, particularly fresh blood and pooled platelet donations, and organ and bone marrow transplantation. It is thus a real hazard in transplant patients and in patients with leukaemia, since the transmission of the virus may be followed by serious infection owing to the immunocompromised state, leading to hepatitis, haemolytic anaemia, leucopenia and thrombocytopenia. The average reported mortality of this generalized CMV disease is 2% but can be as high as 15–20%, especially in bone marrow transplant recipients.

The infection may be transmitted to the fetus across the placenta. This may result in intrauterine death and spontaneous abortion. The vast majority of congenitally infected babies appear normal at birth, but 10–30% of them will suffer brain damage (microcephaly) and mental retardation. A few babies show the classic cytomegalic inclusion disease, the features of which are similar to those of the generalized disease encountered in immunosuppressed adults.

Infection in a normal adolescent may be asymptomatic or the individual may develop fever, sore throat, lymphadenopathy and hepatosplenomegaly. The clinical picture is very similar to that of glandular fever but the Paul–Bunnell test is negative. The blood may contain the characteristic intranuclear inclusions (owl eye) within atypical mononuclear cells. Anti-CMV antibodies can be demonstrated following the primary infection.

In susceptible immunocompromised patients, the risk of CMV infection may be reduced by using blood and organs from CMV-negative donors, transfusion of leucocyte-free blood and administration of high-titre anti-CMV immunoglobulins to the recipients.

Epstein–Barr virus infections

This gammaherpes virus was the first virus to be identified in human neoplastic cells. In excess of 90% of the world population becomes infected with EBV before adolescence. Aside from causing glandular fever (infectious mononucleosis), infection with EBV leads to the development of a number of tumours, e.g. lymphoproliferative disorders (endemic Burkitt's lymphoma, opportunistic lymphoma, nasal natural killer cell lymphoma), gastric carcinoma (10–15% of cases worldwide), nasopharyngeal carcinoma and spindle cell tumours (in immunocompromised hosts). Individuals who become infected with EBV become life-long carriers. The virus homes on two target cell types – B-lymphocytes (latent virus) and the epithelial cells of the oropharynx (replicating virus) – which are thus the main site of intermittent production of infectious virus, the B-lymphocytes becoming infected by circulating within the oropharyngeal mucosa. The infected B-lymphocytes then carry the virus elsewhere, with infection of other epithelial sites.

Infectious mononucleosis is a disease of the West with a peak incidence in adolescence and young adult life. It is transmitted in the saliva by kissing and is often referred to as the 'kissing disease'. The incubation period varies from 4 to 7 weeks and is followed by the development of malaise, fever, asthenia, sore throat, lymphadenopathy and splenomegaly. The blood picture shows a lymphocytosis with more than 10% atypical monocytes. The Paul–Bunnell test, which detects the presence of heterophile antibodies to sheep red cells, is positive. The liver function tests are often deranged during the first week of the illness, which usually lasts for 3–4 weeks. However, prolonged asthenia and debility for several months after the acute illness are quite common.

Human papillomavirus

HPVs are DNA viruses that infect the skin and squamous epithelium of the mouth and throat, the cervix and the anus. There are more than 150 different types of HPVs designated by a specific number. HPV infection is very common and most people have HPV infection at some time during their lives. In the majority the infection is asymptomatic and is cleared by the body defence system. HPV infections are usually acquired at an early age before the development of specific immunity. Some types of HPVs, if persistent, cause changes in the cervix, lips, buccal, oropharyngeal and anal mucosa and collectively are known as high-risk HPVs because they initiate dysplastic changes that may progress to *in situ* and invasive cancers. It has been estimated that HPV infection accounts for approximately 5% of all cancers worldwide.

Other types of HPVs cause warts, verrucas and perianal warts (condylomata); these are often referred to as the 'wart or genital wart viruses' and include types 6 and 11. Genital warts may appear within several weeks after sexual contact with a person who is infected with HPV, or they may take months or years to appear. They produce warts and verrucas most commonly on the hands and feet, and in the genital and perianal areas, but they can occur elsewhere in the body. These HPVs do not usually cause precancerous lesions, and for this reason are referred to as low-risk HPVs. Infection of low-risk HPVs is by skin contact with an affected person. Common warts are caused by HPV types 1 and 2, whereas genital warts are commonly caused by types 6 and 11, although several other types may be responsible. HPV infections of the mouth and pharynx are usually through kissing and genital HPV is transmitted by unprotected sex.

Human papillomavirus and cervical cancer

The high-risk HPVs that increase the risk of cervical cancer are types 16, 18, 31, 33 and 45. Almost all women who develop cervical cancer have at least one of these types of HPV in the cells of their cervix. Types 16 and 18 cause approximately 70% of cancers of the cervix; the other types account for the remaining 30% of cervical cancers. Other factors, in addition to persistent infection with these high-risk HPVs, are involved in the development of cervical cancer in the individual patient and these include the immune status, smoking and multiparity. Individuals with low immunity from any cause (including drug induced) have an increased risk of cervical cancer. HPV DNA testing is now available in most countries and, since April 2011, it has become part of the UK National Health Service Cervical Screening Programme. HPV DNA tests look for viral DNA before any cell abnormalities become visible. The test is offered to women with borderline or low-grade cervical changes detected in the first round of cervical screening. Women who test positive for high-risk types of HPV are referred for a colposcopy. Those who are negative for HPV will only be offered monitoring to establish whether the cervical changes will resolve within a few months. There is no treatment for eradicating the HPV virus. The risk of cervical HPV infection is reduced but not abolished by protected sex with use of a condom. Vaccines are now available to prevent infection with types of HPV that can lead to cervical cancer. These include the Gardasil and Cervarix cervical cancer vaccines, which have been licensed in the UK since 2007. These vaccines should prevent this type of cancer in the future. Currently, all girls aged 12 or 13 in the UK are offered the cervical cancer vaccine subject to approval by their parents.

Human papillomavirus and other cancers

Some types of HPV increase the risk of developing other cancers: anal cancer, cancer of the penis, vaginal and vulval cancer and oropharyngeal cancers (middle part of the throat, including the soft palate, the base of the tongue, and the tonsils). HPV type 16 causes approximately 85% of anal cancers. Some oropharyngeal cancers are caused by HPV infection, almost exclusively by HPV type 16.

Treatment of lesions caused by human papillomavirus infections

Methods commonly used to treat cervical lesions include cryosurgery, electrosurgical excision procedure and conization (removal of cone-shaped areas of tissue containing the dysplastic epithelium from the cervix and cervical canal). Warts are treated by excision, fulguration or cryotherapy.

Viral hepatitis

There are many viruses that can infect the human liver and cause hepatitis of varying severity (Table 11.2). Some are essentially hepatotropic, i.e. the liver is the primary site of infection.

At least six distinct viruses fall into this category: A, B, C, D, E and G. In addition, others are still undefined and are referred to as non-A and non-B (NANB).

Viral hepatitis is the most common liver disease today and constitutes a worldwide problem. Following the acute illness that may progress to fulminant liver failure, persistence of the virus leads to chronic liver disease, the severity of which varies from healthy asymptomatic carrier to ongoing chronic active disease with progression to cirrhosis and, in the case of hepatitis B and C disease, the development of hepatocellular carcinoma.

Hepatitis A

Hepatitis A virus (HAV) is also known as enterovirus type 72 and the disease was formerly known as infectious hepatitis. The virus is shed in large numbers in the faeces for a few weeks before the overt clinical illness, which varies in severity. The immunoglobulin (Ig) M antibody to the virus (anti-HAV) is present in high titres in the serum early on during the acute disease and is detected for 6 months after an acute infection. The IgG antibody indicates past infection and is present in 40–50% of the urban population in the UK. Hepatitis A rarely gives rise to chronic liver disease and carries a low mortality.

There are two vaccines (Havrix and VAQTA) which are used in the prophylaxis against hepatitis A. Both contain no live virus and are very safe. In addition, combined vaccine (Twinrix) is available against both hepatitis A and B and is used in adults (individuals over age 18). Protection from HAV starts about 2–4 weeks after the first injection. A second dose is necessary to ensure long-term immunity. Vaccination against HAV is recommended in the following:

- All children older than 1 year are recommended to get the vaccine if they live in communities where the prevalence of HAV infection is high or where there are periodic outbreaks of hepatitis A.

Table 11.2 Viruses causing acute hepatitis and chronic liver disease

Virus	Transmission route
Hepatitis A	Enteral transmission, rarely causes liver cell necrosis
Hepatitis B (HBV)	Transmitted by blood products, needles, tattooing, sexual activity, mothers to babies, aerosol (dental treatment); can progress to liver cell necrosis and chronic liver disease
Hepatitis C	Transmitted sexually and by blood products, can progress to liver cell necrosis; high incidence of progression to chronic liver disease
Hepatitis delta	Incomplete hepatotropic virus; capable of infection only when activated by HBV. Acquired either as a coinfection with HBV or as superinfection in HBsAg carriers
Hepatitis E	Enteral transmission. Mild self-limiting disease. Does not progress to chronic liver disease
Hepatitis G	Transmitted by blood products. Uncertain clinical significance
Epstein–Barr virus	Agent of infectious mononucleosis. Hepatitis rare and usually mild
Cytomegalovirus	Immunosuppressed patients and infants
Yellow fever virus	Can cause liver cell necrosis when mortality is high
Ebola and Marburg virus	Causes African haemorrhagic fever, consisting of papular rash, DIC, pancreatitis and hepatitis. Spread by needles and person to person. High mortality. No specific therapy available
Others	

DIC, disseminated intravascular coagulation; HBsAg, hepatitis B surface antigen.

- Individuals who are likely to be exposed to HAV at work: staff in research virology laboratories, healthcare workers, food service workers, day care personnel, and sewage and waste-water workers.
- Individuals travelling to developing countries known to have a high prevalence of HAV; vaccination advised at least 4 weeks before travel.
- Active practising male homosexuals.
- Drug addicts.
- Individuals with impaired immunity and/or chronic liver disease.
- Haemophilic patients needing clotting factors therapy.

If an uninfected person is exposed to hepatitis, treatment with immune serum globulin is advised and if administered within 2 weeks after exposure may prevent infection.

Hepatitis B

Hepatitis B virus (HBV) infection is caused by a double-stranded DNA virus that replicates by reverse transcription. Hepatitis B is endemic in the entire human population and hyperendemic in many parts of the world. The extent of the infection is indicated by the estimated 300 million people who have persistent infection with the virus. The transmission of the acute disease is by the parenteral route and was formerly common as a complication of blood transfusion; hence, the old terminology of 'serum or post-transfusion hepatitis'. With the testing of donors for the HBV, and the heat-inactivation methods for the preparation of the protein fractions, hepatitis B after transfusion of blood and blood products has been virtually eliminated. The HBV has great infectivity and is transmitted by needle sharing in drug misusers, in whom it is prevalent. It has caused disease in surgeons and nurses as a result of accidental injuries by 'sharps'.

The HBV has been fully characterized. The whole virus (virion) is known as the Dane particle and consists of a core covered by surface antigen [hepatitis B surface antigen (HBsAg)]. The latter is formed in excess as separate tubules and spheres. The centre of the virus contains a core antigen (HBcAg) that is never found in the circulating blood, the 'e' antigen (HBeAg), double-stranded DNA and a DNA polymerase. Antibodies are formed to the various antigens and can be detected in the peripheral blood at some time in all patients during the acute infection and in some carriers. The HBeAg is encountered early on during the course of the acute hepatitis, and is usually associated with high titres of HBsAg and the presence of Dane particles (complete HBV). It is the best marker of probable infectivity, and is usually replaced by the anti-HBeAg antibody soon after the jaundice develops. Anti-HBsAg denotes recovery from acute infection and immunity. Anti-HBcAg is detected in the peripheral blood early on during the acute infection. It is not protective and is found in all carriers. Anti-HBeAg is present in convalescent patients and in the majority of carriers. This antibody is associated with a low probability of infectivity. The interpretation of the various serum markers of hepatitis B is shown in Table 11.3.

Hepatitis B may be followed by chronic liver disease, which in some types progresses to cirrhosis and end-stage liver disease requiring liver transplantation. It is also responsible for the development of hepatocellular carcinoma. The viral genome (DNA) of HBV becomes incorporated in the host DNA and this integration has been shown to be a necessary step in the development of primary hepatocellular carcinoma. The important role of HBV infection in the development of hepatocellular carcinoma is now well established in hyperendemic areas.

Chronic hepatitis B

Chronic infection with HBV occurs in 5–10% of adult patients who are unable to eliminate the HBsAg within 3 months from the acute infection. The previous classification of chronic hepatitis B into the healthy HBsAg carrier state and patients with chronic B hepatitis (chronic persistent and chronic active) has been superseded by a more valid classification that has therapeutic and prognostic implications. The new classification is based on (1) the presence or absence of HBV replication (assessed by measuring HBV DNA or HBeAg in the serum, or HBcAg in the liver) and (2) the presence or absence of liver cell inflammation by assay of the serum aminotransferase activities, ASAT (ALT) or SGOT. Replication of HBV is usually associated with raised ASAT or SGOT. Three categories are thus recognized:

1. chronic HBeAg-positive hepatitis (CHBe^{+})
2. chronic HBeAg-negative hepatitis with normal aminotransferase activity (CHBe^{-}/ASAT^{-})
3. chronic HBeAg-negative hepatitis with raised aminotransferase activity (CHBe^{-}/ASAT^{+}).

Chronic HBeAg-positive hepatitis

Antigen-positive disease with evidence of viral replication constitutes 15% of patients. The disease is usually associated with continued liver cell inflammation (raised transaminases) and is symptomatic. On follow-up seroconversion from HBe^{-} to HBe^{-} occurs in about 50% of patients during the ensuing 5 years, with improvement in symptoms and normalization of the liver function tests. However, subsequent reactivation (with seroconversion to HBe^{-}) occurs in 5% of patients. The overall 5 year mortality is 10%.

Chronic HBeAg-negative hepatitis with normal aminotransferase activity

The 'normal carrier' state accounts for the majority of cases (60%). These patients have no viral replication or symptoms and their liver function tests are normal. The outcome of this group of patients is good and the mortality is low but they are subject to superinfection with hepatitis delta virus (HDV) (see below). The reactivation with seroconversion to HBe^{-} is low in these patients.

Table 11.3 Guide to the interpretation of serum markers of hepatitis B

HBsAg	HBeAg	Anti-HBe	Anti-HBc	Anti-HBs	Interpretation
+	+	–	–	–	Incubation period or early acute hepatitis B
+	+	–	+	–	Acute hepatitis B or persistent carrier
+	–	+	+	–	Late acute hepatitis B of persistent carrier
+	–	–	+	–	Late acute hepatitis B or persistent carrier
–	–	+	+	+	Convalescent acute hepatitis B
–	–	–	+	+	Past infection

HBeAg; HBsAg, hepatitis B surface antigen.

Chronic HBeAg-negative hepatitis with raised aminotransferase activity

This is encountered in 25% of patients and forms a heterogeneous group with either ongoing HBV replication (liver HBcAg$^-$ despite being seronegative for HBeAg) or other hepatic disease, e.g. concomitant HDV infection, autoimmune reactivity, alcohol misuse, drug-related hepatitis, hepatocellular carcinoma or schistosomiasis. The outcome in the individual patient depends on the exact aetiology. Symptomatic decompensated cirrhosis is highest in this category and develops in 20–30% of patients.

Drug treatment of chronic hepatitis B

Tenofovir disoproxil is a nucleotide analogue. It works by blocking the enzyme reverse transcriptase, which is responsible for HBV replication. Tenofovir disoproxil is used for the treatment of chronic hepatitis B in adults with compensated liver disease, with evidence of active viral replication, persistently elevated serum alanine aminotransferase (ALT) levels and histological evidence of active inflammation and/or fibrosis. Adverse events associated with the use of nucleotide analogues include lactic acidosis and progression of hepatomegaly. Other side effects reported for tenofovir disoproxil include headache, fatigue and gastrointestinal disorders.

Vaccination against hepatitis B

There is now an official recommendation that health service workers, particularly all doctors and nurses, should undergo active immunization against hepatitis B. Within the UK all students seeking admission to medical schools must also undergo this vaccination. The licensed vaccines that are available are prepared either by means of genetic engineering (recombinant hepatitis B vaccine) or from fully purified formalin-inactivated B surface antigen (HBsAg) obtained from the plasma of known carriers. Both types of vaccine are safe and effective. The vaccination programme consists of three doses administered at zero time, 2 months and a booster at 6 months. This regimen is effective in preventing the development of hepatitis B if immunization is started within a few weeks of exposure, that is, after an interval which is less than the incubation period of the disease. It is the recommended treatment in non-immunized medical and nursing staff who sustain accidental injury by 'sharps' contaminated with blood from an infected patient. Some also advise the administration of hepatitis B–specific immunoglobulin for additional (passive) immunization. The previous concern that some of these commercial IgG preparations were unsafe because of contamination by HIV has been abolished by HIV testing of donors and the introduction of rigorous techniques that ensure viral inactivation during the processing of the donated plasma.

Hepatitis C

The hepatitis C virus (HCV) is a small (40–60 nm) bilipid enveloped, single-stranded RNA virus of the family Flaviviridae and genus *Hepacivirus* (Figure 11.21). There are various major genotypes and more than 50 subtypes of HCV depending on geographical distribution of the virus. HCV is spread primarily by contact with blood and blood products. Since the introduction of routine blood donor screening for HCV, transfusion-related hepatitis C has virtually disappeared. At present, injection drug use is the most common risk factor, although many patients acquire hepatitis C without any known exposure to blood or to drug use. Aside from drug users and patients who had blood transfusions or blood products before donor testing (1992), e.g. haemophiliac and transplant patients, the other at-risk group consists of blood-borne infection of babies of HCV-infected mothers and healthcare workers who sustain needle-stick injuries. There is also some evidence that hepatitis C is common in promiscuous individuals with multiple sexual partners and cocaine addicts who use shared equipment for intranasal administration. However, in 10% of patients who contract acute hepatitis C, the cause is not known as there are no obvious known risk factors. These are referred to as sporadic or community-acquired infections and they make up 30% of patients with chronic hepatitis C.

HCV is a major cause of chronic liver disease and hepatocellular carcinoma worldwide. Following the acute infection, 85% of patients develop chronic infection with persistent viraemia. Chronic hepatitis may run a mild course with fluctuating levels of transaminase levels over several years, but progression to cirrhosis is encountered in 30% of cases. The variable course is thought to be the result of host factors, e.g. route and size of the infecting inoculum, patient's sex, age at time of infection and alcohol consumption. Thus, severe chronic disease is rare in females, whereas chronic alcohol consumption and increasing age at the time of infection are strong risk factors for disease progression. Cirrhosis due to HCV is now the most common indication for liver transplantation in the West. Recurrence of HCV in the grafted organ is very common and 50% of transplanted patients develop chronic hepatitis. Early intervention with interferon and ribavirin may prevent or delay the progression of HCV-related graft disease. As with HBV, there is a strong link between persistent HCV infection and the development of hepatocellular carcinoma. Thus, anti-HCV antibodies are found in over 70% of non-hepatitis B patients who develop this tumour.

RNA genome

Figure 11.21 Hepatitis C virus (HCV).

Clinical features

Many patients have asymptomatic disease or suffer from mild, non-specific symptoms, e.g. fatigue, mild right upper quadrant discomfort, nausea, poor appetite and myalgia. Likewise, physical examination is normal except for mild hepatic enlargement/tenderness. Those with established liver disease may exhibit the symptoms and signs of cirrhosis: hepatomegaly, jaundice, splenomegaly, fluid retention, etc. A small percentage of patients with chronic hepatitis C develop cryoglobulinaemia, vasculitis and glomerulonephritis.

Acute hepatitis C is diagnosed by (1) marked (more than 10 times upper limit) elevation of serum aminotransferases; (2) positive anti-HCV is present in serum; and (3) its confirmation by the presence of HCV RNA in serum. *Chronic hepatitis C* is diagnosed when anti-HCV is present and serum aminotransferase levels remain elevated for more than 6 months. Testing for HCV RNA (by PCR) confirms the diagnosis as almost all patients with chronic infection will have the viral genome detectable in serum.

Serological testing for anti-HCV antibody by enzyme immunoassay (EIA-3) is the initial test but in view of false-positive results that may occur with EIA-3 testing, confirmatory testing with assay for HCV RNA by PCR or transcription-mediated amplification is necessary for confirmation of diagnosis. A positive HCV RNA in serum indicates active infection. Testing for HCV RNA is always necessary in immune-suppressed/-compromised patients. The anti-HCV serological test (EIA-3) may be negative in the early stages of acute HCV infection but becomes positive in almost all patients within 2–8 weeks of onset of acute illness. Western blot assays (immunoblot assays) are also used to confirm anti-HCV. Immunoblot tests are used routinely in blood transfusion departments for further testing of blood donor samples positive on screening with EIA-3. Quantitative tests for HCV RNA in serum are used as an indirect assessment of viral load and are based on quantitative PCR and a branched DNA testing. Most patients with chronic hepatitis C have levels of HCV RNA (viral load) between 100 000 and 10 000 000 copies/mL. Although viral loads do invariably correlate with the disease severity or poor prognosis, they are useful in the identification of patients who are likely to respond to antiviral therapy. Liver biopsy is not necessary for diagnosis but is helpful for grading the severity of disease based on extent of liver parenchymal damage: periportal inflammation/fibrosis, piecemeal necrosis and established cirrhosis. Specific immunohistochemical stains for HCV have not been developed. Liver biopsy is also helpful in ruling out other causes of chronic liver disease.

Genotyping and serotyping of hepatitis C virus

Aside from varying with the geographical location and thus being useful in analysis of epidemic outbreaks, these tests are important as they impact on management, particularly on medical treatment. Thus, patients with genotypes 2 and 3 are more likely to respond to interferon-based therapy than patients with genotype 1 and require only a 6 month course of combination treatment using interferon and reduced daily dose (800 mg) of ribavirin, whereas patients with genotype 1 require a longer course (12 months) and a full dose of ribavirin (1000–1200 mg daily).

Treatment

Currently, the optimal regimen is a 24 or 48 week course of the combination therapy consisting of pegylated α-interferon and ribavirin. Pegylated α-interferon therapy, which has replaced other recombinant forms of α-interferons, is complexed with polyethylene glycol, which prolongs its half-life, thereby enabling weekly injection. Moreover, pegylated interferons are more active than standard interferons in inhibiting HCV and yield higher sustained response rates.

Ribavirin is an oral antiviral agent that has activity against a broad range of viruses. By itself, ribavirin has little effect on HCV, but, as combined therapy with interferon, it increases the response and viral clearance rates. Ribavirin causes certain side effects, including anaemia, fatigue and irritability, itching, skin rash, sinusitis and cough. It also causes a dose-related haemolysis of red cells. For these reasons, ribavirin should not be used in patients with pre-existing anaemia or in patients with significant coronary or cerebral vascular disease. If such patients require therapy for hepatitis C, they should receive α-interferon monotherapy. Ribavirin has been shown to cause birth defects in animal studies and is thus contraindicated in pregnancy and in women/couples who are unwilling/unable to practise contraception.

Combination therapy, when possible, is the standard treatment for hepatitis C, and interferon monotherapy is indicated only when ribavirin is contraindicated. The two forms of pegylated interferon used clinically are peg-interferon α-2a (Pegasys) and peg-interferon α-2b (Pegintron). Both are administered subcutaneously at weekly intervals but in different dosage: peg-interferon α-2a in a fixed dose of 180 μg/week and peg-interferon α-2b in a subcutaneous dose of 1.5 μg/kg. Ribavirin is administered orally in a dose of 200 mg b.d. up to a total administered dose of 1.0 g in patients weighing less than 75 kg, and 1.2 g when weight exceeds 75 kg. In certain situations, an 800 mg dose (400 mg twice daily) is recommended (see below).

Combination therapy leads to rapid improvements in serum ALT levels and disappearance of detectable HCV RNA in up to 70% of patients. Long-term improvement in hepatitis C occurs only if HCV RNA disappears during therapy and remains undetectable once therapy is stopped. Some patients relapse after treatment is stopped but the relapse rate is less with combination therapy.

For patients treated with combination therapy, the optimal duration of treatment depends on viral genotype. Patients with genotypes 2 and 3 have a high rate of response to combination treatment (70–80%), and a 24-week course of combination therapy is sufficient. In contrast, patients with genotype 1 have a lower response rate to combination therapy (40–45%), and a 48-week course is necessary. The optimal dose of ribavirin also varies with the genotype, 800 mg daily being adequate for patients with genotypes 2 or 3 but a full dose (1.0–1.2 g depending on body weight) being required to achieve control of the viral load.

Combination medical therapy is indicated in all patients with anti-HCV, HCV RNA, elevated serum aminotransferase levels, and evidence of chronic hepatitis on liver biopsy in the absence of contraindications. In essence, combination therapy for hepatitis C is indicated in all patients who have histological evidence of progressive disease. Patients with less severe histological disease are managed on an individual basis. Patients with cirrhosis are candidates for combination therapy only if they have compensated cirrhosis (Child A disease). Elderly patients (>60 years) have a higher incidence of adverse side effects but are still candidates for combination therapy on an individual basis. Patients with both HCV and HIV infection should be offered therapy for hepatitis C as hepatitis C tends to be more rapidly progressive in patients with HIV coinfection. However, treatment for hepatitis C is withheld in patients with advanced HIV disease as complications of therapy are common and response rates are low. In patients with clinically significant extrahepatic manifestations, such as cryoglobulinaemia and glomerulonephritis, therapy with α-interferon can result in remission.

Combination antiviral treatment for hepatitis C is recommended in:

- patients at increased risk for cirrhosis (persistent elevation of ALT, high levels of HCV RNA in the blood, evidence of early fibrosis, moderate to severe inflammation and piecemeal necrosis on liver biopsy)
- patients who are coinfected with HCV and HIV, because these patients have a more rapid progression of the disease
- persistent cryoglobulinaemia.

Combined antiviral therapy is inadvisable in:

- patients with non-progressive disease and near normal ALT
- patients who are unable to comply with the treatment schedule
- patients in whom treatment is unsafe (for example, allergy to the medications)
- transplant patients
- pregnant women and females unwilling to practise adequate contraception during treatment, or who have reversible serious untreated conditions such as unstable heart disease
- uncontrolled high blood pressure
- untreated major depression.
- patients with decompensated cirrhosis (Child C disease)
- clinically decompensated cirrhosis due to hepatitis C.

α-Interferon can induce adverse neuropsychiatric effects, including marked irritability, anxiety, personality changes, depression, and even suicide or acute psychosis. α-Interferon therapy can also induce formation of autoantibodies, especially in patients with an underlying susceptibility to autoimmunity. Exacerbation of a known autoimmune disease, e.g. rheumatoid arthritis or psoriasis, is common during interferon therapy. Contraindications to α-interferon therapy include:

- severe depression or other neuropsychiatric syndromes
- drug or alcohol abuse
- autoimmune disease that is not well controlled
- patient with bone marrow compromise
- females unable/unwilling to practise birth control.

Contraindications to ribavirin are:

- marked anaemia
- renal dysfunction
- coronary artery or cerebrovascular disease
- females/partners unable/unwilling to practise birth control.

All patients with HCV should be vaccinated against hepatitis B and hepatitis A. They also should be counselled on measures to prevent the spread of HCV and advised to abstain from alcohol use. Finally, all patients with HCV should be tested for HIV.

Hepatitis delta virus disease

HDV is an incomplete hepatotropic virus that is unable to replicate on its own. It is thus capable of infection only when activated by the presence of HBV, when it forms a virion particle consisting of an outer coat (from the HBs antigen of HBV) and an inner core of HDAg and RNA genome. Estimates indicate that more than 15 million people are infected worldwide. There are eight reported genotypes of HDV with varying pathogenicity. Areas with the highest prevalence include southern Italy, North Africa, the Middle East, the Amazon Basin and the American South Pacific islands. HDV infection is more common in adults than in children.

The disease may be acquired either as a coinfection together with HBV in previously normal individuals or as superinfection in carriers of HBsAg. Special subsets of HBsAg carriers are at high risk of superinfection. These include those individuals who are exposed to multiple blood and interpersonal contacts such as intravenous drug addicts, haemophiliacs, institutionalized patients, prisoners and homosexuals. Parenteral inoculation appears to be the most efficient mode of transmission. It is now known that blood that is negative for the HBsAg may transmit HDV at a frequency of 1 in 3000 transfusions.

Coinfection in previously normal individuals usually leads to a self-limiting hepatitis with a variable clinical presentation. Both IgM (during acute illness) and IgG (in the convalescent period and for 1–2 years after clearance of the HBsAg) anti-HDAg antibodies appear in the plasma in moderate to severe disease, which may progress to fulminant hepatic failure. The more usual mild form of coinfection causes a minimal serological response. Coinfection rarely progresses to fulminant liver failure (1% of patients) but complete clinical recovery and clearance of HBV and HDV are the most common outcomes.

Infection with HDV in a patient who is already positive for the HBsAg is known as superinfection and results in severe fulminant liver failure in 5% of patients and approximately 80–90% develop chronic HDV infection. These patients progress more rapidly to develop cirrhosis and may develop hepatocellular carcinoma. In superinfection, the HDV aggravates pre-existing type B hepatitis (chronic aggressive hepatitis) or induces new HDV disease in healthy HBsAg carriers. In the latter group, the hepatitis is often severe and may progress to fulminant hepatic failure.

Treatment consists primarily of support. Patients with evidence of decompensated liver disease or fulminant liver failure should be immediately transferred to a transplant centre.

Currently there is no effective treatment for HDV. However, a study of the efficacy of peg-interferon α-2a found that treatment with or without adefovir over 48 weeks resulted in sustained HDV RNA clearance in approximately 25% of patients.

Hepatitis E

Hepatitis E virus (HEV) consists of a non-enveloped single-stranded RNA, which causes enterally transmitted hepatitis. The epidemiological features are similar to those of hepatitis A but the E virus is serologically different and it can infect individuals who have recovered from hepatitis A. The disease is spread by contamination of drinking water with sewage. Risk factors for HEV infection include poor sanitation and HEV shedding in faeces. Person-to-person transmission is uncommon. There is no evidence for sexual transmission or infection by blood transfusion. Epidemics of hepatitis E occur in Central and South East Asia, North and West Africa, and in Mexico. However, sporadic cases of hepatitis E are well documented in other regions, suggesting a global distribution. Hepatitis E is extremely common in developing countries, where it accounts for over 50% of cases of acute viral hepatitis.

Typical signs and symptoms of hepatitis include jaundice, anorexia, an enlarged, tender hepatomegaly, abdominal pain and tenderness, nausea and vomiting, and fever, but in most instances the disease is subclinical or causes a mild self-limiting illness often not requiring hospitalization. Diagnosis is based on serological tests for elevated antibody levels to hepatitis E based on reverse transcriptase PCR. At present, no commercially available vaccines exist for the prevention of hepatitis E. Occasionally, a fulminant form of hepatitis develops, with overall mortality rates ranging between 0.5% and 4.0%. Fulminant hepatitis occurs more frequently in pregnancy, usually in the third trimester, and is attended with a reported mortality rate of 20%.

Non-A, non-B hepatitis

This term is reserved for hepatitis by as yet unidentified viruses and the diagnosis is made by exclusion of the known hepatotropic viruses and CMV. Hepatitis C was grouped within this category before its isolation and cloning. Non-A, non-B (NANB) hepatitis (with unidentified viruses) remains the problem facing the transfusion of blood and blood products (as there are no tests to screen donors who may harbour these viruses). It accounts for the vast majority of all transfusion-related hepatitis and approximately 7–10% of transfused patients develop the infection. NANB is also transmitted by clotting factor concentrates (factors VIII and IX) and for this reason is very common in haemophiliac patients. Outbreaks following intravenous administration of immunoglobulin have been reported. The incubation period of NANB hepatitis varies widely but averages 8 weeks. The disease is clinically indistinguishable from hepatitis A and B and may indeed cause fulminant liver failure. However, in most instances, the hepatitis is mild and may only be represented by an elevation of the serum aminotransferase enzymes. Nonetheless, significant cohorts of patient who contract NANB infection go on to develop chronic liver disease. The clinical significance of the recently isolated hepatitis G virus reported in patients after blood transfusion remains uncertain.

There is increasing evidence for a non-A, non-B, non-C virus that causes aplastic anaemia and fulminant hepatitis. The affected patients develop jaundice followed, within 90 days, by aplastic anaemia. Some patients develop the aplastic anaemia after liver transplantation for NANB hepatitis.

Acquired immunodeficiency syndrome and related conditions

There is no doubt regarding the worldwide devastation caused by AIDS and its allied conditions: persistent generalized lymphadenopathy (PGL) and AIDS-related complex (ARC). Since the first few cases were recognized in the USA in 1981, estimates from the WHO from 180 countries show that over 10 million people are infected with the virus (HIV positive) but are currently well. The majority of these will, in time, develop the disease and eventually die from it. AIDS has particular relevance to surgeons and other healthcare workers who, by virtue of their occupation, are at risk, although with suitable precautions the risk of acquiring the infection from patients is small.

Virology and immune deficiency

The first virus was isolated in France from a patient with lymphadenopathy and was therefore called lymphadenopathy-associated virus. In the USA the virus was first isolated from AIDS patients and was thus named human T-cell lymphotropic virus type III (HTLV-III) to distinguish it from other known lymphotropic viruses (home in on lymphocytes) such as HTLV-I and HTLV-II. The former is associated with a special form of leukaemia/lymphoma. There is now international agreement that the term HIV should be used to describe the agent responsible for AIDS and allied conditions (PGL, ARC). More recently, a variant, HIV-2, has been isolated from African patients, but there does not appear to be any material difference in the disease potential between these two viruses and the collective term HIV is recommended for either agent.

The structure of HIV is shown in Figure 11.22. It is a retrovirus, i.e. its genome contains only RNA; in order to replicate once it invades the host cell, the viral RNA is transcribed into DNA by a special viral enzyme called reverse transcriptase, i.e. new viral RNA is made using the host DNA as the template (reverse of the normal process: DNA makes RNA makes protein). Once introduced into the bloodstream, HIV homes in on the T-helper lymphocytes, monocytes and macrophages that carry the surface receptor, CD4, on to which the virus latches. The T-helper lymphocytes (CD4) thus colonized are progressively destroyed. By contrast, the colonized macrophages, although providing a reservoir for continued viral replication, seem to be resistant to its destructive effects. HIV also colonizes the neural tissue and this accounts for the dementia that develops in some patients.

The T-suppressor/cytotoxic lymphocytes are not colonized because they contain a different receptor (CD8). The replication and expression of the virus in the T-helper lymphocyte terminates when the cell dies prematurely. The longitudinal consequence of this HIV/T-helper lymphocyte interaction for the infected patient are impaired function and progressive gradual depletion of the T-helper lymphocytes, reversal of the helper/inducer (CD4) to suppressor/cytotoxic (CD8) cell ratio and progressive decrease in the level of detectable virus in the blood. The immunological depression is characterized by several abnormal parameters (Box 11.1).

Laboratory evidence of human immunodeficiency virus infection

The current routine tests are based on the detection of antibodies to circulating HIV. Following infection, antibodies to the various antigens appear in the circulation. These do not appear to confer any benefit but are used in the diagnosis (HIV antibody testing). Regrettably, there is a long period (usually 6 weeks but sometimes several months) between infection and the appearance of antibodies. There is, therefore, a long 'window' when an individual may have negative antibody testing to HIV and still be infected.

Other tests include viral cultivation from the patient's lymphocytes, detection of circulating viral P24 antigen (useful in helping to establish infection in an infant whose HIV antibodies may be maternal) and the use of PCR, by which the very small amount of viral DNA in infected cells can be greatly amplified. The PCR method is the gold standard test for the confirmation of HIV infection.

Transmission of human immunodeficiency virus infection

The proven vehicles of infection are blood, semen and vaginal secretions. The disease is transmitted by penetrative unprotected sexual intercourse (homosexual and heterosexual), needle sharing by drug misusers and blood products. Prior to the introduction of HIV testing of donors, a large proportion of haemophiliacs were infected by contaminated clotting factor concentrates, as were a few patients who received blood transfusion to cover surgical procedures, especially cardiac operations. With the introduction of testing of blood donations, this route of transmission has now been eliminated but regrettably many of the infected haemophiliacs have died of AIDS and some have transmitted the disease to their sexual partners. The largest two groups contracting HIV infection are still active homosexuals (especially those with multiple partners) and drug addicts and users, in whom HIV is spread by sharing contaminated needles.

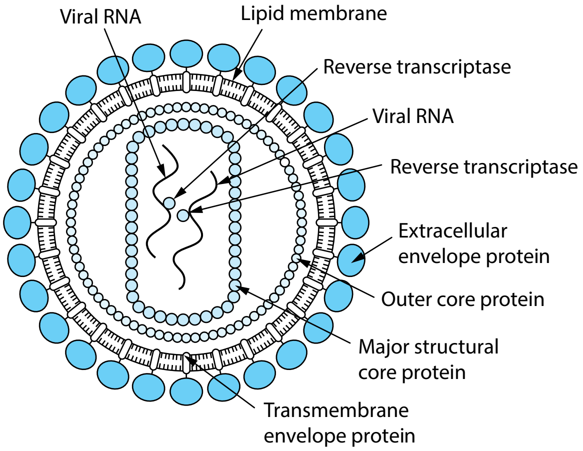

Figure 11.22 The structure of human immunodeficiency virus.

BOX 11.1 Parameters of immunodeficiency disorder in AIDS, persistent generalized lymphadenopathy (PGL) and AIDS-related complex (ARC)

- Decreased CD4+ lymphocytes and lymphopenia
- Decreased ratio CD4:CD8 lymphocytes
- Reduced cytotoxic response
- Reduced monocyte function
- Increased immunoglobulins
- Decreased blastogenic response of lymphocytes to mitogens
- Cutaneous anergy to multiple skin test antigens
- Increased levels of circulating immune complexes

Babies of HIV-positive mothers have a 25% risk of contracting the infection *in utero* or perinatally and by breast feeding. By contrast, parents of infected children have not been shown to be at risk. Oral zidovudine during late pregnancy and labour reduces the rate of mother to child transmission of HIV by 51%. The longer course reduces it by 67%. Breast feeding with the short remains a problem, as this is responsible for one-third of the maternal transmission. Thus, in short-course prevention, breast feeding has to be replaced by formula feeding of the babies.

There is no evidence that HIV is transmitted by non-sexual social contact (including sharing meals), accidental contamination with blood during participation in contact sport or by blood-sucking insects. Transmission by human bites is possible and occurs if blood is transmitted.

The risk of transmission to healthcare workers is due to certain mishaps:

- direct percutaneous inoculations of infected blood, e.g. accident by sharps (needle pricks, scalpel stab injuries, etc.)
- spillage of infected blood onto skin may introduce infection through minute scratches or abrasions
- contamination of mucosal surfaces by infected blood, e.g. accidental splashing of eyes
- transfer of infected material via environmental surfaces, e.g. blood-contaminated equipment and instruments.

The question concerning the risk involved in mouth-to-mouth resuscitation in an emergency remains unsettled, although there have been no such reported incidents to date.

Clinical features of human immunodeficiency virus infection

The majority of patients do not develop any symptoms after infection and are discovered to be HIV positive with testing. A small proportion of individuals acquire a self-limiting illness that resembles infectious mononucleosis a few weeks to months after the infection and others exhibit transient encephalitis. Several months later, some infected subjects develop a more lasting generalized enlargement of the lymph nodes, PGL. Significant symptoms start to appear with disease progression and these include weight loss, chronic diarrhoea, minor opportunistic infections and candidiasis. The deterioration in health and physique is clear-cut with progression to full-blown AIDS, the clinical features of which vary in accordance with the type of indicator illness that develops. The average incubation period from the time of infection to full-blown AIDS is 8 years, although faster progression is well documented. In the past, the available evidence suggested that eventually most HIV-positive subjects developed AIDS, although the time frame was variable This situation has changed drastically with highly active antiretroviral therphy (see Treatment). The clinical markers associated with an increased risk of progression to AIDS are constitutional symptoms, oral candidiasis and oral hairy leucoplakia. The laboratory indices that are also predictive of progression to AIDS include anaemia, lymphopenia, neutropenia, raised erythrocyte sedimentation rate (ESR), reduced T-helper (CD4) lymphocytes, raised CD8 lymphocytes, elevated viral antigenaemia (P24) and reduced anti-P24 antibodies.

The following clinical definitions are now accepted:

- AIDS: acquired immunodeficiency syndrome is defined as a syndrome in which a person has a reliably diagnosed disease that is at least moderately indicative of an underlying cellular immune deficiency (e.g. an opportunistic infection or Kaposi's sarcoma in a person younger than 60 years) but who, at the same time, has no known underlying cause of cellular immune deficiency or any other cause of reduced resistance reported to be associated with that disease. The reliably diagnosed disease is referred to as the indicator disease. The nature of this varies according to the absence (Box 11.2) or presence of laboratory evidence of HIV infection (Box 11.3). Absence of laboratory evidence may arise because the tests for HIV were not performed (for any reason) or gave inconclusive results. In the UK, the most commonly diagnosed indicator illness for AIDS is pneumonia due to *Pneumocystis carinii*.
- PGL: persistent generalized lymphadenopathy is defined as lymphadenopathy at two or more non-contiguous, non-inguinal sites for 3 months or longer in the absence of any current illness or medication known to cause enlarged lymph nodes.
- ARC: AIDS-related complex is defined as weight loss of more than 10%, intermittent fever of more than 38°C, intermittent or continuous diarrhoea, fatigue and malaise, night sweats and PGL.

In addition, both PGL and ARC must be accompanied by at least two abnormalities indicative of an immune deficiency/disorder. With the definitions and criteria shown in Boxes 11.1 and 11.2, an alternative useful clinical classification of HIV infection, which embraces all stages, is shown in Table 11.4.

Tumours in acquired immunodeficiency syndrome

The tumours that develop in AIDS patients are Kaposi's sarcoma, primary cerebral lymphoma and non-Hodgkin's lymphomas. Kaposi's sarcoma is one of the most common manifestations of AIDS and carries a high mortality (usually from severe opportunistic infections) with a median survival of 18–24 months. The tumour is a multifocal metastasizing malignant reticulosis, with features resembling those of angiosarcoma. It involves principally the skin (multiple red violaceous nodules), mucous membranes and lymph nodes, although visceral lesions are sometimes encountered. The disease in AIDS sufferers differs in several respects from Kaposi's sarcoma developing in immunocompetent individuals. There is now an established association of AIDS Kaposi's sarcoma with CMV infection. Significant palliation can be obtained by local radiotherapy.

The non-Hodgkin's lymphomas which develop in AIDS patients are of either -cell or indeterminate origin and of certain histological types: small non-cleaved lymphoma (either Burkitt's or non-Burkitt's), immunoblastic lymphoma, large-cell lymphoma, diffuse histiocytic lymphoma, diffuse undifferentiated lymphoma and high-grade lymphoma.

Antiviral therapy for acquired immunodeficiency syndrome

There have been considerable advances in antiretroviral drug therapy such that adequately treated AIDS with a combination of three or more anti-HIV drugs, sometimes referred to as highly active antiretroviral therapy (HAART), is compatible with long-term survival with the HIV virus.

The classes of antiretroviral drugs used in AIDS are:

1. Nucleoside/nucleotide reverse transcriptase inhibitors (NRTIs) interfere with the action of an HIV protein called reverse transcriptase, which the virus needs to make new copies of itself.
2. Non-nucleoside reverse transcriptase inhibitors (NNRTIs) also stop HIV from replicating within cells by inhibiting the reverse transcriptase protein.
3. Protease inhibitors (PIs) inhibit protease, which is another protein involved in the HIV replication process.

BOX 11.2 Indicator diseases for case definition of AIDS for surveillance purposes without laboratory evidence regarding HIV infection (Centers for Disease Control, Atlanta, GA)

- Candidiasis of the oesophagus, trachea, bronchi or lungs
- Extrapulmonary cryptococcosis
- Cryptosporidiosis with diarrhoea >1 month
- Cytomegalovirus disease of an organ other than liver, spleen or lymph node in a patient >1 month old
- Herpes simplex virus infection causing a mucocutaneous ulcer that persists longer than 1 month; or bronchitis, pneumonitis or oesophagitis for any duration affecting a patient >1 month old
- Kaposi's sarcoma affecting a patient <60 years old
- Primary lymphoma of the brain affecting a patient <60 years old
- Lymphoid interstitial pneumonia and/or pulmonary lymphoid hyperplasia affecting a child <13 years old
- *Mycobacterium avium* complex or *Mycobacterium kansasii* disease, disseminated (at a site other than or in addition to lungs, skin, cervical or hilar lymph nodes)
- *Pneumocystis carinii* pneumonia
- Progressive multifocal leucoencephalopathy
- Toxoplasmosis of the brain affecting a patient >1 month old

4 Fusion or entry inhibitors prevent HIV from binding to or entering human immune cells.
5 Integrase inhibitors interfere with the integrase enzyme, which HIV needs to insert its genetic material into human cells.

BOX 11.3 Indicator diseases for case definition of AIDS for surveillance purposes with laboratory evidence regarding HIV infection (Centers for Disease Control, Atlanta, Georgia)

- Bacterial infections, multiple or recurrent (any combination of at least two within a 2 year period), of the following types affecting a child <13 years old: septicaemia, pneumonia, meningitis, bone or joint infection, or abscess of an internal organ or body cavity (excluding otitis media or superficial skin or mucosal abscesses), caused by *Haemophilus*, *Streptococcus* or other pyogenic bacteria
- Coccidioidomycosis, disseminated (at a site other than or in addition to lungs or cervical or hilar lymph nodes)
- HIV encephalopathy (HIV/AIDS dementia)
- Histoplasmosis, disseminated (at a site other than or in addition to lungs or cervical or hilar lymph nodes)
- Isosporiasis with diarrhoea persisting >1 month
- Kaposi's sarcoma at any age
- Primary lymphoma of the brain at any age
- Other non-Hodgkin's lymphoma of -cell or unknown immunological phenotype
- Any mycobacterial disease caused by mycobacteria other than *M. tuberculosis*, disseminated (at a site other than or in addition to lungs, skin, or cervical or hilar lymph nodes)
- Disease caused by *M. tuberculosis*, extrapulmonary (involving at least one site outside the lung, regardless of whether there is a concurrent pulmonary involvement)
- *Salmonella* (non-typhoid) septicaemia, recurrent
- HIV wasting syndrome (emaciation, slim disease)

Table 11.4 Alternative useful clinical classification of HIV infection

Group	Definitio
I	Acute infection: infectious mononucleosis-type illness
II	Asymptomatic infection: asymptomatic HIV-positive subjects
III	Persistent generalized lymphadenopathy (PGL)
IV	
A	Constitutional disease: fever, diarrhoea and weight loss lasting >1 month
B	Neurological disease: dementia, myelopathy and peripheral neuropathy
C	Secondary infectious disease: opportunistic
C_1	Specified in US Centers for Disease Control surveillance definition of AIDS
C_2	Other infections: oral hairy leucoplakia, nocardiosis, oral candidiasis, etc.
D	Secondary cancers: Kaposi's sarcoma, non-Hodgkin's lymphomas, primary cerebral lymphoma
E	Other conditions: other disorders attributable to HIV infection

The currently used drugs in these five categories are:

1 NRTIs: lamivudine, abacavir, zidovudine, didanosine, emtricitabine.
2 NNRTIs: delavirdine, efavirenz, etravirine, nevirapine, rilpivirine, atazanavir.
3 PIs: amprenavir, fosamprenavir, atazanavir, darunavir, indinavir, ritonavir, saquinavir, maraviroc.
4 Fusion or entry inhibitors: enfuvirtide.
5 Integrase inhibitors: raltegravir.

Protease inhibitors are generally less suitable for starting treatment in resource-limited settings owing to the cost, number of pills which need to be taken, and the particular side effects caused by protease drugs.

The CD4 test

The CD4 test is used to determine the need for treatment since it measures the number of T-helper cells (CD4 count), which normally ranges between 500 and 1200 cells/mm^3. HIV drug treatment is indicated when the CD4 count is <350 cells/mm^3. The WHO 2010 guidelines recommend starting treatment for all patients with CD4 counts of <350 cells/mm^3 in all countries but the treatment guidelines may differ from WHO recommendations, e.g. in the USA, where treatment is recommended for patients with a CD4 count between 350 and 500 cells/mm^3.

A basic clinical assessment should be carried out before treatment to establish the general condition and body weight of the patient, existing disease (hepatitis, tuberculosis), injection drug use, pregnancy in females, psychiatric illness and any oral medications which might cross-react with the antiviral drugs. The patients must be psychologically ready to start and persist with therapy despite the demanding regimen and associated side effects. HAART first-line therapy consists of a combination of three or four drugs: a typical antiretroviral combination consists of two drugs from the NRTI class and one drug from another class.

If facilities are available preliminary tests for HIV drug resistance are carried out before finalizing the regimen in the individual patient as some HIV strains have become resistant to a certain class of drug. Reports indicate that approximately one in 10 HIV-infected individuals in Europe and the USA are infected with a type of HIV that is resistant to at least one class of antiretroviral drug. Testing for drug-resistant strains may not, however, be available in some poor countries. Another practical consideration related to interaction with other medications. This is a common problem among older patients with HIV, as they are usually on drugs for age-related illnesses. Some drugs may cause side effects or decrease the effectiveness of some antiretroviral drugs.

Once patients start HIV treatment, it is essential that (1) they comply fully (adhere) with the treatment and (2) they are monitored regularly to ensure that the treatment is effective in reducing the viral load and improving the CD4 count. Adherence signifies that the patient is taking the drugs exactly as prescribed, i.e. taking all the drugs at the right time and in accordance with instructions. Anything below full adherence has been associated with increased viral load and the development of drug resistance.

The aim of antiretroviral treatment is to keep the viral load as low as possible. The viral load test is carried out shortly after initiation of antiretroviral treatment. Successful therapy is signified by a dramatic drop to an undetectable level (below 50 copies/mL) within 3–6 months. However, some patients never reach undetectable levels. Viral load tests are then carried out every few months.

Side effects

Side effects of antiretroviral drug therapy are common. In some people these are mild, but in others they are severe enough to warrant use of alternative drugs. Another complication is immune reconstitution inflammatory syndrome (IRIS), which occurs in a minority of patients soon after treatment is started. It is due to an excessive response by the recovering immune system to opportunistic infections already present, but which were previously dormant. Symptoms of IRIS are often mild, but occasionally they can be life-threatening. If the symptoms of IRIS are mild, no change in therapy is needed as the symptoms disappear within a few weeks. However, with severe IRIS involving severe opportunistic infections, e.g. cryptococcal meningitis or tuberculosis, it may be necessary to stop antiretroviral therapy until the infection is treated.

A change of treatment is indicated if the antiretroviral regimen fails to slow down the viral replication. Some experts recommend changing as soon as the viral load starts to rise, whereas others recommend monitoring the trend of the viral load before making a decision to change the regimen. When viral load testing is not available, the WHO staging system for HIV disease (determines the stage of HIV infection based on clinical symptoms) is used instead:

Stage I:	HIV disease is asymptomatic and not categorized as AIDS.
Stage II:	includes minor mucocutaneous manifestations and recurrent upper respiratory tract infections.
Stage III:	includes unexplained chronic diarrhoea for longer than a month, severe bacterial infections and pulmonary tuberculosis.
Stage IV:	includes toxoplasmosis of the brain, candidiasis of the oesophagus, trachea, bronchi or lungs and Kaposi's sarcoma; these diseases are used as indicators of AIDS.

Salvage therapy

Salvage therapy is the term often used to describe the treatment for those who are resistant to drugs in the three original drug classes: NRTIs, NNRTIs and PIs. In these patients it may be difficult to find a drug regimen that suppresses the viral load to undetectable levels. The option is the use of much higher doses. The two additional classes of drugs introduced since 2003 (fusion or entry inhibitors and integrase inhibitors) are better treatment options in these resistant cases. It should be stressed that although antiretroviral drugs suppress HIV they do not eliminate the risk of HIV transmission completely, even when the viral load becomes undetectable. Thus, unprotected sex between two HIV-positive people is not without risk in view of the many different strains of HIV. For the majority of patients, HAART results in a near normal life expectancy.

Acquired immunodeficiency syndrome and hospital surgical practice

Experience in the UK and other countries suggests that the risk to healthcare workers is low provided certain universal and specific precautions are adopted routinely. As many infected individuals are unaware that they are HIV positive, all patients should be assumed to be infectious for HIV and other blood-borne pathogens. It is unsafe to apply universal precautions only in high-risk groups and in patients known to be HIV positive. The universal precautions (Box 11.4) apply to all health workers exposed to the following body fluids: blood, amniotic fluid, pericardial fluid, peritoneal fluid, pleural fluid, synovial fluid, cerebrospinal fluid, and semen and vaginal secretions. Universal precautions do not apply to exposure to faeces, nasal secretions, sputum, sweat, tears, urine and vomit. Although saliva is not regarded as a risk vehicle, precautions are needed in dental and oral work, as the saliva is then likely to be contaminated with the patient's blood.

When blood samples are obtained the doctor should wear disposable gloves. Plastic aprons and eye protection are needed when splashing or spurting is likely. Blood should be collected preferably with Vacutainers and on no account must the needle be resheathed. In high-risk cases, all specimens sent to the laboratory must be sealed in a plastic bag and marked with a red hazard sticker, as for hepatitis B. Accidental spillage of blood should be treated with 1% sodium hypochlorite solution. The specific guidelines for operating theatre staff are outlined in Box 11.5. All staff involved in the operating theatre should wear plastic aprons, disposable gowns, goggles, gloves and impermeable leg and footwear.

Action in the event of an accident involving possible transmission to medical and nursing staff

The rate of transmission resulting from accidental inoculation of healthcare workers with blood from individuals known to be infected has been reported to be of the order of 0.13–0.55, i.e. 1:770 to 1:200 chance of infection as a result of any single event. When such an accident occurs, the following procedure is necessary:

- Contaminated areas (spillage and splashes) or injury site (from sharps) should be immediately and thoroughly washed with soap and water.
- The incident is reported to the occupation health officer.
- If the HIV status of the source patient is not known, the patient consent's for HIV testing is obtained. This is usually forthcoming, but, if the patient declines consent, the statement by the General Medical Council becomes relevant: 'Only in the most exceptional circumstances, where a test is imperative in order to secure the safety of persons other than the patient, and where it is not possible for the prior consent of the patient to be obtained, can testing without explicit consent be justified.' In such a difficult situation, this statement implies that HIV testing of a blood specimen that had previously been obtained from the patient for other purposes is permissible.
- The exposed health worker should be counselled and expert advice sought. Consent for HIV testing from the individual concerned should be obtained, in which event, an immediate specimen (baseline) followed by others at intervals are necessary. Seroconversion usually occurs within 3 months.

BOX 11.4 Universal precautions against the spread of AIDS

- These apply to all patients irrespective of risk category or HIV status (known or unknown)
- Care in the handling of sharps: needles, scalpels, sharp instruments, etc.
- All cuts and abrasions on patients and staff should be covered with a waterproof dressing. Personnel should wear plastic aprons and disposable gloves when dealing with blood or secretions
- Parenteral procedures should be kept to a minimum
- External surfaces of equipment and bench surfaces which may have been contaminated by blood and other secretions should be wiped with a fresh preparation of sodium hypochlorite solution 1% (10 000 p.p.m. available chlorine) or 2% activated glutaraldehyde. Contaminated gloves, paper tissues and cotton wool should be incinerated
- In the event of the death of a person with AIDS, the body should be wrapped in impermeable plastic sheeting or a polythene cadaver bag before coffining
- Equipment being sent for maintenance and servicing should be disinfected with glutaraldehyde before leaving the ward or theatre
- Disposable equipment should be used wherever possible, and reusable equipment immersed in 2% glutaraldehyde for 1 hour before being returned for processing
- Walls and floor should be cleaned with soap and water

Fungal infections of surgical importance

From the clinical standpoint, fungal infections are best divided into cutaneous, subcutaneous and deep. Risk factors include prolonged antibiotic therapy that encourages growth of commensal fungal organisms, and leucopenia and T-helper lymphocyte (CD4) depression that are associated with invasive and potentially fatal fungal disease. The *cutaneous* (superficial) mycoses have a worldwide distribution and include dermatophytosis (ringworm), superficial candidosis (thrush) and pityriasis versicolor. The *subcutaneous* fungal infections are largely restricted to the tropical and subtropical regions, and often arise by direct implantation of soil fungal organisms through the skin of the soles of the feet, e.g. mycetoma and sporotrichosis.

A number of conditions result from *deep-seated* fungal infections that may be difficult to treat and prove fatal, particularly in immunosuppressed or debilitated patients. These include some fungal infections that have similar clinical characteristics, e.g. histoplasmosis, cryptococcosis, coccidiomycosis and blastomycosis. They are all caused by inhalation of infected soil dust and the primary lesion is pulmonary. Although usually self-limiting, the disease may spread via the bloodstream to involve other organs, causing serious or fatal illness. Many of the histological features of these deep-seated fungal infections are similar to those found in tuberculosis.

BOX 11.5 Guidelines for operating theatre staff

- It is justifiable to set aside a theatre and staff solely for HIV-positive patients
- Shaving should be avoided
- The anaesthetic room staff should wear disposable masks, plastic aprons, gloves and overshoes
- The anaesthetic machine and work surfaces should be stripped of all but essential equipment
- All theatre staff should wear impermeable overshoes, which must not be taken out of the theatre
- All staff, scrubbed and unscrubbed, should wear disposable gowns, plastic aprons, goggles and gloves (double for the surgeons and scrub nurse)
- Disposable drapes should be used. Swabs should be counted on a polythene sheet on the floor, not on the swab rack
- Only disposable scalpels are used. All instruments should be handed to and from the surgeon on a tray such that the surgeon or nurse picks the instrument without any direct transfer from nurse to surgeon and vice versa
- Suction bottles should be half filled with freshly prepared 2% glutaraldehyde solution
- Spilt blood or body fluids must be diluted with fresh 2% glutaraldehyde and mopped up with white paper towels. All consumables should be placed in a watertight bag for plastic incineration
- Splashes of blood or body fluids or accidental puncture wounds should be immediately and thoroughly washed with soap and water and the consultant should then inform the occupational health service of such an incident
- The operating nurse must ensure that the patient's skin is completely free of blood after the operation
- The patient should wear a clean operating gown before transfer back to the ward

Finally, *systemic mycoses* may arise from superficial and deep-seated fungal infections when the patient's immune response is depressed or the patient is critically ill. These are commonly encountered in ICU patients.

Candidosis (candidiasis)

The *Candida* species of fungi occur as commensals in the mouth, alimentary tract and vagina. Infection with *C. albicans* is common in clinical practice, and usually arises as an opportunistic superinfection in debilitated or critically ill and immunosuppressed patients.

The infection is encountered in several clinical forms. Oral candidosis (thrush) and the vaginal and perianal infections are common and usually occur as a consequence of antibiotic therapy (Figure 11.23). Vaginal candidosis is also found in conditions that result in a low pH of the vaginal secretions from excess glycogen in the vaginal cells, e.g. pregnancy, diabetes and females on the contraceptive pill. Cutaneous circumoral infection (perlèche) and chronic paronychia may also occur in these patients.

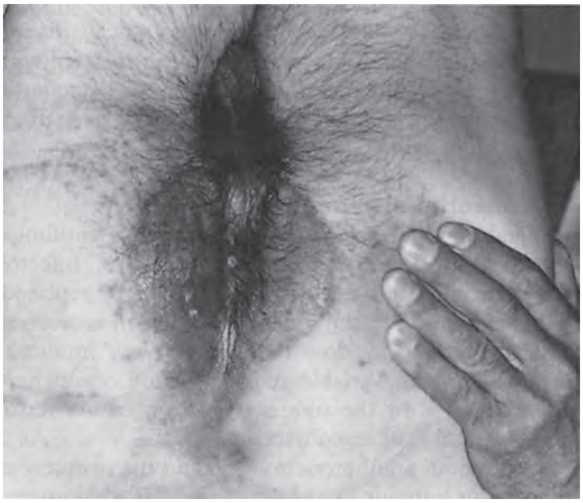

Figure 11.23 Perianal candidosis.

Alimentary and pulmonary candidosis

The oral infection may extend to involve the gastrointestinal tract, particularly the oesophagus, following prolonged therapy with broad-spectrum antibiotics. Both alimentary and pulmonary candidosis may arise as opportunistic infections in the presence of impaired cell-mediated immunity, e.g. immunosuppression from illness, malignancy or drugs.

Generalized (systemic) candidosis

This is the most serious form and is characterized by bloodstream spread to any organ, but most commonly to the lungs, kidneys and the endocardium. This serious systemic infection is encountered in patients on parenteral nutrition, patients with prosthetic devices, transplant patients and critically ill patients. The general clinical features of systemic candidosis include high fever, hypotension, rigors and renal impairment. The reported overall survival following appropriate systemic antifungal therapy is 65–70%.

Pulmonary candidosis

There are two types of pulmonary candidosis: monilial bronchitis and monilial pneumonia. The treatment is with 5-flucytosine, which is the drug of choice if the organism is sensitive; otherwise, intravenous or inhaled amphotericin B may be tried (see below).

Monilial bronchitis

This occurs in infancy, fibrocystic lung disease and debilitated elderly patients. The bronchial walls are studded with greyish-yellow plaques containing fibrin, hyphae and spores. Clinically, there is an irritating cough productive of scanty, 'milky' sputum. The chest radiograph may be normal or show basal striations.

Monilial pneumonia

This is a necrotic pneumonia that occurs in critically ill and debilitated patients, giving patchy, ill-defined shadows on the chest radiograph. The patient has a high fever with tachycardia, dyspnoea and cough productive of blood-stained sputum.

Chronic mucocutaneous candidosis

Several types of primary immunological disease affecting the T-lymphocyte function are associated with widespread development of chronic mucocutaneous candidosis. The immunological deficit varies from patient to patient.

Treatment of systemic fungal infections

General considerations are important since antifungal therapy alone may be insufficient. Thus, infected prosthetic implants need to be removed or replaced. Whenever possible, the immune depression is reversed at least partially by dose reduction of any immunosuppressive drug. Variable and conflicting results have been obtained by the administration of transfer factor and transfusion of leucocytes.

Intravenous amphotericin B remains the mainstay of therapy for systemic fungal infections. It is administered in 5% dextrose, initially in a dose of 0.25 mg/kg/24 h and increasingly gradually over a period of 4–6 days to 1.0 mg/kg/day. The daily dose is administered over a period of 3–4 hours. Since it deteriorates rapidly in solution on exposure to sunlight, the intravenous solution must be shielded. Treatment is monitored by blood levels, which should be kept in the 1–3 μg/mL range. The main disadvantage of amphotericin B is its toxicity: rigors, hypotension, phlebitis, hepatic damage, renal damage, anaemia, leucopenia and hypokalaemia. The prior intravenous administration of either hydrocortisone (50–100 mg) or chlorpheniramine (10 mg) is said to reduce some of the early side effects. In order to minimize toxicity, amphotericin B is often administered in a reduced dose in combination with other drugs. Various combinations are used, including amphotericin B + 5-flucytosine for cryptococcosis and rifampicin + amphotericin B for candidosis and blastomycosis. Altering the rate of infusion and alternate-day treatment may help to reduce the incidence and severity of side effects. Other measures that are used to reduce toxicity include heparin infusion against phlebitis, and mannitol and bicarbonate to minimize renal damage. 5-Flucytosine is a synthetic antifungal agent that can be administered orally or intravenously. It is active mainly against *Candida* and *Cryptococcus.* Apart from its side effects (diarrhoea, rashes, leucopenia and hepatitis), its main disadvantage is the rapid emergence of resistance.

A number of imidazoles have significant antifungal activity. The two most often used are ketoconazole, which is administered orally (200–600 mg), and miconazole, which is given intravenously since it is poorly absorbed after oral administration. Ketoconazole has fewer side effects than miconazole, which may cause rashes, phlebitis, ventricular tachycardia and anaphylaxis. Drug resistance to the imidazoles is rare and they have a broad spectrum of activity against many fungi (except for aspergilli) and some Gram-positive bacteria. All other imidazoles (clotrimazole, econazole, tioconazole) are mainly used as topical antifungal agents. Oral ketoconazole is advocated as prophylaxis in transplant patients.

Treatment of cutaneous fungal infections

Topical polyenes (natamycin, nystatin, candicidin) are used as 1–2% creams or ointments, as suspensions or tablets (oral or vaginal). The topical imidazole preparations are also effective. In chronic mucocutaneous candidosis associated with T-lymphocyte immune defects, treatment with transfer factor gives varying results.

Mycetoma

This is a localized infection of the skin and subcutaneous tissues of the extremities, usually of the feet and less frequently of the hands. It is found in developing countries. The infection is caused by organisms normally resident in the soil, which are implanted by thorn and similar injuries in individuals who walk barefooted. *Bacterial mycetoma* is caused by infection with species of *Nocardia* or *Actinomyces* (actinomycetoma). *Fungal mycetoma* (eumycetoma, maduromycosis) is endemic in certain countries, e.g. India, and is caused by various fungi including *Madurella mycetoma, Allescheria boydii* and *Aspergillus nidulans.* The disease results in chronic suppuration with severe tissue destruction and multiple discharging sinuses (Figure 11.24). In both bacterial and fungal mycetoma, osteomyelitis of the bones of the foot may develop.

Aetiology

The most common fungi to cause mycetoma with black or red grains are *Leptosphaeria senegalensis* (Africa), *Madurella grisea* (Africa, South and Central America), *Madurella mycetoma* (worldwide) and *Pyrenochaeta romeroi* (Africa, South America). Other fungal infections cause mycetoma with white grains, e.g. *Acremonium* species (Africa, Middle East), *A. nidulans* (Africa, Middle East), *Noetestudina rosatii* (Africa) and *Pseudallescheria boydii* (worldwide).

The common actinomycetes causing mycetoma usually with white/yellow grains are: *Actinomadura madurae* (worldwide), *Nocardia asteroides* (worldwide), *Nocardia brasiliensis* (Central America). *Actinomadura pelletieri* (Africa) and *Streptomcyes somaliensis* (North Africa, Middle East) cause mycetoma with brown or red grains in the discharge.

Clinical features

Mycetoma is more common in males than in females, and affects usually individuals aged 20–50 years. It presents as a subcutaneous single hard painless lump most commonly of the foot (70%), which persists and become indurated as it gradually involves the underlying muscles and bones. Eventually the lesion ulcerates through the skin with the formation of sinuses discharging pus containing the characteristic grains. The condition causes considerable deformity, rendering walking difficult, but does not cause pain, although itching and burning sensation are common, as is secondary bacterial infection including osteomyelitis and atypical mycobacterium infection.

The diagnosis of mycetoma is made on identifying grains and culture of pus. The colour of the grains often suggests the likely diagnosis: black or red grains in fungal infection, white grains in *Nocardia*, etc. Microscopy of smears stained with potassium hydroxide confirms the diagnosis and type of mycetoma, but Agar plate cultures at 25–30°C for up to 6 weeks may be needed for definite diagnosis.

Treatment

In bacterial mycetoma, treatment with the appropriate antibiotics together with surgical drainage and debridement may prove efficacious. Bacterial actinomycetoma responds well to treatment with prolonged appropriate antibiotic therapy (6–12 months). Single or combination treatment may be used: streptomycin injections; oral cotrimoxazole, amikacin, dapsone, rifampicin or minocycline. Surgical treatment is used for debridement with foot preservation, but severe disease with bone involvement may require amputation.

The fungal eumycetomas, by contrast, seldom respond to antifungal chemotherapy as the organisms acquire a protective cement sheath or develop thickened cell walls. Nonetheless, a trial of treatment with an antifungal agent, e.g. griseofulvin, 5-flucytosine or ketoconazole or itraconazole, may be effective in patients with early and limited disease, and without bone involvement. In most instances, however, amputation is necessary to eradicate the disease.

Parasitic infestations of surgical importance

Hydatid disease

The disease can be caused by one of three species of the genus *Echinococcus: Echinococcus granulosus, Echinococcus multilocularis* and *Echinococcus oligettas.* Since the epidemiological and pathological features of these three tapeworms are very similar, a detailed description of *E. granulosus* only is given here. Hydatid disease, which is caused by the larval form of *E. granulosus,* has a cosmopolitan distribution, being particularly prevalent in sheep- and cattle-raising areas.

Parasitology

The adult *Echinococcus* is a small tapeworm that inhabits the upper part of the small intestine of canines, especially dogs and wolves. When the ova, which are passed in the faeces, are swallowed by humans or other intermediate hosts, e.g. sheep and cattle, the enclosed embryo is liberated in the duodenum. It penetrates the intestinal mucosa to reach the portal circulation, and is usually held up in the liver to develop into a hydatid cyst. If the embryo passes through the liver filter, it enters the general circulation and thus reaches the lungs and other parts of the body. Two main varieties of cyst occur: unilocular and multilocular. The unilocular hydatid cyst (Figure 11.25) develops a wall with two layers: an outer, thick, laminated layer and an inner (germinal) layer, which is composed of a protoplasmic matrix containing many nuclei. Around the cyst there is a connective tissue capsule formed by the tissues of the host. Bulb-like processes known as brood capsules arise from the germinal layer. The brood capsules undergo localized proliferation and invagination of their walls to form scolices (tapeworm heads). Each scolex has suckers and hooklets. Some of the brood capsules separate from the walls and settle to the bottom of the cyst as fine granular sediment 'hydatid sand'. As the hydatid cyst enlarges, invaginations of the wall may give rise to daughter cysts. In some cases in which no effective encapsulation occurs, the daughter cysts develop as a result of evaginations of the cyst wall, producing the multilocular or alveolar hydatid cysts. This variety of cyst is caused by *E. multilocularis.*

When the hydatid is eaten by definitive hosts, e.g. dogs, foxes or wolves, the numerous larvae develop into sexually mature worms in a few weeks. Dogs are usually affected when they eat the infected viscera of sheep or cattle (Figure 11.26). Humans acquire hydatid disease when they swallow infected ova as a result of their close association with dogs. Although infection is usually acquired in childhood, clinical symptoms do not appear until adult life. The dog faeces contaminating the fleeces of sheep can also be an indirect source of human infection.

Pathology

When the ingested ovum reaches the duodenum, the hexacanth embryo is released and penetrates the intestinal mucosa to reach the portal circulation and thence the liver, most commonly the right lobe. Hydatid cysts are usually single but may be multiple and involve the left lobe. Larvae may pass through the liver to infect other organs, e.g. lungs (71%), muscle (5%), brain (5%), spleen (2.5%), kidneys (2%), other abdominal organs (5%), bone (0.5%) and rarely the heart. During the stage of migration, there may be a mild reaction with fever and urticarial skin rash. There is an eosinophilic reaction to the larva itself, which subsides as the host's fibrous tissue capsule thickens. In humans the hydatid cyst may be the classic unilocular, the osseous or the alveolar.

The alveolar multiloculated hydatid cyst is usually found in the liver and has a sponge-like appearance (Figure 11.27). In the brain it resembles a bunch of grapes (Figure 11.28). The alveolar multiloculated cyst may metastasize.

The classic unilocular hydatid cyst may be sterile but is usually fertile and surrounded by a fibrous capsule. Rupture of fertile cysts, depending on their site, causes dissemination of daughter cysts with the formation of secondary metastatic hydatids. The escape of the cyst fluid and 'hydatid sand' may

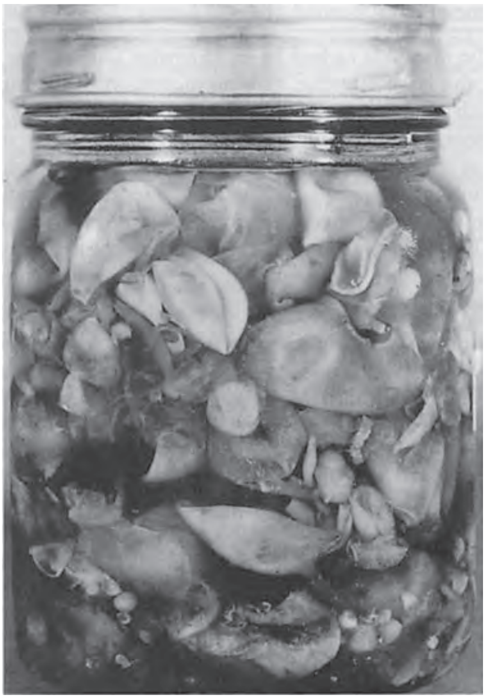

Figure 11.28 Hydatid cysts removed from the brain at necropsy.

cause a severe allergic reaction with urticarial lesions, pruritus, fever, abdominal pain, dyspnoea, cyanosis, delirium and syncope. In addition, there is marked eosinophilia. In bone the usual fibrous capsule of the host is not formed and, instead of being round, the cyst assumes an irregular branching shape as it penetrates the bony canals. Erosion of bone occurs and the medullary cavity is eventually invaded, when the cyst assumes its normal spherical form. The more highly vascularized areas, the epiphyses of long bones and the centres of the vertebral bodies, ilium and ribs, are the most frequently affected sites. Radiologically, they appear as rounded areas of rarefaction. Spontaneous fractures may occur.

Clinical features

The liver and lungs are the organs involved in the disease in over 90% of cases and hepatic hydatid disease accounts for 75% of these. Although the infection is usually acquired in childhood, a hepatic hydatid cyst may not produce symptoms until adult life and the interval between infection and manifestation of symptoms may exceed 30 years. At presentation the majority of cysts occur in the right lobe. Exogenous cysts may communicate with the biliary tract and these contain bile-stained fluid (Figure 11.29). Secondary infection may occur with *Salmonella* and pyogenic organisms.

Rupture of the cyst may result from secondary infection or trauma and may be accompanied by severe allergic manifestations that can be life-threatening. Rupture may involve the peritoneal cavity, the gallbladder, biliary tract, pleural cavity or hepatic veins, when secondary metastatic cysts develop in the lungs.

The alveolar cyst may occur in the liver but is most frequently found in the lungs in children. Infection of the cyst results in a chronic pulmonary abscess. The cyst may rupture as a result of coughing or secondary infection. The cyst may rupture into the bronchus, when scolices may be detected in the sputum, into the mediastinum or pleural cavity, with secondary dissemination and the development of pneumothorax and haemothorax. In the brain, the cysts are usually single and present with symptoms of a space-occupying lesion. Rupture may disseminate the lesions in the subarachnoid space of the spinal cord, which may also be involved by extension of a hydatid cyst involving the vertebrae or paravertebral tissues. Cerebral emboli, secondaries have been reported from primary hydatid cysts in the lung, liver and heart.

Hydatid disease of the heart may be first discovered at autopsy. During life, the cysts may rupture into the pericardium or into the chambers of the heart, with consequent pulmonary metastases or systemic embolization causing thrombosis, infarction or aneurysm formation. Constrictive pericarditis may complicate rupture into the pericardium.

Occasional involvement of the spleen and kidneys by solitary cysts is well documented. In the kidney rupture into the renal pelvis results in renal colic and dysuria, with passage of hydatid material in the urine. Rarely, there is involvement of other sites, e.g. orbit, ovaries, broad ligament and uterus.

Investigations

Moderate eosinophilia (300–2000/mm^3) is usually present and the immunoglobulin level is elevated. Hydatid contents (hooklets, scolices) may be detected in the faeces, sputum or urine if the cyst ruptures. A plain radiograph of the chest and abdomen may be suggestive (Figure 11.30), although more information is obtained by ultrasound examination and especially by CT, which gives valuable information on the contents, size and precise location of the cyst (Figure 11.31). CT is the best method of establishing the diagnosis of liver, pulmonary and cerebral hydatid disease.

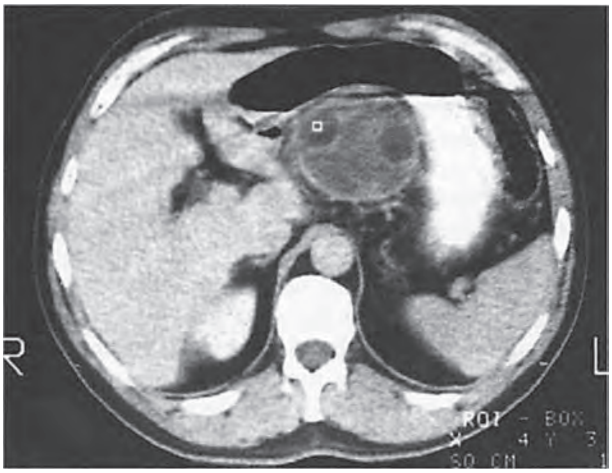

Figure 11.31 CT scan showing a large hydatid cyst of the pancreas containing daughter cysts. The pancreas is a rare site of involvement by hydatid disease. (Courtesy of Dr Moh'd Saad, Adan Hospital, Kuwait.)

The Casoni test using crude sterile hydatid fluid is unreliable. An intradermal test antigen made from an extract of lyophilized material of *E. multilocularis* from experimental infections in gerbils is preferable. The detection of circulating scolex antigen by countercurrent immunoelectrophoresis or the enzyme-linked immunosorbent assay (ELISA) gives the most reliable results. The dot-ELISA test is a field test for hydatid disease that can be carried out rapidly without specialized equipment. It detects antibody to purified parasite antigen (bound to strips of nitrocellulose paper) in a small finger-prick sample.

Treatment

The methods used to control the disease are aimed at prevention of access to infected carcasses by dogs, and registration and regular treatment of dogs with effective anthelmintics

The use of mebendazole often results in death and shrinkage of the hydatid disease, thereby avoiding the need for surgical intervention. Serum levels >1100 ng/mL 1–3 hours after an oral dose may be required to kill the parasite. To achieve this, a dose of 200 mg/kg/day of mebendazole in three divided doses is required for about 16 weeks. Albendazole, a more absorbable derivative, is even more effective. It is administered in a dose of 12–15 mg/kg/day for 28 days.

Surgical treatment

This has to be individualized to the pathology in the individual patient and the clinical presentation. The surgical approach may be open or laparoscopic, although most advise that the laparoscopic approach should be restricted to cysts in an accessible location, namely the left lateral and right anterior segments. The various procedures performed for hepatic hydatid cysts may be classified as (1) conservative or (2) radical. The conservative operations are:

- de-roofing of the cyst and extraction of the parasite with omentoplasty and external drainage of the cyst cavity: Mabit procedure
- de-roofing of the cyst with captionage of the cavity without drainage: Posadas procedure
- partial pericystectomy: leaving a deep part of the cyst within the liver
- marsupialization
- internal cystojejunal drainage
- external drainage: not recommended as it is associated with a high incidence of infective complications (30%) and biliary fistulae (8%) and has largely been replaced by omentoplasty, which carries a significantly lower incidence of biliary fistula and infection.

The more radical procedures are:

- pericystectomy (removal of cyst and 1–2 cm of normal parenchyma)
- total cystectomy (complete removal of cyst)
- liver resection.

Pericystectomy consists of removing the cyst together with a 1–2 cm rim of surrounding liver parenchyma. Pericystectomy is an ideal procedure for multivesicular cysts and calcified cysts, especially if there is bile duct communication, but is contraindicated for cysts impinging on major hepatic veins or inferior vena.

Some 25–30% of patients with hydatid disease of the liver present with complications, most commonly infection and rupture of the cyst into the biliary tree, although other complications may occur including intraperitoneal or intrathoracic rupture and rupture into hollow viscera and rarely into the vascular tree. The most common infection of hydatid cyst in the liver is by *E. coli* and these infected cysts invariably have bile-stained contents owing to communication with the biliary tree. The clinical features of intrabiliary rupture include jaundice and cholangitis. The diagnosis of intrabiliary rupture is best confirmed by endoscopic retrograde cholangiopancreatography or magnetic resonance cholangiopancreatography. The operative treatment consists of emptying the mother cyst with removal of hydatid membranes and supraduodenal exploration and clearance of the CBD. The biliary communications with the cyst are identified and sutured, following which the choledochostomy is closed over a T-tube. In patients with gross dilatation of the CBD or incomplete clearance or a large biliary communication which cannot be closed, a choledochoduodenostomy is performed. Omentoplasty is an effective alternative treatment if the biliary fistula is small. Omentoplasty has the added benefit of promoting reabsorption of serosal fluid. Internal drainage is a safe and useful procedure and is advised in the presence of a major biliary communication that is difficult to close or when closure of the communication may compromise biliary drainage or when the CBD is grossly dilated. Cystojejunostomy has the dual advantage of internal draining of the biliary fistula and the residual cyst cavity provided the cystojejunostomy is fashioned in a dependent position to avoid stagnation of the cyst contents.

Intraperitoneal rupture is most common with cysts bulging through the anteroinferior surface of the liver; when this occurs, it is accompanied by shock with signs of diffuse peritonitis. These patients require emergency resuscitation followed by surgical treatment with peritoneal lavage using protoscolicidal agents and hypertonic saline. Rarely, intraperitoneal rupture is clinically silent and the patient presents years later with disseminated abdominal hydatidosis.

Amoebiasis

The disease is caused by *E. histolytica*. The parasite lives in the large intestine, causing ulceration of the mucosa with consequent diarrhoea. Secondary lesions may occur, most commonly in the liver, but other tissues may be affected, e.g. lung, brain, genital organs and skin. Amoebiasis has a worldwide distribution but clinical disease occurs most frequently in tropical and subtropical latitudes. It is found in countries where standards of personal and environmental sanitation are low.

Parasitology

The amoeba, which multiplies by binary fission, lives in the lumen of the large intestine where, under suitable conditions, it invades the mucosa/submucosa and ingests red blood cells. When diarrhoea occurs, amoebae are expelled and can be detected in freshly passed fluid stools. In the absence of diarrhoea and when other conditions are favourable for encystation, the amoebae cease feeding, become spherical and secrete a cyst wall, and the nucleus divides twice to form the characteristic mature four-nucleate cyst. This is the infective form and, when ingested, the cyst hatches in the lower part of the small intestine/proximal colon and a four-nucleate amoeba emerges. After a series of nuclear and cytoplasmic divisions, each multinucleate amoeba gives rise to eight uninucleate parasites that establish themselves and multiply in the large intestine.

In endemic areas, the prevalence is stable and the morbidity rate from the disease is low. The disease is spread by cyst passers, who fall into two groups: (1) convalescents who have recovered from an acute attack and (2) individuals who can recall no clinical symptoms or signs of infection. Poor sanitation is more important than climate in the predominance of overt infection in the tropics. Carrier rates of *E. histolytica* among symptomless subjects vary from 20% to 80% in different communities. The parasite can be transmitted by direct contact through contaminated hands of cyst carriers. It is also transmitted indirectly through contaminated food, e.g. raw vegetables.

Pathology

The primary sites of infection in order of frequency are the caecum, colonic flexures, descending colon and rectum. The appendix is sometimes involved and rarely the ileum. Macroscopically, the large intestine becomes studded with discrete ulcers with overhanging edges, the intervening mucosa being relatively normal. The ulcers spread laterally in the submucosa and become confluent. Large areas of mucosa thus become devitalized and form greenish shaggy sloughs. The necrotic process may involve the muscularis propria and even extend to the serosa in severe cases. In patients in whom the host–parasite balance has been altered by drugs, concurrent disease or pregnancy, the entire mucosa may be sloughed. The wall of the bowel is thickened and friable (Figure 11.32).

The amoebae spread laterally beneath the intestinal epithelium and form large 'flask-shaped' or 'water-bottle' ulcers that have overhanging edges and consist of a zone of necrosis surrounded by chronic inflammatory infiltrate of lymphocytes and macrophages with a variable fibroblastic reaction. Amoebae are found at the periphery of the lesion in the submucosa and muscle layers and in the necrotic tissue itself (Figure 11.33).

Liver abscess (Figure 11.34) is the most common extraintestinal complication. The abscess is usually solitary but multiple abscesses are not uncommon. The right lobe of the liver is most frequently affected. Bile appears to destroy the amoebae and for this reason the gallbladder is never affected. In over 50% of patients with amoebic liver abscess, there is no evidence of amoebic infection on stool examination. The amoebae cause lysis of the liver parenchyma, primarily in the periportal region. An expanding area of necrosis ensues and the abscess cavity may reach large proportions. The cavity contains sterile, chocolate-coloured fluid, granular debris and a few inflammatory cells. Amoebae may or may not be present in the pus. Histologically, the wall of the abscess consists of necrotic tissue and compressed liver parenchyma containing a variable infiltrate of monocytes, plasma cells, lymphocytes and fibroblasts.

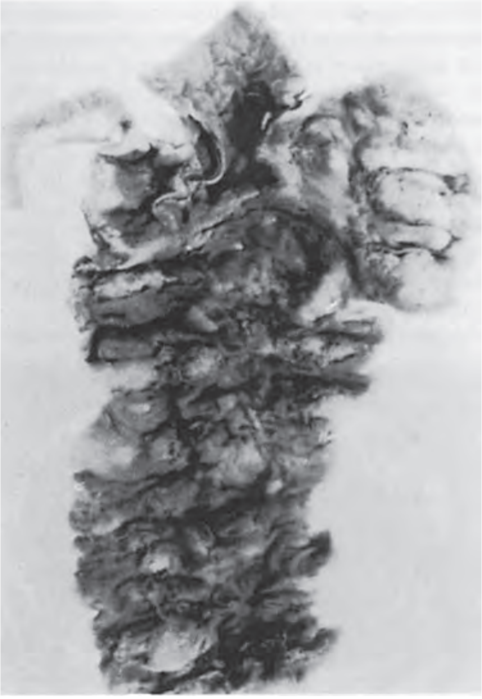

Figure 11.32 Fulminating amoebic colitis resulting from the use of steroids given for a mistaken diagnosis of ulcerative colitis.

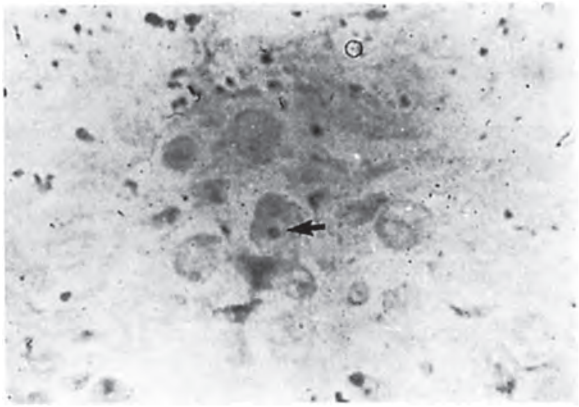

Figure 11.33 Amoebic colitis section of colon. Note *Entamoeba histolytica* trophozoites.

Clinical features

The classic disease is amoebic dysentery, the symptoms of which appear within 1–2 weeks of infection but may be delayed for months to years. The onset is usually gradual, with some looseness for a few days followed by evacuation of 6–12 mucoid, blood-stained motions per day. Colic and tenesmus are unusual unless there is a lesion immediately inside the anus. Physical examination may be negative. Occasionally, during an acute attack, there is palpable thickening of the caecum or left colon with tenderness on palpation. Pyrexia is absent and there is little prostration. The duration of an attack of average severity may be a few days but it may linger on for some weeks. The attack usually subsides spontaneously. There follows a period of remission varying from a few days to several months, even years. During remission, the patient is often constipated. Another attack of dysentery then follows. This sequence of relapses and remissions may continue for several years and is typical of the disease. Complications, e.g. liver abscess, may develop at any time. Complications are encountered in 20% of neglected cases.

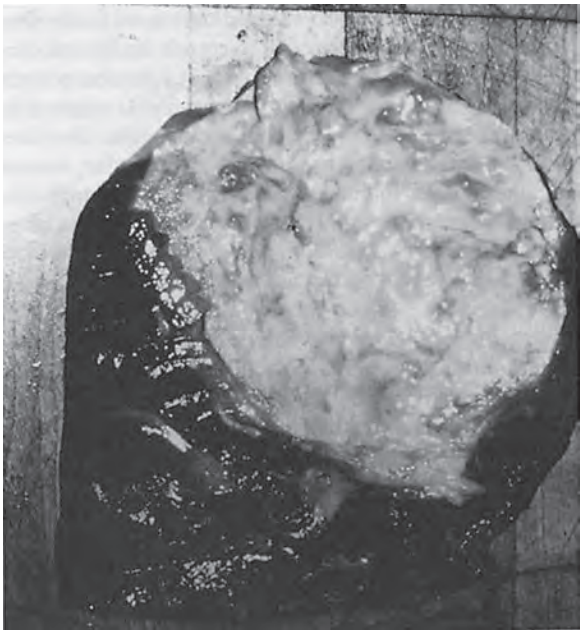

Figure 11.34 Large single amoebic abscess of the liver.

In malnourished individuals or in patients with comorbid disorders, the attacks may be prolonged, severe and even fatal. Fulminating amoebiasis is also encountered in immunosuppressed patients. The fulminating disease has a sudden onset with swinging pyrexia, chills, sweating and very severe dysentery with rapid dehydration and prostration. In such cases the stools are watery with flecks of faecal matter and variable amounts of blood and mucus. There may be severe intestinal haemorrhage or perforation with amoebic peritonitis. The mortality of these cases is high.

The direct complications of an intestinal infection are haemorrhage from erosion of a large intestinal blood vessel, transmural extension of the infection with the formation of amoebic granulomas (amoebomas) and frank intestinal perforation. In addition, a form of slow intestinal leakage through extensively diseased bowel may result in localized peritonitis. This should be suspected in patients whose condition deteriorates and in whom there is increased abdominal distension with signs of ileus. Plain radiology reveals free gas under the diaphragm. Other local complications include amoebic strictures that may occur in any part of the colon and intussusception, which is rare. All of these complications are unusual in the common attacks of average severity.

The clinical features of amoeboma include a palpable mass, usually in the right iliac fossa, low-grade fever, tenderness, and symptoms and signs of intestinal obstruction. Clinically, such a lesion may be indistinguishable from a neoplasm, ileocaecal tuberculosis, appendix mass or actinomycosis.

In the early stages of an amoebic liver abscess, the patient complains of discomfort and fullness in the liver region. The liver enlarges and becomes tender. Moderate fever develops, at first intermittent and subsequently remittent. Sweating is severe, especially at night. The patient becomes anorexic and loses weight. The liver tenderness is maximal over the site of the abscess, usually in the right intercostal region laterally. The enlarged liver may cause obvious bulging of the chest wall and upper abdomen. Chest wall movement is restricted on the affected side. Breathing is painful and the patient develops shallow tachypnoea. The liver dullness is increased upwards and radiology reveals a raised, immobile hemidiaphragm. The liver edge is usually palpable well below the costal margin, and is firm and tender. Jaundice is uncommon. Most patients have a moderate polymorphonuclear leucocytosis. The ESR is raised. Signs of pulmonary involvement (collapse and pleural effusion) are usually limited to the base of the right lung. When the abscess ruptures through the diaphragm into the lung, the abscess contents discharge into the bronchial tree and the patient develops a cough with expectoration of the classic 'anchovy sauce' sputum. Untreated, the abscess may involve other regions, e.g. pericardial sac, peritoneal cavity and parieties. Embolic spread may result in abscess formation in other organs, including the brain. Although usually secondary to liver disease, primary amoebic abscesses of the lung and brain are well documented.

The diagnosis of amoebiasis is established by the identification of *E. histolytica*. Microscopic examination of stool specimens during an acute attack will reveal motile amoebae. In asymptomatic infections and during remissions, the stools contain *E. histolytica* cysts. Repeated stool examinations (minimum of six) should be made before absence of infection can be assumed. Culture methods may assist diagnosis in scanty infections. Sigmoidoscopy often yields useful information. The appearances consist of small yellow ulcers with surrounding hyperaemia, and a normal mucosa in between the ulcers. In chronic cases, amoebic lesions may appear as 'pin-point craters' that are irregularly disposed.

The diagnosis of extraintestinal amoebiasis can be difficult as concomitant dysentery is present in only 5–10% of patients. Posteroanterior chest radiography shows abnormalities in 75% of cases: elevated diaphragm, basal collapse, patchy opacities and pleural effusion. Ultrasound or CT examination of the liver is necessary for establishing the diagnosis and for percutaneous aspiration of the abscess (Figure 11.35).

Serological tests are useful in suspected cases of amoeboma and in those patients diagnosed as having ulcerative colitis who have been to the tropics. The serodiagnostic tests include direct immunofluorescence, ELISA and an isoenzyme electrophoretic technique that differentiates the invasive from the non-invasive form of *E. histolytica*.

Treatment

Medical treatment

Asymptomatic intestinal amoebiasis

In this condition *E. histolytica* is confined to the bowel lumen. Nonetheless, treatment is recommended because invasive disease may develop and because shedding of *E. histolytica* cysts in the environment promotes spread and is thus a public health concern. Treatment is by *luminal* or *contact* amoebicides. There are several such drugs, but few are completely reliable in eradicating amoebae. Diloxanide furoate for 10 days is the most commonly used contact amoebicide, although 10 day courses of Clefamide (2,2-dichloro-*N*-(2-hydroxyethyl)-*N*-[p-(p-nitrophenoxy)benzyl]acetamide) is also used as it is well tolerated and of low toxicity.

Amoebic dysentery

Metronidazole is the standard treatment for acute amoebic dysentery and for amoebic liver abscess. Tinidazole (Fasigyn) is also effective. Metronidazole treatment is usually accompanied by a luminal agent to eradicate colonization. Broad-spectrum antibiotics are added if perforation is suspected.

Amoebic liver abscess

Amoebic liver abscess can be cured without drainage and even by one dose of metronidazole. Clinical defervescence should occur during the first 3–4 days of treatment. Failure of resolution with metronidazole is an indication for surgical intervention.

Disseminated amoebiasis

This is treated with metronidazole (passes the blood–brain barrier).

Surgical treatment

Surgical intervention may be necessary in:

- fulminating amoebic colitis
- amoebic perforation of the colon
- amoebic liver abscess.

Fulminating amoebic colitis

Surgical treatment is indicated when the patient deteriorates despite medical therapy, in the presence of radiological evidence of toxic dilatation, and the onset of an acute episode, e.g. perforation, severe bleeding. The operative treatment consists of resection of the diseased segment with exteriorization of the bowel ends.

Amoebic bowel perforation

This occurs in 1–2% of patients hospitalized for the disease. Although any segment of the small and large intestine may be involved, the most common sites are the caecum, ascending and sigmoid colon. Multiple localized or diffuse perforations are encountered in 25% of cases presenting for surgery. Three types of perforation are recognized: extraperitoneal, perforation of a granuloma or ulcer without acute dysentery, and perforation associated with fulminant disease. Antiamoebic therapy is the primary treatment for all localized extraperitoneal perforations.

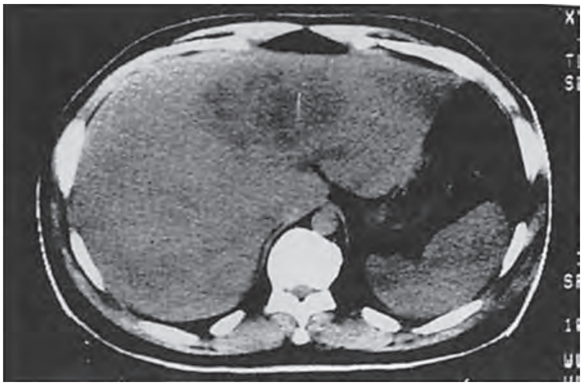

Figure 11.35 CT scan of amoebic abscess of the liver.

Surgery is indicated only if the patient's condition deteriorates and rupture appears imminent. Diversion of the faecal stream by an ileocolic anastomosis beyond any colonic involvement and local drainage is the recommended treatment, except in perforations associated with gangrene and fulminant colitis.

Amoebic liver abscess

The majority of amoebic liver abscesses respond to therapy with metronidazole with or without percutaneous CT or ultrasound-guided aspiration. Surgical treatment is reserved for when medical therapy and percutaneous aspiration have failed and for certain specific indications that include:

- frank or impending rupture
- onset of complications, e.g. secondary infection or haemorrhage
- abscess in the left lobe because of difficulties in aspiration in this area and the risk of rupture into the pericardial sac.

Surgical drainage

In general, patients requiring surgical drainage have advanced disease and the overall mortality of this group is high (30%). A period of therapy with metronidazole lasting for a minimum of 4 days before surgical intervention has been shown to reduce mortality significantly. Transbronchial rupture is usually well tolerated and is often curative, although rarely it may cause fatal pneumonia or lung abscess. Rupture into the pleural cavity is accompanied by shock, respiratory distress and empyema. This situation requires urgent intervention to drain the abscess and the empyema, and to ensure early re-expansion of the collapsed lung. Intraperitoneal rupture requires adequate peritoneal toilet in addition to drainage of the abscess cavity.

Complications following surgical drainage

Apart from respiratory complications and shock, these include liver failure, biliary peritonitis and fistulas. Massive haemorrhage is rare and amoebiasis of the skin is unusual if adequate antiamoebic therapy is started before surgery.

Schistosomiasis

The three species infecting humans are *Schistosoma haematobium, Schistosoma mansoni* and *Schistosoma japonicum*. About 200 million people are affected in various parts of the world. *Schistosoma haematobium* occurs in many parts of Africa, parts of the Middle East and a few foci in southern Europe (Portugal). *Schistosoma mansoni* is found in the Nile delta, Africa, South America and the Caribbean. *Schistosoma japonicum* occurs in China, Japan, the Philippines and other foci in the Far East. Other schistosomes that infect humans include *Schistosoma bovis, Schistosoma matthei* and *Schistosoma intercalatum*.

Parasitology

These worms are trematodes with the peculiar morphology whereby the male is folded to form a gynaecophoric canal in which the female is carried. The adult worms are found in the veins: *S. haematobium* predominantly in the vesical plexus, *S. mansoni* in the inferior mesenteric vein and *S. japonicum* most commonly in the superior mesenteric vein. The female lays eggs, which pass through the bladder or bowel into urine or faeces. A proportion of the eggs remain in the tissues and some are carried to the liver, lungs and other organs. If an excreted egg lands on water, it hatches and produces a free-living form, the miracidium, which swims about by ciliary activity. It next invades an intermediate host, a snail of the appropriate species. Within the snail, it undergoes asexual multiplication, passing through intermediate stages of redia and sporocyst to become the mature cercaria. This is the infective larval stage for humans. It emerges from the snail and swims, being propelled by its forked tail. On contact with humans, the cercaria penetrates the skin, sheds its tail and becomes a schistosomule that migrates to the usual site for mature adults of the species. The respective life cycles are shown in Figures 11.36–11.38.

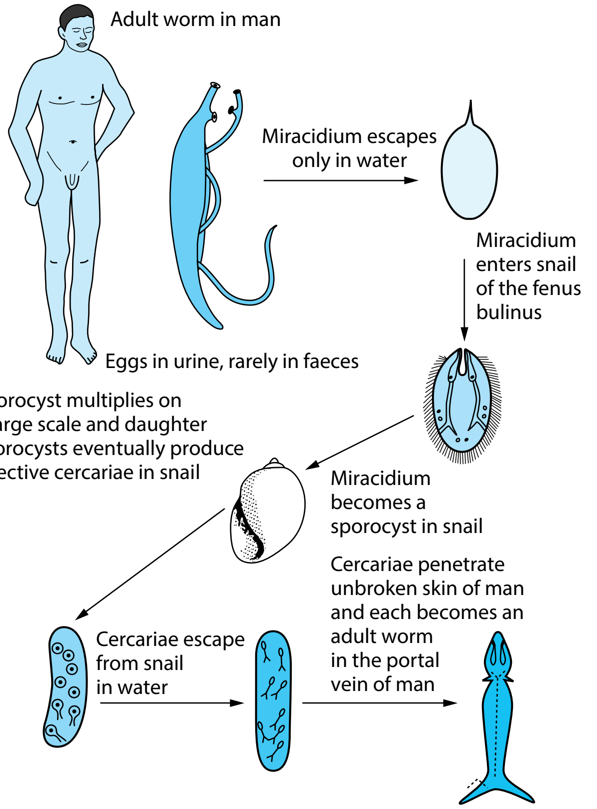
Humans are the reservoir of *S. haematobium* but naturally acquired infection with *S. mansoni* has been found in various animals, including primates. *Schistosoma japonicum* is widely distributed in various animals (cats, dogs, cattle, pigs, rats, etc.) and these constitute a significant part of the reservoir. Humans acquire the infection by wading, swimming, bathing or washing clothes and utensils in polluted waters. The age and sex distribution of schistosomiasis varies from area to area. One common pattern is of high prevalence rates of active infection in children, who excrete large quantities of eggs, and a lower prevalence of active infection among adults, with the latter exhibiting late chronic manifestations of the disease. The load of infection is an important factor in determining the severity of the pathological lesions and the disease.

Pathology

Schistosoma haematobium

This affects mainly the urinary tract. The bladder lesions include acute and polypoid lesions, fibrous plaques, 'ground-glass' lesions, sandy patches, ulceration, stricture, leucoplakia and cystitis glandularis, fibrosis, calcification of the bladder wall and bladder neck obstruction. However, the bladder may appear normal macroscopically even in fairly severe infections, and mucosal biopsies and press preparations are necessary if *S. haematobium* is suspected.

In the acute stage the bladder may only be hyperaemic, with or without petechial haemorrhages. Ova retained in the vesical tissues, most commonly in the subepithelial layer, result in the formation of pseudotubercles, when the bladder becomes studded with small, yellow, seed-like bodies surrounded by a zone of hyperaemia. They are most frequently situated in the trigone, with the base and lateral walls next most commonly affected. Adult schistosomes are often present in the neighbouring vesical veins. Nodules or polyps may be formed by coalescence of these tubercles, hyperplasia of the mucosa, and early fibrosis and hypertrophy of the muscle. These papillomatous or granulomatous lesions are responsible for the filling defects seen on cystography in the early stages (Figure 11.39). They subsequently shrink to form white fibrous plaques as the ova become calcified. The bladder mucosa may eventually present a ground-glass appearance as a result of the mucosal atrophy and submucosal fibrosis. A fibrocalcific type of polyp is also encountered.



Adult worm in man
Miracidium escapes only in water
Miracidium enters snail of the fenus bulinus
Eggs in urine, rarely in faeces
Sporocyst multiplies on a large scale and daughter sporocysts eventually produce infective cercariae in snail
Miracidium becomes a sporocyst in snail
Cercariae penetrate unbroken skin of man and each becomes an adult worm in the portal vein of man
Cercariae escape from snail in water

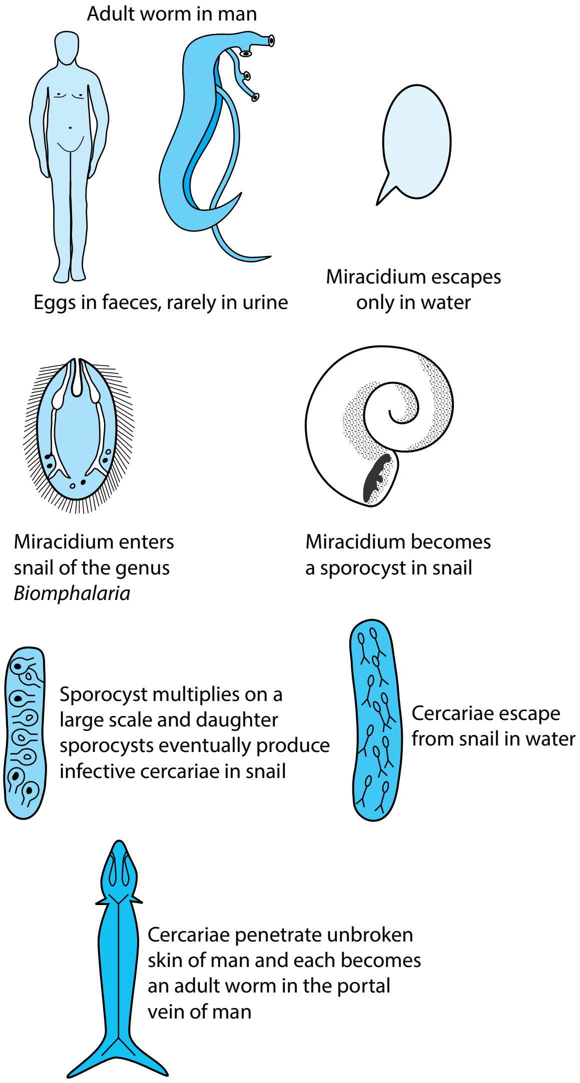
Figure 11.36 Life cycle of *Schistosoma haematobium.*

It forms a small, usually solitary lesion consisting of dense fibrous tissue surrounding dilated capillaries and calcified ova and without a covering epithelium. Villous polyps may also form but are less common. They have club-shaped fronds covered by hyperplastic epithelium.

The most common lesion encountered in vesical schistosomiasis is the 'sandy patch'. This late lesion is seen in the trigone, where the mucosa appears roughened, raised and greyish-brown in colour (Figure 11.40). The overlying epithelium may be irregularly thickened or atrophic with areas of metaplasia. In the submucosa and muscularis, pseudotubercles and foreign body granulomas surround ova in various stages of disintegration or calcification, but the predominant feature is dense fibrosis.

The bladder epithelium may undergo atrophy or become hyperplastic. Foci of leucoplakia may be present. Epithelial down growths into the submucosa (Brunn's nests) are a common feature and they may become vesicular (cystitis glandularis). Squamous metaplasia may supervene. Intractable ulceration leads to bacterial infection that may spread to involve the entire urinary tract with abscess formation and septicaemia. The urethra is often involved with stricture formation.

Varying degrees of ureteric involvement, usually the lower two-thirds, are encountered in 70% of cases and are more common in males. Linear calcification in the lower end of the ureter is pathognomonic. In addition, there may be secondary changes in the ureters induced by the bladder lesions, e.g. vesicoureteric reflux and hydronephrosis. Obstructive renal failure may result from ureteric involvement. Renal lesions directly due to the parasite are rare.

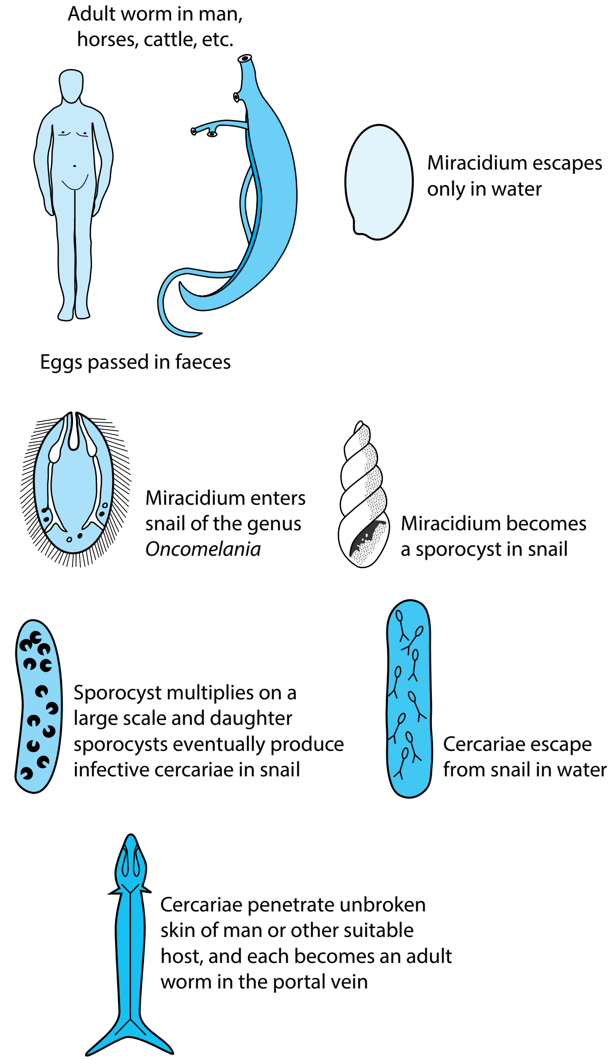


Adult worm in man
Eggs in faeces, rarely in urine
Miracidium escapes only in water
Miracidium enters snail of the genus *Biomphalaria*
Miracidium becomes a sporocyst in snail
Sporocyst multiplies on a large scale and daughter sporocysts eventually produce infective cercariae in snail
Cercariae escape from snail in water
Cercariae penetrate unbroken skin of man and each becomes an adult worm in the portal vein of man

Figure 11.37 Life cycle of *Schistosoma mansoni.*

Schistosoma mansoni and Schistosoma japonicum

Ova are discharged in the faeces but some are retained in the tissues and excite an eosinophilic reaction with the formation of multiple abscesses. In the large intestine, the mucosa is reddened and granular, with pinpoint yellowish elevations surrounded by a hyperaemic zone. Shallow ulcers may form. The inflammatory reaction in the submucosa leads to the formation of sessile or pedunculated polyps. These are found in 17–20% of Egyptian patients. The muscular and serosal layers are also involved with pseudotubercles and these may be associated with a focal peritonitis and intestinal adhesions. Inflammatory masses may be produced in the intestinal wall (bilharzioma). With progressive fibrosis, the intestinal wall becomes rigid and the lumen stenosed. The mesentery is thickened and thrombosis of its veins may occur. Granulomatous lesions may form in the mesenteric and retroperitoneal nodes. These form masses that may simulate a neoplasm (pseudotumour); caecocolic intussusception, intestinal obstruction and rectal prolapse may supervene. With secondary infection, ischiorectal and anorectal abscesses and fistulas may form. Pyloric obstruction has been described in *S. japonicum* infections, and lesions may be found in the stomach, peritoneum



Adult worm in man, horses, cattle, etc.
Miracidium escapes only in water

and pancreas. Infection of the appendix is common and rarely the small intestine may be more affected than the colon.

As the ova are released into the portal system, the liver is invariably involved. Hepatic involvement is more severe in *S. japonicum* owing to the larger number of ova produced by this schistosome. The liver may be enlarged or contracted and its surface shows a fine to coarse nodularity. Its consistency is firm and the cut surface exhibits white 'clay-pipe stem' fibrosis. This fibrosis is produced by ova in and around the portal venous radicals (Figure 11.41). The ova are usually trapped in the portal venous radicals and only occasionally reach the hepatic sinusoids. The affected portal venules become obstructed from thrombophlebitis. Thin-walled vascular channels form in the fibrosed portal tracts (angiomatoids) and result either from recanalization of thrombosed veins or as adaptive communications between the portal and arterial circulations. An increase in the number and size of the intrahepatic branches of the hepatic artery accounts for the maintenance of a normal liver blood flow in the majority of patients. The parenchymal cells of the liver are usually unaffected and the overall liver function remains good despite established portal hypertension.

The pulmonary changes are usually encountered in the late stages of *S. japonicum* and *S. mansoni* infections. They include widespread fibrosis with the development of cor pulmonale and chronic respiratory failure. Cerebral involvement is more common in *S. japonicum* and spinal disease in *S. mansoni*. Small tubercles are found in the meninges and in the white and grey matter of the brain and spinal cord.

Clinical features

During the stage of invasion and maturation of the worm, which lasts for 12 weeks, the patient may develop a generalized illness with fever, malaise, exhaustion and sometimes diarrhoea and abdominal discomfort. Urticaria may supervene and eosinophilia is invariably present. This initial illness is known as Katayama syndrome and is thought to result from a temporary state of antigen excess that exists until the host's antibody production is mobilized. It may occasionally be very severe and fatal. This stage occurs in all three infections.

Schistosoma haematobium

The stage of established infection occurs 10–12 weeks after cercarial penetration and is manifested by frank haematuria with egg extrusion. The haematuria is intermittent and often transitory. Episodes of haematuria continue to be experienced by untreated patients, although the attacks become less severe

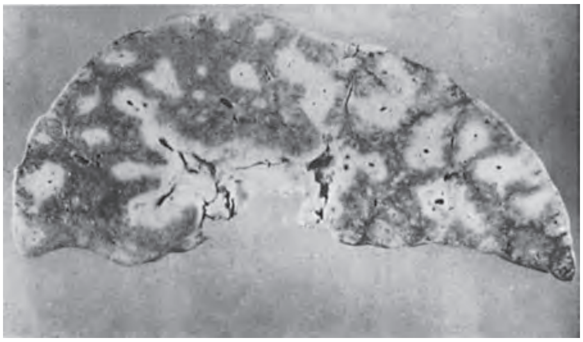

Figure 11.41 Gross appearance of the cut liver surface in *Schistosoma japonicum* infection.

with time. Microscopic examination of urine reveals red blood cells between attacks.

Bladder

Initially, the patient complains of dysuria, frequency and urgency of micturition. Bladder ulceration is accompanied by suprapubic and perineal pain. Two clinicopathological entities have been described: (1) sloughing of polypoid patches in early active disease and (2) chronic ulceration at sites of heavy egg deposition. Increasing frequency accompanies vesical fibrosis and contraction of the bladder. Occasionally, the bladder is large and atonic. This may result from reduced blood supply or bladder neck obstruction.

Kidneys and ureters

Ureteric involvement is common and is usually bilateral. Loin pain results from hydroureter and hydronephrosis. Proximal bacterial infection and stone formation are frequent complications. Pyelonephritis is thus frequent. Two varieties of nephrotic syndrome have been described in Egypt and Brazil. In Egypt, the nephrotic syndrome is related to *Salmonella* septicaemia and the glomerular lesions are proliferative and reversible. *Schistosoma haematobium* infection in Egypt predisposes the patient to the development of a carrier state for *Salmonella typhi* and *Salmonella paratyphi*. In Brazil, the lesions are predominantly membranoproliferative and irreversible with no association with *Salmonella* infection. Bacteriuria is often present in hospital patients and the urine contains eosinophils.

Calculi

These are common in Egypt, where they occur in 25% of infected patients, but are rare in other parts of Africa. They occur in the bladder, ureters, kidneys and urethra and consist of a central core of oxalate surrounded by an outer coat of urate incorporating ova. These stones may disappear following successful medical therapy and this is most likely to happen in young patients in whom fibrosis and irreversible stenosis are absent.

Association with vesical cancer

This is now established. Schistosomal bladder cancer is frequently of the squamous cell type (40–75%) and arises commonly from the trigone and superior apical regions. It is diffuse (multicentric) in one-third of cases. Various theories have been proposed to explain the association but the most favoured is the β-glucuronidase hypothesis. The enzyme β-glucuronidase is excreted in the urine of patients with active *S. haematobium* infection (from the adult worm). The increased urinary β-glucuronidase may hydrolyse inactive carcinogenic glucuronides, releasing active carcinogens. Thus, in Egypt raised levels of urinary metabolites of tryptophan, serotonin and the carcinogen 3-hydroxyanthranilic acid have been demonstrated in the urine of infected patients, and very high levels in patients with established bladder cancer.

Hepatic involvement

The clinical picture is dominated by bleeding oesophageal varices. The spleen is invariably massively enlarged in these patients, who have good liver function despite the portal hypertension (Child A or Child B).

Schistosoma mansoni *and* Schistosoma japonicum

The onset of egg laying in a first infection is accompanied by bloody diarrhoea. The lesions in the colon are variable. There may be segmental roughening of the mucosa with congestion, small ulcers and, in the late stages, sandy patches. Polyps may develop, especially in *S. mansoni* infections. Polyp formation is due to high localized egg burden damaging the muscularis mucosa. These polyps are therefore inflammatory in nature and are thus reversible with medical treatment.

In some cases, severe dysentery with frank ulceration and massive haemorrhage occurs and is often fatal. Perforation and stricture of the colon are uncommon complications. Rectal prolapse is usually associated with polyps. Pseudotumour results from an excessive connective tissue reaction to schistosomal granulomas. It may be located within or outside the intestinal lumen and may be palpable. Pseudotumour often causes stenosis.

Hepatosplenic schistosomiasis occurs in patients with a heavy worm load about 5–15 years after infection. Ova are deposited in the terminal radicles of the portal vein with granuloma formation and fibrosis of the portal tracts leading to portal hypertension, massive splenomegaly and ascites. These patients often have associated HBV infection. *Schistosoma mansoni* infections may be associated with chronic *Salmonella* infection and the nephrotic syndrome.

Diagnosis

Diagnosis is established by the demonstration of living schistosome eggs in the urine (*S. haematobium*) or stools (*S. mansoni, S. japonicum*) or biopsy material. Dead eggs only signify past infection.

Medical treatment

The only broad-spectrum antischistosomal agent that is effective against all *Schistosoma* species is praziquantel. Oxamniquine is only effective against *S. mansoni*, while metrifonate is only effective against *S. haematobium*.

Praziquantel is the drug of choice and is given in the following dosage:

- *S. haematobium*: 30 mg/kg (single dose)
- *S. mansoni* with acute intestinal infection: 20 mg/kg daily for 3 days
- *S. mansoni* with colonic polyposis: 20 mg/kg twice daily for 3 days

- *S. mansoni* with hepatosplenic disease: 30 mg/kg daily for 6 days
- *S. japonicum*: 20 mg/kg three times for 1 day.

Surgical aspects

The need for surgical intervention in schistosomiasis may arise from the development of complications of the disease.

Portal hypertension

Schistosomiasis causes a parenchymal block, usually without significant hepatocellular dysfunction or reduction of the hepatic blood flow. Minor degrees of portal hypertension and hypersplenism may be reversed with anthelmintic therapy. Treatment for oesophageal varices is only required if bleeding has occurred. Many of these patients may be managed with sclerotherapy or banding of the varices. Surgical intervention is indicated if bleeding cannot be controlled in this way, or recurs after repeated sclerotherapy. Portacaval shunts are contraindicated in these patients because of the high risk of severe encephalopathy. Selective decompression by a Warren shunt gives good results. The favoured procedures are, however, either splenectomy with porta-azygos disconnection or the more extensive devascularization operation of Sigiura.

Bilharzial granuloma of the gastrointestinal tract

This complication predominantly affects the large bowel, with small intestinal and appendiceal lesions being uncommon. Small bowel granuloma usually presents with acute intestinal obstruction, or more rarely with mesenteric infarction.

The clinical features of large bowel bilharzial granuloma are varied. The patient may have chronic symptoms, e.g. vague abdominal pain, palpable mass in the lower abdomen, passage of blood and mucus, anaemia and rectal prolapse. In these cases, the diagnosis is usually made by sigmoidoscopy and biopsy. Less commonly, the patients present with large bowel obstruction and at operation a lesion in the sigmoid or descending colon or rectum is found (pseudotumour) that is macroscopically indistinguishable from carcinoma. Resection without primary anastomosis is performed in these patients. In the elective situation after adequate bowel preparation resection with primary anastomosis is safe.

Obstructive uropathy

Cystoscopy should be avoided when possible because of the risk of introducing secondary infection. It is reserved for diagnostic problem cases, e.g. exclusion of neoplasm. The surgical treatment of obstructed ureters remains controversial. An accurate assessment of the extent of the disease and the state of the bladder by intravenous pyelography and ultrasound is essential. Adequate excision of the diseased segment with direct reimplantation or by means of ileal conduits with vesicoileal anastomosis gives the best results. More severe ureteric and bladder disease requires major surgical treatment (ileocaeco-urethroplasty, etc.) in specialized urological units.

Malaria

Malaria is still the most widely spread communicable disease in the topics. About 1 billion of the world's population are still at risk. The two most common parasites are *Plasmodium vivax* and *Plasmodium falciparum*.

Parasitology

The complete life cycle of the human malaria parasite embraces a period of development within the mosquito and a period of infection in humans (Figure 11.42). After ingestion of infected human blood, a period of development (10–14 days) occurs in the mosquito, resulting in the production of sporozoites. A mosquito bite infects the human host with these forms, which remain in the circulating blood for 30 minutes, then enter tissue cells, notably the liver. During the next 7–9 days, the sporozoites develop in the hepatocytes. This stage of development is known as the pre-erythrocytic cycle. The cryptozoic schizonts that form rupture and release numerous merozoites, most of which enter the circulation to invade the erythrocytes, thus starting the erythrocytic cycle. No symptoms of malaria are experienced during the pre-erythrocytic cycle. The plasmodium first appears in red cells as a small speck of chromatin surrounded by scanty cytoplasm and soon becomes a ring-shaped trophozoite. As the parasite develops, pigment particles appear in the cytoplasm and the chromatin becomes more prominent. Chromatin division then proceeds and, when complete, the mature schizont containing daughter merozoites has formed. The parasitized red blood cells now rupture, releasing merozoites, the majority of which re-enter erythrocytes to reinitiate erythrocytic schizogony. In *P. falciparum* infection, the erythrocytic cycle takes 36–48 hours (subtertian); in *P. vivax* and *Plasmodium ovale* infection 48 hours (tertian); and in *Plasmodium malariae* 74 hours (quartan). The extent of the red cell infection differs from parasite to parasite, being highest (15%) with *P. falciparum*.

In response to an unknown stimulus, a number of the merozoites released when the red cells rupture develop into male and female gametocytes that are inert in the human but provide the reservoir of infection, enabling mosquitoes to perpetuate the malaria cycle. A certain proportion of the merozoites liberated in the pre-erythrocyte phase do not enter the bloodstream. Instead, they re-enter the liver cells to produce metacryptozoic schizonts that are responsible for the persistence of the exoerythrocytic cycle (EE) that occurs in *P. vivax, P. ovale* and *P. malariae* but not in *P. falciparum*. The EE cycle is responsible for the reappearance of malaria some years after clinical cure. The exception to this is *P. falciparum,* in which relapses are not encountered after adequate medical treatment.

Clinical features

Plasmodium falciparum

This is the only type of malaria that may be directly fatal. The clinical picture is extremely variable. A common misconception concerns the periodicity of the fever which, especially in first attacks, is irregular and occurs daily. Headaches, malaise, nausea, vomiting and generalized joint pains are frequent, presenting symptoms of an uncomplicated attack. On physical examination, there is hepatosplenomegaly and a variable degree of anaemia. This rather non-dramatic clinical picture can deteriorate suddenly into one with severe manifestations and a fatal outcome. Abdominal presentation resembling acute appendicitis

can occur. The severe manifestations include cerebral malaria, algid malaria, severe malarial anaemia, hyperpyrexia, jaundice, pulmonary oedema and malarial haemoglobinuria. Patients are usually dehydrated and may have herpes labialis.

Plasmodium malariae

This produces the nephrotic syndrome in children with longstanding infection.

Plasmodium vivax

Fever is the most constant sign. Initially remittent, the pattern changes to intermittent, regularly recurring fever every second day. In children convulsions occur when the fever is high. The classic features of the attack, i.e. cold stage, hot stage and sweating, are unusual in infants and children. General symptoms are similar to those of *P. falciparum* but milder. The spleen enlarges early in the disease, some degree of anaemia may be present and there is often mild leucopenia. The disease is rarely fatal unless the spleen ruptures. A conclusive diagnosis of malaria is made by detection of the parasite in the blood.

Treatment

Treatment consists of antiparasite chemotherapy and supportive management of the various manifestations. Only *P. falciparum* has become resistant to chloroquine. The drugs used in chloroquine-resistant areas include quinine, Fansidar, Metakelfin, mefloquine (Lariam) and halofantrine (Halfan). In areas with resistance to both chloroquine and Fansidar, treatment is with quinine + tetracycline or mefloquine or halofantrine.

Primary chemoprophylaxis is important for visitors to endemic regions and is outlined in Table 11.5. Estimates indicate that every year up to 30 000 travellers contract malaria. Fever developing in a traveller within 3 months of leaving a malaria-endemic area should be investigated urgently. All visitors to endemic malarious areas require prophylaxis. Pregnant women, infants and young children and people who have undergone splenectomy should avoid travel to malarious areas as they are at higher risk. The choice of chemoprophylaxis varies depending on the species and drug resistance prevalent in a country. No chemoprophylaxis regimen provides 100% protection. Thus, an essential component of prophylaxis is the prevention of mosquito bites. Malaria develops up to a year after visiting an endemic area, although it usually develops within 3 months of the visit. The prophylactic treatment should be started 1 week before departure and continued for 4 weeks after returning from the endemic area.

Multidrug-resistant malaria

In areas of Thailand near the borders with Cambodia and Myanmar and in Western Cambodia, *P. falciparum* infection is resistant to chloroquine or pyrimethamine–sulphadoxine, and sensitivity to quinine is reduced. In these areas, chemoprophylaxis with doxycycline is recommended along with rigorous personal protection measures. Doxycycline is contraindicated in pregnant women and children below the age of 8 years.

Filariasis

The more common of the several species of filarial parasites transmitted by various arthropod vectors include *Wuchereria bancrofti, Onchocerca volvulus, Brugia malayi* and *Loa loa.* Some of these essentially tropical and subtropical diseases produce filarial elephantiasis of the lower limbs and genitalia as a result of the occlusion by sclerosis of the lymphatics by adult worms resulting in gross lymphoedema. Many manifestations remain subclinical.

The life history of the various parasites that infect humans follows a common pattern, although details vary from species to species. The adult male and female worms of the infected person reproduce in the skin or lymphatics. The long, thin larvae are known as microfilariae. These enter the peripheral bloodstream at specific hours depending on the filarial species and the feeding habits of the associated arthropod vector. In the insect (mosquitoes, black flies, midges, etc.), the microfilariae mature and migrate to the biting structures of the arthropod and thus enter the bloodstream or skin of the next victim of the insect bite. Further maturation occurs in the human, where the adult

Table 11.5 Primary chemoprophylaxis of malaria

Chloroquine-sensitive areas	Chloroquine 300 mg once weekly, or proguanil 200 mg daily
Chloroquine-resistant areas	Chloroquine 300 mg once weekly and proguanil 200 mg daily, or mefloquine 250 mg once weekly

worms congregate into masses causing granulomatous painful swellings. *Wuchereria bancrofti* is the main cause of elephantiasis and hydrocele.

Pathology

Filarial infection generates a pronounced significant inflammatory immune Th2 response that leads eventually to symptomatic lymphatic obstruction. Symptoms usually do not manifest until adolescence or adulthood, when worm burden is usually the highest. The various conditions caused by these parasites are best considered as (1) lymphatic filariasis, (2) onchocerciasis and (3) loiasis.

Lymphatic filariasis

This arises from infection with *Brugia timori*, *B. malayi* or *W. bancrofti*. The clinical course is broadly divided into (1) asymptomatic microfilaraemia, (2) acute phases of adenolymphangitis and (3) chronic irreversible lymphoedema. Acute adenolymphangitis is characterized by sudden onset of febrile painful lymphadenopathy, which usually subsides within 1 week. However, the acute phase may consist of filarial fever only without the associated lymphadenitis.

Hydrocele is the most common manifestation of chronic *W. bancrofti* infection in males in endemic areas, but is rare with *B. malayi* and *B. timori* infection. Chyluria also may be present in chronically infected persons. However, the main feature of the disease is severe lymphoedema, most frequently in the lower extremities, but it may involve the arms, breasts, scrotum, penis and vulva.

The WHO has developed a grading system for the severity of the lymphoedema:

- Grade 1: pitting oedema, reversible with limb elevation.
- Grade 2: non-pitting oedema, irreversible with limb elevation.
- Grade 3: severe swelling with sclerosis and skin changes.

Onchocerciasis

This is also known as leopard skin or river blindness. Initially, the symptoms result from the presence of microfilariae in the skin and include pruritus, subcutaneous lumps and lymphadenitis. Patients with onchocerciasis may develop impaired vision and even blindness. The hallmark clinical triad consists of dermatitis, skin nodules (onchocercomas) and ocular lesions. Skin lesions include oedema, pruritus, erythema, papules, scab-like eruptions, altered pigmentation and lichenification. Skin nodules are common over bony prominences. Eye lesions are caused by an abnormal host immune response to microfilariae and include punctate keratitis, pannus formation, corneal fibrosis, iridocyclitis, glaucoma, choroiditis and optic atrophy.

Loiasis

This is caused by *L. loa* infection. The manifestations are usually confined to subcutaneous swellings on the extremities, localized pain, pruritus and urticaria. The diagnostic feature of loiasis is a large transient area of localized non-erythematous subcutaneous oedema most commonly around the joints. Other rare features include arthritis, breast calcification, meningoencephalopathy, endomyocardial fibrosis, peripheral neuropathy, pleural effusions and retinopathy.

Treatment

Symptomatic lymphatic filariasis is treated with diethylcarbamazine. Onchocerciasis is treated by diethylcarbamazine and suramin with inpatient care recommended to monitor for reactions and complications of therapy. Infestations with *Mansonella perstans*, which is resistant to standard antiparasitic treatment, is with doxycycline, which kills or sterilizes the filarial nematode. Annual mass treatment with albendazole and ivermectin is used to interrupt transmission of *W. bancrofti*.

Surgical treatment

The treatment of lymphoedema is unsatisfactory. Perhaps the most important practical consideration is the prevention of secondary bacterial infections, attention to hygiene and skin care with prompt antibiotic treatment of bacterial infections when they arise. Some have reported benefit with oral administration of the benzopyrene 5,6-benzo-[alpha]-pyrone in reducing both filarial and non-filarial lymphoedemas of the extremities. A large variety of surgical procedures, which include lymphangioplasty, lymphovenous anastomosis and excision (debulking) of fibrotic subcutaneous tissue, have been used but are of limited value. However, large hydroceles and scrotal elephantiasis can be managed effectively with surgical excision.

Elephantiasis of the lower limbs occurs in certain areas of East Africa and Ethiopia, where there is no filariasis. These cases of non-filarial elephantiasis of the lower limbs are the result of an obstructive lymphopathy of the peripheral lymphatics caused by aluminosilicate and silica absorbed from the soil through the skin of the feet.

CHAPTER 12

Surgical nutrition

SIR ALFRED CUSCHIERI

Introduction

This chapter describes the causes, recognition and clinical consequences of malnutrition. The principles of artificial nutrition support are discussed. The indications and clinical management of the techniques of enteral and parenteral nutrition are outlined, with particular reference to the surgical patient.

Pathology of protein energy malnutrition

The development of disease may be accompanied by a loss of appetite, intestinal malfunction associated with the impaired absorption of nutrients and in some cases metabolic changes leading to tissue wasting. Thus, in many patients there is an inadequate supply of nutrients which, in combination with the influence of inflammatory mediators, leads to weight loss and defective organ function. This process is described by the term *disease-associated malnutrition* (DRM).

The normal feeding–fasting cycle is characterized by the postprandial deposition of glycogen and fat and protein synthesis, modulated by the secretion of insulin. Subsequently, a reduction in the secretion of insulin and an increase in the secretion of glucagon facilitates the mobilization of glucose from glycogen, and proteolysis and lipolysis to provide energy substrates.

During prolonged starvation the supply of glycogen is rapidly exhausted and glucose, an essential fuel for the brain, is formed in the liver from amino acids derived from muscle protein (gluconeogenesis). As the insulin concentrations fall, lipolysis liberates free fatty acids; these compete with glucose for cellular uptake and are used for the generation of energy by organs including muscle and the liver, thereby minimizing the requirement for glucose. Within the liver, fatty acids are converted to ketone bodies; unlike fatty acids, ketones gain access to the central nervous system and supply some energy to the brain, further reducing the requirement for gluconeogenesis. Thus, the wasting of muscle tissue is minimized. The amount of muscle tissue metabolized for the production of glucose is reduced from 75 g on day 3 to 20 g on day 40 of starvation. Nevertheless, tissue wasting, which progresses during the course of starvation, involves the respiratory muscles, the heart and the intestine, in addition to the adipose stores.

In the previously fit subject death from complete starvation occurs after the loss of 30–40% of the initial body weight, usually by 60–70 days, when organ impairment may be irreversible. In the hospital the rate of nutritional depletion is influenced by several factors. Many patients experience partial starvation when nutritional decline is slower, similar to the Minnesota experiment in which previously fit males were given a 1600 kcal diet for 12 weeks. Patients may receive a diet that is inadequate not only in the energy content but also in the range of nutrients. The historic view that the provision of carbohydrate without protein leads to kwashiorkor, through increased insulin concentrations and the suppressed breakdown of muscle protein, thereby depriving the liver of amino acids for albumin synthesis, is no longer tenable. The deficiency of antioxidant micronutrients, in addition to the generation of cytokines, is the more likely cause of this nutritional disorder. Cytokines, small peptides, notably tumour necrosis factor and insulin-like growth factor 1 (IGF-1), which originate from lymphoid and haemopoietic cells in response to tissue damage, promote lipolysis and proteolysis.

Infections, burns and trauma, including surgical operations, lead to accelerated nutritional decline. Although this has been explained by a presumed increase in energy requirements in the stressed patient, and the humoral response to stress, most of the observed changes are attributable to the release of cytokines. Energy requirements in critical illness have previously been

BOX 12.1 Metabolic effects of cytokines

- Anorexia
- Pyrexia
- Release of amino acids from muscle tissue
- Increased glucose transport
- Stimulation of hepatic lipid synthesis
- Promotion of acute phase protein synthesis
- Reduced albumin synthesis
- Increased vascular permeability
- Immune cell availability

overestimated; any increased energy needs are often matched by a reduction in mobility. Cytokines such as interleukin, tumour necrosis factor and interferons, which are principally responsible for the metabolic changes, share multiple activities, some of which are listed in Box 12.1.

Furthermore, in severely ill patients, especially those in intensive care, the effect of the initial pathology may be compounded by the secondary effect of the breakdown in the gut mucosal barrier, with increased permeability to microbial toxins, and enhanced translocation of bacteria, continuing cytokine generation and leading to greater tissue and organ damage. Data to support the concept that such a breach of intestinal barrier function promotes the systemic inflammatory response in this manner have largely been derived from the animal model.

Disease-associated malnutrition syndrome

The prevalence of DRM in hospital admissions in the UK is high with studies indicating that 40% are malnourished to variable extents and, according to the McWhirter and Pennington study, the nutritional state of many of these patients deteriorates further during the course of hospitalization. In a study of 25 general practitioner practices, 10% of patients in primary care were malnourished. Other surveys have shown that many malnourished patients admitted to hospital go undiagnosed because of inadequate screening (European Nutrition for Health Alliance 2008). DRM results in a decrease in food intake that, if sustained, leads to metabolic changes, which alter body composition and depress function, which become manifest with apparent weight loss, reduced subcutaneous fat and muscle wasting. Chronic malnutrition has adverse effects on virtually all body systems:

- *respiration*: atrophy/weakness of respiratory muscle, decreased lung volumes
- *circulation*: degenerative changes in cardiac muscle, reduced cardiac output
- *haemopoiesis*: anaemia, leucopenia, thrombocytopenia
- *gut*: atrophy of the gut mucosa, decreased gastric acid production
- *immune system*: depressed cellular and humoral immunity
- *skeleton*: decreased bone strength/mass
- *skin*: atrophy, local oedema, increased friability, risk of pressure ulcers
- *kidney*: impaired filtration and excretion.

In surgical practice, DRM increases morbidity and mortality following surgery, especially infective complications (skin and surgical site) and delayed wound healing/dehiscence, and retards patient recovery with increases in hospital stay and costs. Hence patients with significant DRM require preoperative nutritional therapy.

The economic importance of detection of DRM and its treatment by supplements is confirmed by the report of the British Association of Parenteral and Enteral Nutrition *Advancing Clinical Nutrition*. This includes a systemic review/meta-analysis of the published surgical studies [seven randomized controlled trials (RCTs) and one cross-over trial) in patients undergoing abdominal and orthopaedic surgery. This analysis showed a net cost saving in favour of supplementation, when calculations were based on bed-day costs (mean value of £166 per patient, and excess bed-day costs £363 per patient). There was also a significant net cost saving in favour of supplementation when calculations were based on average complication costs (£321 per patient). Six RCTs involving abdominal surgery ($n = 418$ patients) that were amenable to a meta-analysis showed a significant cost saving in favour of supplementation.

An International Guideline Committee under the auspices of the American Society for Parenteral and Enteral Nutrition and the European Society for Clinical Nutrition and Metabolism has produced an aetiology-based classification of DRM that incorporates the current understanding of inflammatory response. The Committee proposed the following nomenclature for nutrition diagnosis in adults:

- *Starvation-related malnutrition*: when there is chronic starvation without inflammation; examples include anorexia nervosa.
- *Chronic disease-related malnutrition*: when inflammation is chronic and of mild to moderate degree; examples include organ failure, pancreatic cancer, rheumatoid arthritis or sarcopenic obesity.
- *Acute disease- or injury-related malnutrition*: when inflammation is acute and of severe degree; examples include major infection, burns, trauma or closed head injury.

In surgical practice, the diseases that are commonly associated with protein energy malnutrition include:

- any disorder that impairs the ingestion, digestion or absorption of food
- diseases associated with a prolonged inflammatory response
- diseases which cause an increased energy expenditure.

Some common examples are listed in Table 12.1. There are usually several factors leading to weight loss in each patient. For example, the patient with chronic obstructive pulmonary disease may have difficulty eating because of dyspnoea and the effect of medication such as theophylline, chronic infection due to bronchiectasis, and increase in respiratory workload associated with airways obstruction.

Consequences of malnutrition

The syndrome of malnutrition is associated with a poor outcome in hospital patients. Prolonged hospital stay and increased morbidity and mortality have been documented in affected surgical patients who are at increased risk of infection and poor wound healing.

Table 12.1 Some causes of disease-associated malnutrition

Anorexia	Depression Anorexia nervosa, bulimia Chronic disease
Inability to eat	Neurological disorders Oropharyngeal disease Oesophageal disease
Intestinal disease	Inflammatory bowel disease Gluten enteropathy Radiation enteropathy Hollow visceral myopathy
Catabolic response to trauma	
Specific infections	AIDS Tuberculosis

The adverse consequences of malnutrition stem from (1) protein energy deficit, (2) vitamin deficiencies and (3) deficiencies of trace elements.

Protein energy malnutrition

Malnutrition impairs organ function (Table 12.2). Mental function can be affected, and patients become withdrawn and apathetic. Malnourished patients are often reluctant to co-operate with their treatment. Muscles become weaker and fatigue more rapidly. These effects can be demonstrated in normal people during dietary restriction of only 2 weeks' duration. Not only may such changes affect the mobilization of patients after operative procedures and illness, they may also contribute to respiratory and cardiac failure.

There is a failure of antibody production and phagocyte function. Other aspects of the immune response may be impaired; thus, malnourished patients are at increased risk of infection. Thermoregulation is also defective and this may lead to hypothermia, especially in the elderly.

Table 12.2 Some of the effects of protein energy malnutrition

Impaired mental function	Apathy Fatigue Inability to co-operate with treatment
Impaired muscle function	Respiratory failure Delayed mobilization
Impaired immune function	Increased incidence of infection

Children are particularly vulnerable to the effects of starvation, which results in growth failure. Protein energy malnutrition in children is associated with thymic atrophy and similar changes affect other lymphoid tissues.

Vitamin deficiencies

Some patients demonstrate features of specific nutrient deficiencies, in particular vitamin and trace element deficiencies. Examples of vitamin deficiencies include thiamin and Wernicke's encephalopathy, folate and megaloblastic anaemia, and ascorbic acid and scurvy. Thiamin has an important role in the metabolism of carbohydrates and alcohol. Patients who misuse alcohol and eat a poor diet are at particular risk of deficiency, which might be exposed by the use of a glucose infusion in the fasted hospital patient. Vitamin replacement should precede carbohydrate loading in such patients. Examples of the role of vitamins and the effects of vitamin deficiencies are summarized in Table 12.3.

Deficiencies of trace elements

Deficiencies of trace elements may also lead to specific features, e.g. zinc depletion is associated with skin rashes, impaired sense of taste and immune dysfunction; copper deficiency can cause a microcytic anaemia; and selenium depletion leads to a myopathy, which also affects cardiac muscle (Table 12.4). Cardiomyopathy due to selenium depletion was identified as the cause of premature deaths in the Keshan province in China, where the soil content of selenium is very low. Other deficiencies became apparent when patients first receive prolonged parenteral nutrition without adequate micronutrient supplementation.

Assessment of nutritional status

There is evidence that malnutrition is common in hospital patients and that nutritional status deteriorates during hospital stay. The nutritional status of the patient is not assessed in

Table 12.3 Some examples of the roles of vitamins and the clinical effect of vitamin deficiencies

Vitamin	Biochemical function	Clinical features of deficienc
A	Tissue growth and differentiation	Xerophthalmia, impaired dark adaptation
D	Calcium absorption	Rickets in children, osteomalacia in adults
E	Membrane antioxidant	Haemolytic anaemia, neuropathy, myopathy
K	Synthesis of coagulation factors and osteocalcin	Coagulation defects, possible bone disease
B_1 thiamin	Decarboxylation in carbohydrate, fat and alcohol metabolism	Beri-beri: cardiac and neurological effects, Wernicke–Korsakov syndrome
B_2 riboflavin	Oxidative metabolism	Lesions of the mouth and skin
B_6 pyridoxine	Transamination of amino acids	Anaemia, lesions of the lips and skin
B_{12} cyanocobalamin	Recycling of folate coenzymes	Megaloblastic anaemia, demyelination
C	Antioxidant, iron absorption, collagen synthesis	Impaired wound healing, scurvy
Biotin	Carboxylase reactions in lipogenesis and gluconeogenesis	Scaly dermatitis, hair loss
Folate	Purine and pyrimidine metabolism	Megaloblastic anaemia, growth retardation
Niacin	NAD/NADH in oxidative metabolism	Pellagra: rash, weakness and diarrhoea

Table 12.4 Some examples of the functions of trace elements and the clinical effects of deficiencies

Trace element	Biochemical function	Effect of deficienc
Chromium	Insulin activity, lipoprotein metabolism	Glucose intolerance, weight loss, peripheral neuropathy
Copper	Cytochrome oxidase, superoxide dismutase, encephalins	Hypochromic anaemia, neutropenia, cardiac dysrhythmia
Fluoride	Bone mineralization	Dental caries
Iodine	Thyroxin	Cretinism in children, hypothyroidism in adults
Iron	Haemoglobin–myoglobin–cytochrome system	Anaemia
Manganese	Mitochondrial superoxide dismutase	Lipid abnormalities, anaemia
Selenium	Glutathione peroxidase	Myopathy, pseudoalbinism
Zinc	Enzymes of intermediary metabolism and protein synthesis	Diarrhoea, skin rashes, immune deficiency, growth retardation

routine clinical practice and malnutrition is not recognized in the majority of affected patients. Thus, many patients do not receive appropriate nutritional management. Recognition of nutritional depletion is made difficult by the lack of suitable clinical indices of malnutrition and consequent functional impairment.

Malnutrition is identified after clinical assessment supported by anthropometric measurements and some laboratory investigations. An adequate history includes enquiry about the appetite and changes in the diet and the normal body weight. Examination may reveal evidence of muscle wasting as well as features of micronutrient deficiency, such as bruising, rash and glossitis.

Measurement of body composition

The traditional method of measuring body composition from body density determined by underwater weighing and the use of sophisticated techniques such as dual-energy X-ray absorptiometry are inappropriate or unavailable for routine clinical practice.

Anthropometric measurements

The measurements of weight and height are important. Fluctuation in body weight in the long term may reflect nutritional changes, and in the critically ill patient acute weight change is caused by changes in fluid balance. The measurement of height will determine growth velocity in the child, a sensitive marker of nutrition and disease. In the adult, knowledge of height and weight allows the calculation of the body mass index (BMI) from the [weight (kg)]/[height (m)^2]. The normal range for BMI is between 19 and 25. BMI values below 19 represent malnutrition; patients with a BMI in excess of 25 are overweight; and those with values of 30 are described as obese.

Fasting in the patient who is not metabolically stressed leads to preferential mobilization of fat stores that are measured by skin-fold calipers. In the stressed patient proteolysis leads to muscle wasting measured by calculating the mid-arm muscle circumference (MAMC). The MAMC (cm) is derived from the mid-arm circumference – triceps skin-fold thickness × 0.314.

These measurements are useful for the identification of malnourished patients and monitoring patients who are at nutritional risk as well as those who are receiving long-term nutritional support. Variation in technique between observers and changes in the patient's hydration status can also influence the measurements. Furthermore, in relation to the effect of nutritional depletion and possible need for nutritional intervention, it is the change in nutritional status over time, rather than one single measurement, that is important. For example, a preoperative patient may have suffered from an involuntary weight loss of more than 10%, with an attendant increased risk of operative morbidity, yet still have a BMI within the normal range.

Bioelectrical impedance analysis

Bioelectrical impedance analysis is a non-invasive method of assessment that depends on the difference in electrical conductivity of fat and fat-free mass. The impedance of the body to an electrical current is measured, and is assumed to be proportional to the square of the height of the subject divided by the volume. The resistance between the right wrist and right ankle is measured and used to calculate the conductivity. From the impedance, total body fat and body water are calculated. However, the technique assumes a normal hydration state. This may not be the case in many patients, although there have been attempts to produce prediction equations for different disease states, including general surgical patients. Further validation is needed before this technique can be accepted in routine clinical practice.

Measurement of organ function

Malnutrition leads to impaired muscle strength and increased fatigability. The laboratory methods employed for these measurements using graded electrical stimuli are not suitable for clinical practice. Studies have shown that impaired muscle function can be reversed with nutritional support before improvement in clinical nutritional indices is observed. This observation led to the reappraisal of handgrip dynamometry (Figure 12.1). Handgrip dynamometry, determined by the highest value of three readings recorded with a dynamometer gripped in the non-dominant hand, will give a value that reflects nutritional state when compared with values standardized for age and sex. However, other influences, notably the willingness of the patient to co-operate, reduce the specificity and thus the clinical usefulness of the technique. Tests of respiratory function have also been used for the determination of nutritional status. Unfortunately, the results are influenced by three variables: nutritional state, co-operation and pulmonary disease.

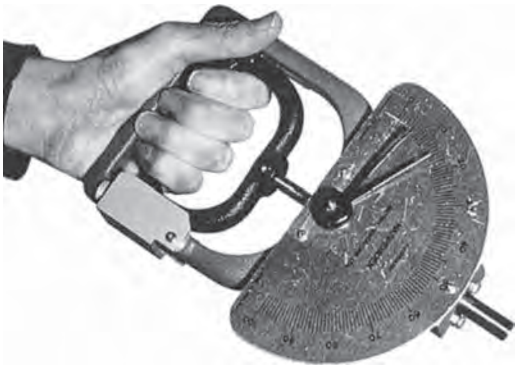

Figure 12.1 Handgrip dynamometer.

Malnutrition leads to anergy, with the loss of cutaneous responses to antigens traditionally determined by the Mantoux response. Many diseases have the same effect. The total lymphocyte count is depressed in malnutrition and has been used to monitor nutritional support. These measurements are little used in this context.

Laboratory investigations

Protein calorie malnutrition causes a decrease in the rate of albumin synthesis. Traditionally, the serum albumin concentration has been advocated as a nutritional marker. Whereas there is evidence to support the use of albumin as a prognostic indicator, in that patients with low serum albumin values have prolonged hospital stay and increased morbidity and mortality, albumin correlates poorly with nutritional status. In the Minnesota experiment the total circulating albumin was reduced by only 2% after 24 weeks of reduced protein and energy intake. This was associated with a 10% reduction in serum albumin concentrations, which may have reflected other influences.

Children with marasmus and adults with anorexia nervosa maintain serum albumin concentrations until the terminal stages of their illness. Conversely, in well-nourished patients who become septic the albumin concentrations fall rapidly, reflecting changes in vascular permeability and fluid retention, as well as a reduction in albumin synthesis caused by the influence of the cytokine responses to infection or tissue damage.

Albumin has a very long half-life of 21 days. Consequently, other proteins have been advocated for diagnosis and nutritional monitoring. They include transferrin, thyroxin-binding prealbumin and retinol-binding protein, with respective half-lives of 8 days, 2 days and 12 hours. These are also influenced by other factors, such as the iron and vitamin A status, and the acute phase response. The IGFs are a family of low-molecular-weight peptides produced by the liver. Studies have suggested that IGF-1, which has a half-life of a few hours, may be a useful marker of nutritional status. Reduced serum concentration may reflect a general decrease in protein synthesis with malnutrition and, unlike the other factors, it is thought not to be influenced by the acute phase response. Currently, this is an expensive assay that requires further validation to define any role in clinical practice.

Clearly, there is no single laboratory marker of nutritional status. However, the laboratory has an important role in the identification of single nutrient deficiencies. The serum values of iron, calcium, magnesium and potassium are commonly measured, along with vitamins such as folic acid, vitamin B_{12} and 25-hydroxyvitamin D, as a guide to replacement during nutritional support, in depleted patients, and in specific disorders of absorption. The measurement of other micronutrients, such as selenium, copper, chromium and manganese, is usually only available in supraregional laboratories. This information is required in severely depleted patients who are receiving prolonged nutritional support, including patients treated by home parenteral nutrition. There is often difficulty in interpretation, blood values do not necessarily correlate with body content and serum values may fall in the context of an acute illness.

Principles of artificial nutrition support

Artificial nutrition support (ANS) may be employed to prevent starvation or to treat malnutrition in patients who are unable to eat or to digest and absorb sufficient nutrients. The potential role of ANS in modifying the inflammatory and immune responses to disease through the provision of specific nutrient substrates – ‘immunonutrition’ – is currently under evaluation.

The need for ANS should be recognized early because impaired organ function can be demonstrated within 2 weeks of starvation, the restoration of nutritional status in the depleted patient is a prolonged process and nutritional repletion may not be achieved in the context of significant illness. ANS may be delivered by the enteral route by oral supplements or enteral tube feeding, or intravenously by parenteral nutrition. Enteral nutrition should be employed wherever possible; it is cheaper, safer and more physiological than parenteral feeding. The intestine has an important immune and barrier function. Luminal nutrition appears to be important for the stimulation of gastrointestinal motility, secretory immunoglobulin (Ig) A and the integrity of the mucosal barrier. Glutamine and short-chain fatty acids are important substrates for the enterocyte and colonocyte, respectively; they are not given in standard parenteral nutrition.

Nutritional requirements depend on the nutritional status of the patient, the nature of the underlying disease and the adequacy of organ function. Any nutrition derived from the oral diet must also be taken into consideration and during enteral feeding the effect of intestinal impairment on energy needs should be considered. In patients who are malnourished some allowance is needed for nutritional repletion, unless the patient is metabolically stressed as a result of sepsis or trauma. The aim in these patients is to maintain nutritional status or minimize tissue loss; repletion is achieved during the recovery phase of the illness. Initial hypocaloric feeding should be considered in patients who are severely wasted to minimize the risk of the refeeding syndrome (see below).

There is no satisfactory bedside method for the measurement of energy requirements. Approximate values can be estimated from the Schofield equation and adjusted for stress, activity and desired energy balance to reflect nutritional status. For the majority of patients 25–35 kcal and 0.2 g nitrogen/kg is sufficient; as a rule, provision should not exceed 40 kcal and 0.3 g nitrogen/kg in the adult. Some patients in the intensive care unit receive lipid energy through medication with propofol, which must be considered when calculating energy needs. The previous views about large energy needs were based on inaccurate methodology; furthermore, it would seem that any increased energy needs associated with illness are balanced by a reduction in energy expenditure through reduced mobility. Excess nutrient delivery leads to futile cycling with lipogenesis, increased production of carbon dioxide, and the consequences of hyperglycaemia and hyperlipidaemia. Cyclical feeding, in which there is an interval free of infusion, has physiological advantages. In comparison with continuous feeding it reduces sodium and water retention, and it may also lead to less fat accretion by avoiding the continuous stimulation of insulin.

Some patients with intestinal disease are able to maintain energy and nitrogen balance, but not electrolyte balance. Patients with Crohn disease frequently develop hypomagnesaemia, and patients with a high jejunostomy become salt and water depleted. This reflects the leaky junctions in the jejunal epithelium, which allow sodium to pass into the intestinal lumen down a concentration gradient. Such patients need additional fluids and electrolytes. Some can be managed satisfactorily with isotonic solutions of sodium and carbohydrate, in which the sodium concentration is approximately 100 mmol/L, provided they avoid drinking hypotonic solutions without sodium, which increase the stomal losses. However, parenteral administration may be required.

Most of the enteral feeds contain the average daily recommended requirement of micronutrients, vitamins and trace elements in a volume of 2 litres. Some commercial trace element and vitamin preparations are compounded with the other nutrients, amino acids, glucose, lipids and electrolytes, for parenteral nutrition. The need for additional supplements in depleted patients should be considered. For example, malnourished alcoholic patients will need additional thiamin, while very malnourished patients who receive nutritional support may require additional phosphate, potassium and magnesium. Electrolyte requirements are also influenced by the administration of drugs such as amphotericin, which can increase the renal excretion of potassium and magnesium, and the presence of impaired organ function, including liver cardiac and renal disease. Under these circumstances the parenteral prescription will need adjustment or special enteral products may be used (see below).

Enteral nutrition

Oral supplements

When used correctly and taken between meals, oral supplements can substantially increase nutrient intake without reducing the consumption of the oral diet. Supplements are useful in anorectic patients and patients with dysphagia pending treatment of oesophageal disease. They have also been shown to reduce morbidity in elderly patients with fracture of the neck of femur, and following abdominal surgery.

Most supplements are milk based, while some are based on soya protein and are fruit flavoured. Not all are nutritionally complete in relation to micronutrients. A complete supplement should be prescribed if it constitutes a substantial proportion of the nutritional intake. The dietician selects the product according to the taste preferences of the patient. Nevertheless, compliance remains a problem, especially in patients with malignant disease.

Enteral tube feeding

Enteral tube feeding is needed in:

- patients with profound anorexia
- patients who are unable to eat or swallow
- some patients with impaired intestinal function.

Anorexia may be a feature of many diseases. Such patients are unable or unwilling to ingest sufficient food or supplements. However, after the initiation of enteral feeding the appetite frequently improves. Oropharyngeal disease, cerebrovascular disease and motor neurone disease are common indications for tube feeding. Tube feeding may also be useful in the postoperative or critically ill patient with gastric paresis, when jejunal feeding may need to be combined with gastric aspiration. Supplemental nocturnal tube feeding is a useful method of exploiting the residual intestinal function in patients with Crohn disease and to increase nutrient intake in patients with cystic fibrosis.

Intestinal access

Access to the intestine will depend on the duration of feeding and gastric function. In the short term and in critically ill patients, fine-bore nasal tubes are convenient. In the long term and for the mobile patient, percutaneous tubes are more suitable. Patients with disease of the oesophagus, impaired gastric function and recent surgery to the upper alimentary tract will need access to the jejunum. The routes of access are summarized in Table 12.5.

There is increasing use of percutaneous endoscopic gastrostomies (PEGs) in patients with chronic neurological disease; once the track has formed the PEG tube can be replaced with a button gastrostomy (Figure 12.2), which is more convenient for the mobile patient. The use of jejunostomy tubes following oesophagogastric surgery can avoid the need for the more expensive and hazardous option of parenteral nutrition.

Nutrient solutions

A wide range of nutrient solutions is available for enteral tube feeding and the types of feed are summarized in Box 12.2.

Table 12.5 Intestinal access for enteral tube feeding

Route of entry	Tip position	Method of placement
Nasal	Nasogastric	Patient or nurse
	Nasojejunal	Endoscopist or surgeon
Percutaneous	Percutaneous gastrostomy	Endoscopist, radiologist or surgeon
	Percutaneous gastrojejunostomy	Endoscopist
	Percutaneous jejunostomy	Surgeon or endoscopist

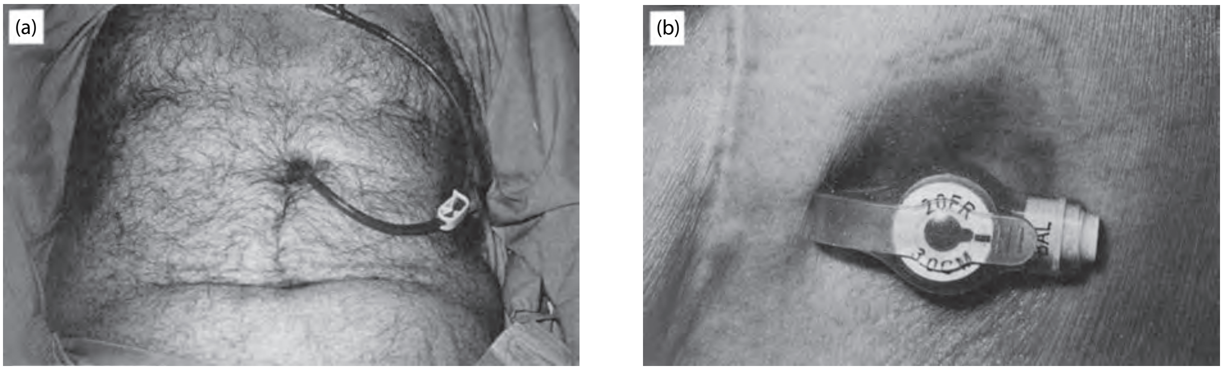

Figure 12.2 (a) Percutaneous endoscopic gastrostomy; (b) button gastrostomy.

BOX 12.2 Types of enteral feed solution

- Oral dietary supplements
- Polymeric feeds
- Predigested chemically defined
- Specialized diets
- Disease-specific feeds

The cheaper whole-protein polymeric diets are preferred for the majority of patients. They comprise whole protein, hydrolysates of starch arid long-chain triglycerides (LCTs). LCTs contain linoleic acid, which is metabolized to arachidonic acid, the precursor of series 2 prostanoids and series 4 leukotrienes that induce inflammation and increase immunosuppression. In contrast, the omega-3 fatty acids lead to the production of series 3 prostanoids and series 5 leukotrienes that have anti-inflammatory and immune-enhancing effects. Some special diets are now available that contain omega-3 fats and additional glutamine. Clinical benefit has been demonstrated in the context of burn injury. Other special diets have a reduced sodium content and are useful in some patients with sodium retention associated with cardiac and liver disease.

Chemically defined diets contain peptides instead of whole protein, and some also contain medium-chain triglycerides. They are used to promote absorption in patients with severe intestinal disease. Disease-specific diets include formulas enriched in branched-chain amino acids for patients with portal systemic encephalopathy due to liver disease, and diets in which a large proportion of the non-protein energy is supplied as lipid for patients with respiratory failure. The clinical evidence to support the use of these disease-specific products is not very convincing.

Nutrient delivery

The need to deliver the nutrient solution at the appropriate rate and to avoid bacterial contamination by the use of clean procedures merits emphasis. Infusion is commenced at 50 mL/h and increased, according to tolerance, to 100 mL/h in the majority of patients who are receiving gastric tube feeding. An initial rate of 25 mL/h may be preferred for critically ill patients, and when initiating feeding in the postoperative patient via a nasojejunal tube. Conversely, flow rates of up to 180 mL/h may be employed in some patients who are receiving enteral tube feeding at home.

Enteral feeding is given by enteral pump infusion, rather than bolus feeding, which is associated with increased gastrointestinal intolerance. When gastric feeding is considered and gastric motility is in question gastric residual volumes are measured. Volumes of up to 400 mL in the critically ill patient do not necessarily preclude gastric feeding, but the volumes should be checked 2 hours after initiating the infusion. This is not necessary with postpyloric feeding. The feeding is given overnight or for longer periods. One further theoretical advantage is that it allows the gastric pH to fall when the buffering effect of the infusion is withdrawn, thus minimizing the tendency to gastric colonization, which might be a factor in the development of infection.

Contamination of the enteral feed should be avoided by the use of a commercial feed, selection of an appropriate reservoir and giving set, and the observance of a protocol when administering the feed. Episodes of infection in the critically ill have been directly related to enteral feeds, and there is the risk of infection with specific intestinal pathogens such as *Salmonella* spp., bacterial translocation in the presence of impaired intestinal and immune function, and bacterial overgrowth, which reduces the efficiency of the feed.

Complications

The complications of enteral feeding can be considered in three groups:

1. nutritional and metabolic
2. complications of nutrient delivery
3. gastrointestinal complications.

Patients require monitoring with respect to fluid and electrolyte status, biochemical parameters and nutritional progress. In particular, fluid retention and electrolyte balance may require attention; hyperglycaemia and hyperkalaemia may be encountered in diabetic subjects and patients with renal impairment. Hypophosphataemia may occur during the refeeding syndrome in the severely malnourished patient. If it is not recognized, the patient may present with thrombocytopenia, cardiac dysrhythmia and mental confusion. Hypomagnesaemia and hypokalaemia are other features of this syndrome, which may reflect rapid cellular uptake with the switch of energy source from endogenous lipid in the starving patient to exogenous carbohydrate. Thiamin deficiency precipitated by glucose infusion represents another example of this problem and is especially relevant in the alcoholic subject.

Complications of delivery are common, especially with nasogastric tubes. More than half of these tubes become displaced and there is a risk of incorrect positioning with the tube in the bronchial tree. Pulmonary aspiration occurs with too rapid infusion or impaired gastric emptying. Complications of the percutaneous tubes include the complications of placement, peritonitis if there is a leak of feed or intestinal contents through the incorrect appositioning of the alimentary tract and the abdominal wall at the site of the tube, and stomal infection.

Diarrhoea is a common problem. Possible causes include bacterial infection of the feed, concomitant antibiotic administration and hypoalbuminaemia. Continuous intragastric infusion of feed has been shown to cause a secretary response in the ascending colon, which is thought to reflect the absence of a normal cephalic phase in tube feeding with an absence of the normal stimulated postprandial peptide YY response. This colonic secretion can be overcome by the instillation of short-chain fats in the caecum; these are normally produced by the action of anaerobic bacteria on dietary fibre. This provides a rationale for the use of fibre-containing feeds and one explanation for the association of antibiotics with diarrhoea. The use of intermittent feeding may allow the gastric pH to fall when the buffering effect of the feed is withdrawn for a period. This may be helpful in reducing gastric and consequently intestinal bacterial colonization, although adequate data to support this suggestion are lacking. Nevertheless, intermittent feeding will minimize fluid and fat accretion in comparison with continuous feeding owing to the effect on insulin secretion.

Parenteral nutrition

The term total parenteral nutrition is frequently used. This implies that the complete range of nutrients is being administered by the parenteral route, which is normally the case, and that nutrition is being delivered exclusively by vein, which is often not the case. Consequently, the term parenteral nutrition is preferred. Parenteral nutrition is often employed to supplement enteral nutrition when there is limited intestinal tolerance or function.

Indications

Examples of common indications for short-term and long-term parenteral nutrition are given in Boxes 12.3 and 12.4.

In the majority of these patients parenteral nutrition will be supplemental. Whereas many patients with wasting due to AIDS have been treated with long-term parenteral nutrition, there is minimal evidence of benefit. Patients with untreatable cancer should only be considered for parenteral nutrition if they are not terminally ill and when the problem is due to untreatable intestinal obstruction and not simply cachexia.

BOX 12.3 Some indications for short-term parenteral nutrition

- Severe inflammatory bowel disease
- Mucositis following chemotherapy
- Severe acute pancreatitis
- Some patients with multiorgan failure
- Following major excisional surgery
- Prior to major surgery in malnourished subjects

BOX 12.4 Some causes of intestinal failure in adults, for which prolonged parenteral nutrition may be needed

- Inflammatory disease
- Crohn's disease
- Gluten enteropathy
- Radiation enteritis
- Motility disorders
- Hollow visceral myopathy
- Scleroderma
- Short bowel syndrome
- Mesenteric infarction
- Miscellaneous disorders
- Inoperable intestinal obstruction
- AIDS

Venous access

The realization that nutrient needs are less than they were previously considered to be, the recognition that most patients receive parenteral nutrition in hospital for less than 2 weeks and the availability of lipid-containing nutrient mixes have led to the use of peripheral veins for the administration of parenteral nutrition. Access may be by conventional Venflon, which should be resited every 1–2 days before thrombophlebitis occurs, or 15 cm ultrafine catheters, which are inserted in one of the antecubital veins (Figure 12.3). The peripheral line should be reserved exclusively for the administration of nutrition and it requires the same standard of care as a central line. Under these circumstances peripheral access will last for 2 weeks or longer.

Central parenteral nutrition is needed when prolonged treatment is envisaged, there are unusual nutritional requirements with volume restriction and a hyperosmolar solution, or in the

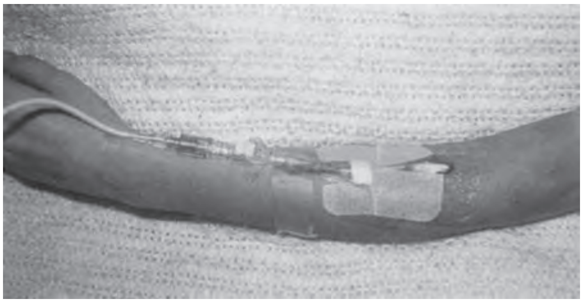

Figure 12.3 Peripheral feeding catheter with Interlink connection device.

absence of adequate peripheral veins. Central access is normally via tunnelled central catheters. For mobile patients and long-term treatment of more than 2 months, cuffed catheters are preferred (Figure 12.4). Some of the latter patients who need home parenteral nutrition may favour an implanted subcutaneous port. More recently, the peripherally inserted central catheter has gained popularity. Central catheters should be placed with the tip in the distal superior vena cava, but not in the right atrium.

All access devices must be managed by staff trained in aseptic procedures following written protocols. This is the only way to ensure the prevention of dangerous and avoidable complications such as catheter-related sepsis.

Nutrients

The nutrients are compounded in a multilayer plastic bag under sterile conditions in the pharmacy. The needs of the majority of patients can be met from a range of standard nutrition solutions. Commonly used parenteral solutions provide 9 or 14 g of nitrogen as amino acids, and 1600 or 2200 non-protein calories as glucose and lipid in 2.5–3.0 litres of water, with 80 mmol of sodium and 60 mmol of potassium. Calcium, magnesium and phosphate are also included, as are commercial preparations of vitamins and trace elements. These provide the currently recommended daily requirements of micronutrients. The need for additional supplements should be considered in patients who are severely depleted when parenteral nutrition is initiated, and in those patients who do not receive a nutrient bag every day. Some patients, especially those with Crohn disease, have suffered from selenium depletion. Conversely, it used to be thought that more manganese is absorbed from the diet than is the case. This led to the formulation of preparations that supplied too much manganese for intravenous administration. Such problems are more common in patients who receive parenteral nutrition at home.

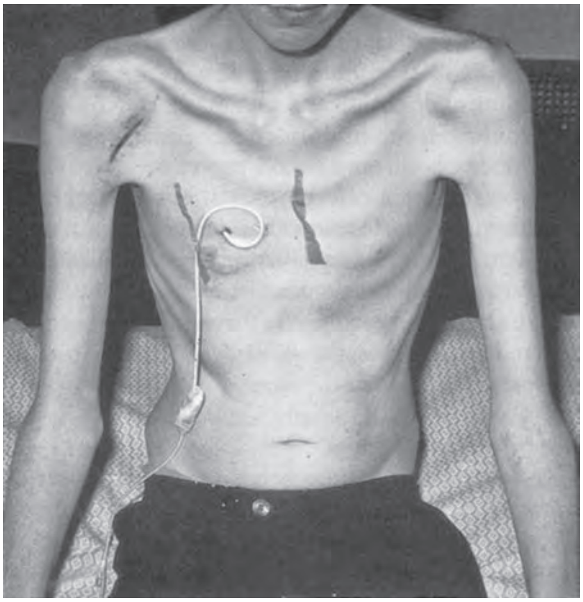

Figure 12.4 Tunnelled central catheter.

The most common adjustments to the nutrient prescription include fluid and electrolytes in patients with increased losses, or reduced tolerance with renal impairment. Considerations of lipid stability limit the addition of electrolytes, especially divalent ions. A separate electrolyte infusion is sometimes needed.

Nutrient delivery

The nutrients are delivered via an infusion pump. As with enteral nutrition, cyclical feeding is preferred in the stable patient, but continuous infusion may be required in the stressed patient. Cyclical infusions facilitate mobilization, and are associated with less fluid retention and fat deposition. Catheter patency is maintained with a heparin lock when the patient is disconnected from the infusion. All catheter procedures must be undertaken according to strict aseptic protocols to minimize the risk of complications.

Complications

Complications of parenteral nutrition may be considered in three groups:

1. nutritional and metabolic
2. catheter related
3. effect on other organ systems.

Nutritional and metabolic complications

Fluid overload, hyperglycaemia and electrolyte imbalance are common potential problems, especially in unstable patients. Patients who are severely malnourished may suffer from the refeeding syndrome (see above). Additional electrolytes may need to be given to some patients; this applies particularly to phosphate, potassium and magnesium. Stressed patients are prone to hyperglycaemia so some of the energy should be provided as lipid and insulin may be needed. Rebound hypoglycaemia can occur after discontinuing the infusion of concentrated glucose solutions until endogenous insulin levels fall. Tapering the rate of infusion before disconnection minimizes this problem.

Long-term patients who receive little nutrition from other sources are at risk of micronutrient deficiencies. Whereas the profile of commercially available trace element solutions has been changed to cover previous deficiencies such as selenium, it is worth remembering that amounts delivered in each nutrition bag are designed to meet estimated daily needs. Thus, patients with initial depletion or who do not require a nutrition bag every day (this applies to many of the patients who receive parenteral nutrition at home) are at risk of deficiency and monitoring is important. The excessive accumulation of aluminium from protein hydrolysates and manganese from incorrectly formulated trace element solutions, leading to bone and neurological disease, respectively, should no longer occur.

The overprovision of macronutrients such as glucose and amino acids is harmful. Excess glucose will lead to hepatic steatosis and is accompanied by increased respiratory demands and the stimulation of the sympathetic nervous system. The excessive administration of amino acids has been associated with cholestasis in paediatric practice and possible alterations in bone metabolism.

Catheter-related complications

Complications associated with catheter insertion are common. They include pneumothorax, damage to adjacent vascular structures and incorrect positioning of the catheter tip. Placement with the aid of screening is important and the use of ultrasound is helpful in minimizing these risks. After correct placement there are four important catheter-related complications:

1. infection
2. thrombosis
3. occlusion
4. fracture.

Catheter-related infection

Three types of infection can be recognized: exit-site infection, tunnel infection and catheter-related septicaemia.

Exit-site infections usually respond to local dressing complemented by systemic antibiotic therapy. However, clearance will not be successful if there is a Dacron cuff, which lies adjacent to the exit site (rather than halfway along the tunnel) when it becomes contaminated. *Infection of the tunnel*, which can complicate exit-site infection, is characterized by pain and redness; it does not respond to treatment and is an indication for catheter removal. Rarely, tunnel infections may arise from retrograde spread of infection from an infected central vein. This is a very serious problem, which reflects previous inadequately treated catheter-related sepsis.

Catheter-related septicaemia is the most serious infection and can be fatal. In the short term, microbes may gain access from the exit site, but after 2 weeks the hub is the most common site of contamination. The problem is usually heralded by pyrexia and rigors during infusion. Diagnosis can be difficult, especially in patients with other sources of sepsis; there may also be other reasons for pyrexia, and these include venous thrombosis. When this complication is suspected, catheter removal is the safest course of action. However, if venous access is difficult and the need for continuing central parenteral nutrition is anticipated, drawback and peripheral blood cultures should be obtained. Semiquantitative cultures have been used to implicate the line as the primary source of infection; however, the use of the endoluminal brush promises more precise and reliable information. While awaiting the results of culture, the central catheter should be locked and the patient is given systemic antimicrobial cover against the most likely infecting organisms; vancomycin + gentamicin is a suitable regimen in the short term. Catheter salvage is possible using antibiotic and urokinase locks. There are insufficient data to recommend specific guidelines in relation to the dose of urokinase and type of antibiotic. One approach involves the insertion of a 2000 U/mL urokinase lock for 1 hour before the infusion of antibiotics; pending the results of blood cultures, vancomycin and gentamicin administered twice a day cover likely pathogens, although blood antibiotic concentrations should be monitored. The antibiotic prescription may need to change according to microbiological results. Salvage should not be attempted when *Candida* and *Staphylococcus aureus* infections are identified: it is unlikely to succeed with subcutaneous ports, and the potential risk of recrudescence and metastatic infection, including endocarditis and osteomyelitis, should be considered.

The emphasis must be on prevention. The development of catheter care protocols and management by nutrition support teams has almost eliminated the problem. The use of antimicrobial agents as additives in the nutrient solution cannot be recommended for routine practice and requires further study, but may help in the management of the difficult patient who is prone to recurrent infection.

Central vein thrombosis

Central vein thrombosis tends to develop after treatment for a few weeks (Figure 12.5). It may be heralded by pyrexia, pulmonary embolism, subclavian vein thrombosis or occlusion of the superior vena cava with facial swelling. This is a serious problem, which impairs venous access and can prove fatal. The diagnosis should be confirmed by bilateral upper limb venography. Rarely in adult practice does the thrombus involve the heart; however, if any new cardiac murmur is heard transoesophageal echocardiography is recommended. Thrombosis accompanies the use of concentrated glucose regimens and a proximal location of the catheter tip in the superior vena cava; thrombotic tendency is reduced by the administration of lipid emulsions. Patients with coagulation disorders such as antithrombin III deficiency and patients with Crohn disease are more likely to develop this problem.

Treatment with thrombolytic drugs such as streptokinase is effective in restoring venous patency. Streptokinase is infused for 48 hours, when repeat venography will usually demonstrate recanalization. The patient is then given heparin and ultimately warfarin. There is a theoretical risk of inducing pulmonary embolism from fragmented thrombi. The use of heparin alone does not lead to significant recanalization in the short term.

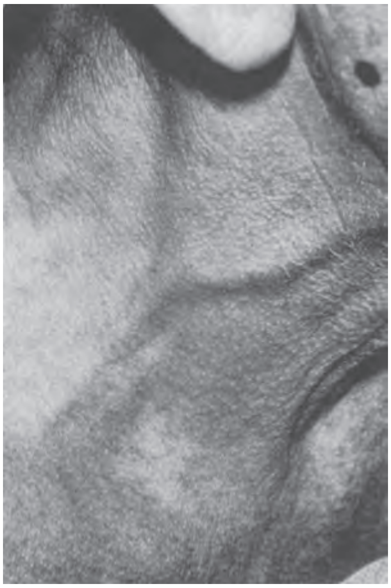

Figure 12.5 Venous thrombosis associated with central parenteral nutrition.

Many authorities use heparin in the nutrient solution as a prophylactic measure. Evidence suggests that there is a need for at least 3 units of heparin/mL of feed solution, although the possible effect on the stability of the emulsion must be considered. There is insufficient evidence to support the routine use of heparin in all patients. Low-dose warfarin may be an effective alternative, notwithstanding interactions between warfarin and the vitamin K derivatives, which occur in the lipid emulsions. The need for prophylaxis will depend on individual circumstances. For example, prophylaxis will be required in patients with a thrombotic disorder and in patients who have already developed venous thrombosis. Conversely, anticoagulation is unwise in some patients with active inflammatory disease in whom there is a significant risk of bleeding.

Catheter occlusion

Catheter occlusion may be due to kinking or luminal deposition of fibrin, lipid sludge or amorphous debris. This is a particular problem with lipid mixes, the tendency to which may be reduced by the use of an ethanol flush before the application of the heparin lock.

When occlusion occurs a chest radiograph should be obtained. Providing the position of the catheter is satisfactory, attempts at line salvage can be considered. When there is evidence for fibrin occlusion, after blood flashback or with a fibrin sleeve, urokinase can be used to clear the catheter. Streptokinase is reserved for the management of serious central vein thrombosis to avoid sensitizing the patient. When occlusion develops with the use of lipid mixes, an ethanol lock may restore the patency of an incompletely occluded catheter.

Catheter damage

The use of connection devices or extension sets reduces the need to clamp the catheter and prolongs catheter life. Repair kits are available if fracture occurs. Subcutaneous ports eventually leak. This becomes apparent when the patient complains of pain around the infusion site. New ports can be attached to the existing catheter.

Effect of parenteral nutrition on other organ systems

Parenteral nutrition may affect the hepatobiliary system, the immune system and the skeleton. Any theoretical detrimental effect must be weighed against the known impairment of organ function associated with the malnutrition that this treatment seeks to prevent or reverse.

Changes in organ function may be a reflection of the underlying disease, malnutrition, drug treatment and lack of oral or enteral nutrition, as well as the effect of parenteral nutrition. The development of hepatobiliary disease in patients who are treated with prolonged parenteral nutrition illustrates this point. Some forms of hepatobiliary disease occur more commonly in patients with inflammatory bowel disease; the lack of oral nutrition leads to biliary sludge and possible changes in intestinal permeability with toxin absorption. The administration of excessive amounts of glucose may cause hepatic steatosis and in neonatal patients the excessive prescription of amino acids has been incriminated in the development of cholestasis. Metabolic bone disease in some patients is attributable to previous malnutrition and exposure to corticosteroid therapy. The influence of parenteral nutrition on bone metabolism is controversial.

Catheter complications can cause serious disease in other systems. Endocarditis and osteomyelitis have been described following catheter-related sepsis, and pulmonary embolism can complicate central vein thrombosis. With due care and the observance of good written protocols parenteral nutrition is relatively safe, and is life saving for a significant group of patients with short- or long-term intestinal failure.

CHAPTER 13

Interventional radiology in general surgery

MOHAMAD S. HAMADY

Percutaneous biopsy

Over the past several decades, percutaneous image-guided biopsy has become one of the most common interventional radiological procedures. In particular, rapid advances in imaging technology, biopsy instruments and techniques have made once difficult-to-reach lesions, historically requiring surgical intervention, accessible and amenable to the ambulatory setting. Furthermore, the development of novel histopathology methods with a greater sensitivity and specificity have increased diagnostic yield.

Biopsy instruments

Biopsy instruments can be classified into aspiration and cutting core needles (Figure 13.1). Each technique has its particular advantages in obtaining either cells for cytological assessment or tissue for histopathological examination.

Aspiration needles

Aspiration needles are predominantly used to procure tissue for cytological analysis. They are particularly useful for the safe biopsy of small lesions (<2.5 cm diameter) lying next to vital organs or vascular structures and have an associated complication rate of <1%. The needles themselves are designed with a bevel-shaped end and range in size from 18 to 25 G. Overall, the aspiration technique is recognized to have a high sensitivity for cancer diagnosis but a low cellular accuracy and cancer specificity.

Cutting needles

Cutting biopsy needles are designed to obtain segments of tissue for histological examination rather than individual cells. The cutting mechanism of the instrument is further subclassified as end-cutting (predominantly for solid lesion biopsy) or side-cutting (mainly for soft lesion biopsy).

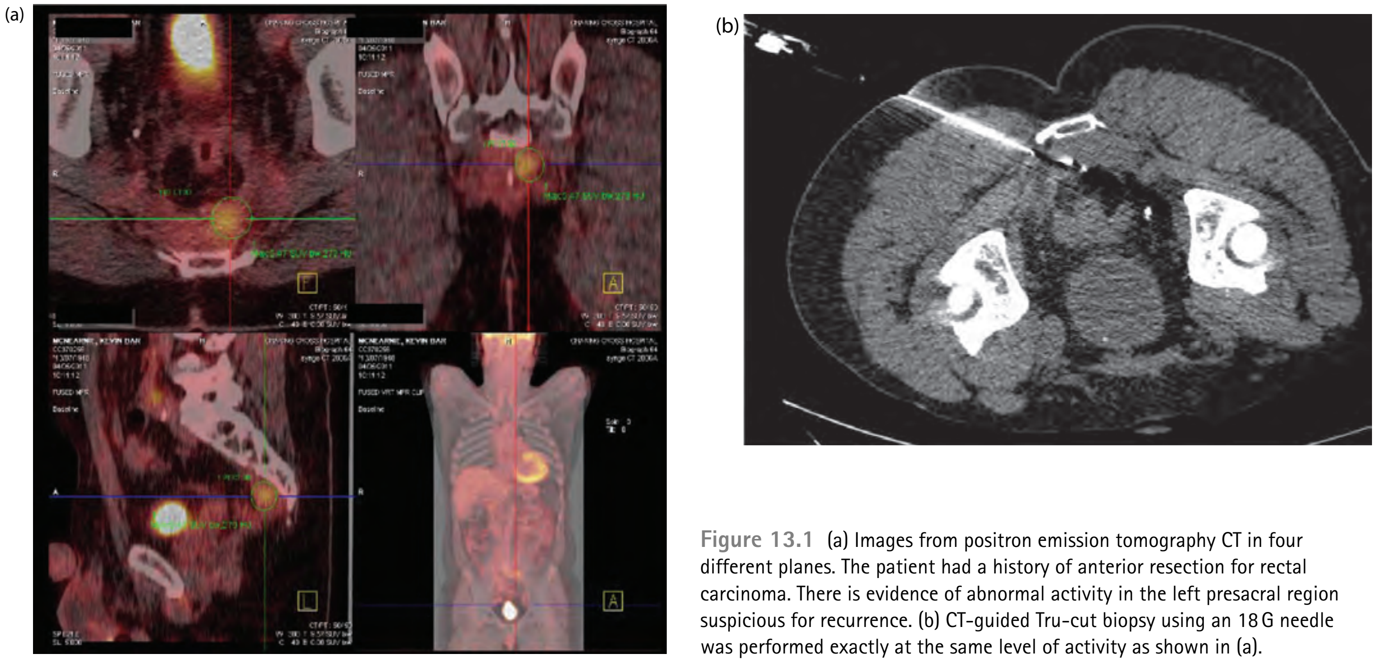

Figure 13.1 (a) Images from positron emission tomography CT in four different planes. The patient had a history of anterior resection for rectal carcinoma. There is evidence of abnormal activity in the left presacral region suspicious for recurrence. (b) CT-guided Tru-cut biopsy using an 18 G needle was performed exactly at the same level of activity as shown in (a).

Cutting needles are advantageous in being able to provide a larger tissue yield and therefore a higher chance of a more accurate diagnosis, particularly for lesions where the primary origin is unknown following standard radiological assessment. They have a low complication profile and are especially safe when used in conjunction with image guidance for percutaneous procedures.

Percutaneous abscess drainage

Indications

Over the course of the past three decades, percutaneous abscess drainage has displaced open surgical intervention to become the first-line treatment for evacuation of abdominal and pelvic collections. In addition to being a minimally invasive technique that obviates the need for open surgery and general anaesthesia, the percutaneous approach allows for the majority of abscesses to be drained fully and safely without the associated morbidity and mortality inherent with laparotomy, while saving the surgical option for particularly resistant or extensive abscesses.

The development of modern, high-resolution imaging techniques coupled with the growing number of experienced interventional radiologists has meant that the vast majority of fluid collections and abscesses in the peritoneal cavity, retroperitoneal space and even, in certain cases, specific organs are today amenable to percutaneous drainage.

Fluid drainage is absolutely indicated when there is a clinical or laboratory suspicion that a defined collection is infected, or causing a mass organ effect. The aim of such drainage is either definitive treatment or as a diagnostic adjunct in preparation for definitive surgery. Patients with diverticulitis and associated abscess collection are occasionally treated with percutaneous drainage in preparation for bowel resection. Additionally, when patients are being palliated or are otherwise unsuitable for surgical intervention, percutaneous drainage offers a minimally invasive treatment option.

Indications for percutaneous drainage include:

- to obtain a fluid sample for diagnostic investigations
- treatment of abscess through a non-surgical modality
- in preparation for a definitive surgical procedure
- as a palliative measure in patients not suitable for surgical intervention.

Contraindications

Although there are no absolute contraindications to percutaneous drainage, the following are considered to be the main relative contraindications to employing this minimally invasive approach:

- severe coagulopathy
- cardiopulmonary compromise
- absence of a safe entry route to the drainage site
- complex, multiloculated collection
- pregnancy
- patient co-operation.

The ultimate decision on whether to attempt a percutaneous drainage or intervene surgically in these circumstances should be taken following multidisciplinary discussion involving surgeons, intensivists and interventional radiologists.

Complications

Major complications such as severe bleeding (due to uncorrected coagulopathy or vascular or solid organ injury), sepsis and organ injury necessitating surgical intervention are relatively rare, with an estimated incidence of <10%. Several measures may be undertaken periprocedurally to reduce these risks:

- correction of coagulation defects
- group and save and transfuse individuals with a low haemoglobin count
- careful imaging of complex or multisegmented, multilocation collections
- early recognition of pathology that requires a surgical intervention, e.g. tumour, complex abscess connecting to an organ structure
- preplanning the safest route of entry with suitable pre- and intraprocedure imaging with consideration of using different windowing techniques of scanners and patient position to obtain the best views and access
- ensuring that the expertise of the interventional radiologist matches the requirement of the procedure to be carried out; if the complexity of the procedure requires greater expertise then consider referring the patient to a specialist centre
- have a surgical team available to assess the patient in case of any complications.

As we have already discussed, the success of drainage through an interventional approach depends not only on the skill and expertise of the interventional radiologist but equally, if not more importantly, on careful consideration of the patient and their underlying pathology, a detailed understanding of the anatomy of the abdomen as a whole and the area to be drained, especially in cases of complex, multiloculated collections. Finally, it is equally essential to recognize when the interventional approach will not succeed and surgery is the only treatment.

Overall, the success rate for percutaneous abscess drainage approaches 90%. However, this figure falls significantly in the presence of multiloculated, large, thick-walled collections having a complex anatomy, in which successful drainage may be achieved in as little as 30% of cases.

Management of the *in situ* percutaneous drain

Although most patients tolerate drain insertion very well, it is not uncommon for some to experience a transient postprocedure fever in the first 24 hours following catheter placement. Most patients will recover within 48 hours but deterioration or lack of improvement in clinical condition may necessitate further patient review and investigation to ensure that there is no new pathology or indeed worsening of existing pathology.

Following insertion of the drainage catheter, its position and patency should be confirmed and checked on a regular basis for the duration that it remains *in situ*. Many radiologists prefer to use double-lumen catheters for drainage purposes.

These provide two advantages. First, the presence of a second lumen permits closed system irrigation with ejection of infused saline (equal to the volume injected) and pus from the cavity, giving an indication of both catheter position and patency. Furthermore, flushing the catheter regularly each day helps to keep the catheter unblocked and clear of debris or pus that can settle there. Second, contrast material can be injected intracorporeally and the patient imaged with fluoroscopy or CT to obtain a further indication of the catheter position, size of the cavity being drained and the volume that remains before deciding on whether the catheter can be removed.

For most cases, routine abdominal imaging to check drainage adequacy is not necessary. Clinical improvement coupled with a reduced drain output to <30 mL/day (in the absence of a blocked drain) is generally an indication that the job of the drain has been completed satisfactorily. Conversely, the persistence of a high output can suggest a fistulous communication being present intracorporeally and it is in this situation that further imaging with (water soluble) contrast enhancement through the drain can prove invaluable.

In addition to the general percutaneous management of intra-abdominal abscesses, it is worth considering how collections associated with individual organs may need a more specialized approach to be adequately treated.

Management of organ-specific abscess and collections

Liver

Liver abscesses can be classified according to their nature as pyogenic, amoebic or fungal or alternatively by their number as singular or multiple. Pyogenic abscesses are mostly polymicrobial and secondary to recent surgical intervention, infected tumour, infected biliary obstruction or bacteraemia in immunocompromised patients. Singular abscesses usually occur on the right lobe and, although the causative agent is often unknown, it can be associated with *Klebsiella pneumoniae*. Multiple abscesses, on the other hand, are usually bilobular and biliary in origin, with *Escherichia coli* being the most commonly isolated organism.

Diagnosis is most commonly made on clinical symptoms and confirmed by radiological imaging such as ultrasound or CT. For the most part, treatment is predominantly medical with supportive and appropriate antimicrobial therapy with percutaneous drainage being reserved for non-responsive and large (>8 cm) abscesses (Figure 13.2).

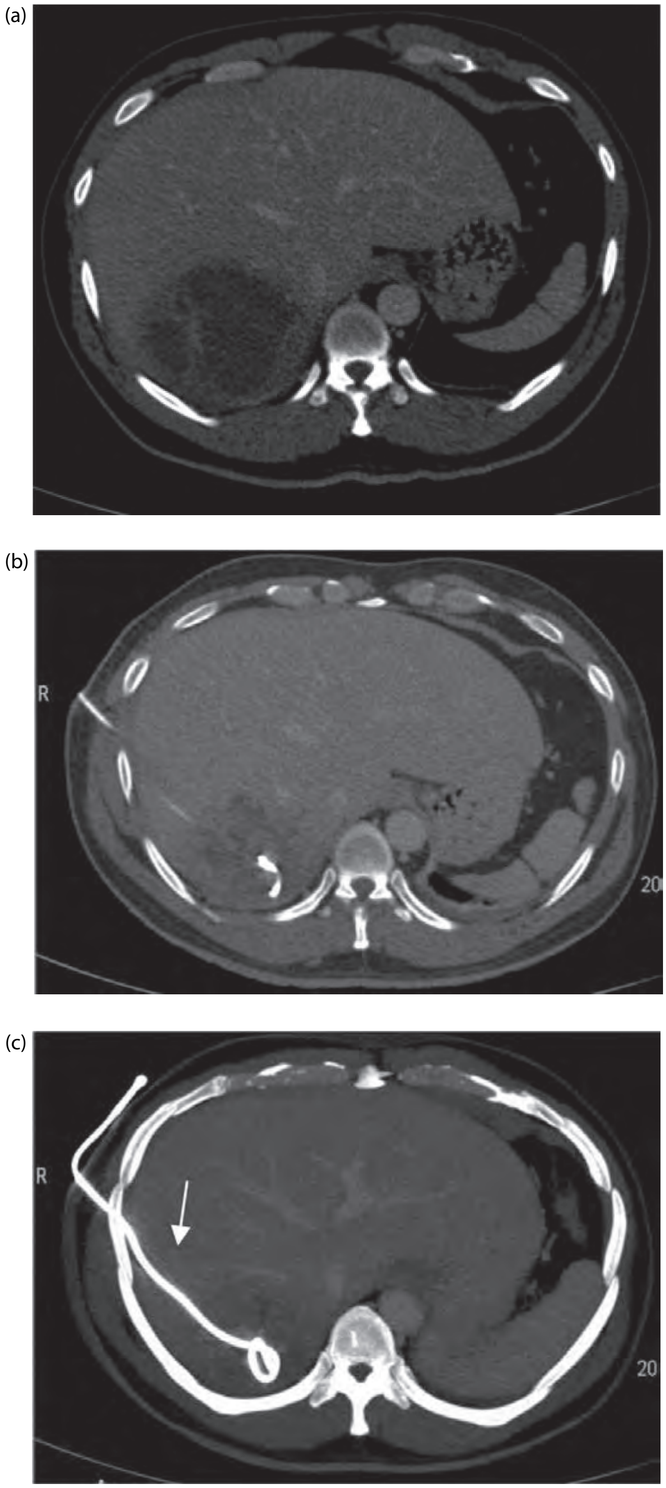

Figure 13.2 (a) Enhanced CT scan slice through the liver shows an 8 cm abscess in segment VI. (b) Enhanced CT slice following percutaneous CT-guided drain insertion. Note the significant reduction in abscess size. (c) Maximum intensity projection image of the liver similar to Figure 13.4b. The safe intercostal path of the drain is shown (white arrow).

Pancreas

The pancreas (Figure 13.3) can be subject to formation of a large variety of collections which may be amenable to percutaneous drainage. Severe acute pancreatitis in particular can result in phlegmon formation, pseudocyst and haemorrhagic necrosis. Pseudocysts and necrotic tissues can be further complicated by added infection. Additionally, up to 40% of patients may develop fluid collections as the pancreatitis resolves. Definitive differentiation of these pathologies is on the basis of imaging findings complemented by clinical features, timeline and aspiration.

Pseudocysts typically develop between 4 and 6 weeks after an episode of severe acute pancreatitis and show discrete wall

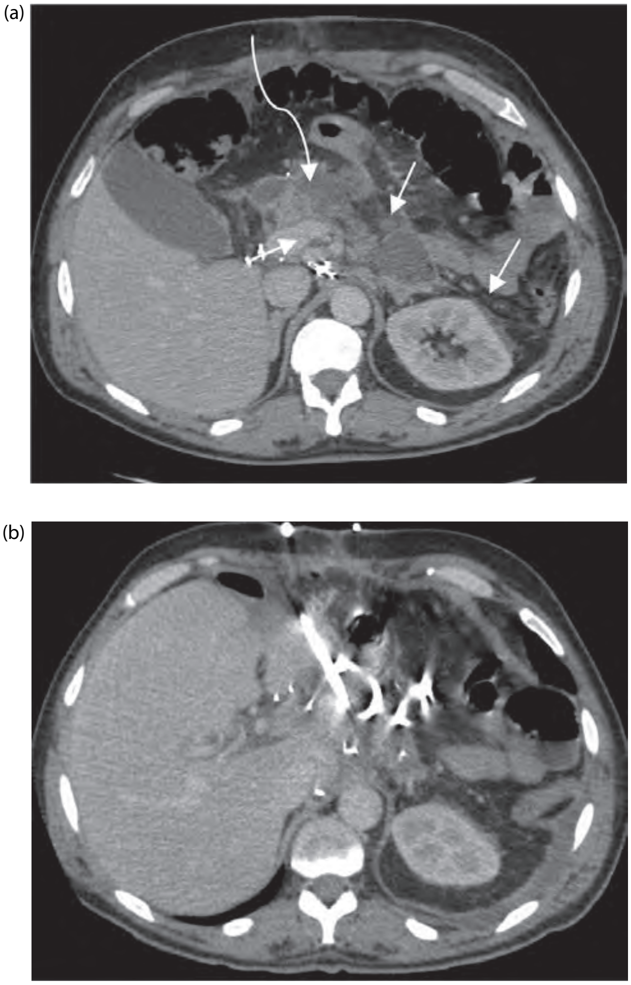

Figure 13.3 (a) CT scan of a 51 year old man following gastrectomy at the level of the pancreas. There is a multiloculated fluid collection around the pancreas (arrows). Note the tight safe window of drainage (curved arrow). (b) CT scan following insertion of two double-lumen pigtail drains under CT guidance. There is complete resolution of fluid collection.

enhancement on CT scan. It has been suggested that serum amylase reflects the maturity of the pseudocyst. As with fluid collections, the great majority of pseudocysts resolve spontaneously and require no radiological or surgical intervention. However, intervention may be indicated in the presence of superimposed infection or mass effects such as recurrent pain and bowel obstruction.

Pancreatic necrosis appears as areas of non-enhancement in contrast-enhanced CT. Treatment of infected pancreatic necrosis has traditionally been the domain of the general surgeon. However, in modern practice, percutaneous image-guided drainage with vigorous irrigation of the necrotic pancreas can achieve good results when performed under meticulous aseptic technique and antibiotic cover. There is a growing trend of draining infected necrosis using large-bore catheters (up to 30 F) with surgical therapy being reserved only for intractable or extensive cases of tissue necrosis.

Renal and perirenal

Renal abscesses are commonly the result of haematogenous spread of infection or pyelonephritis associated with renal stones, obstructive hydronephrosis and septicaemia. Renal abscesses may rupture into the collecting system or into the perinephric space. Both sites of abscess collection are suitable for percutaneous drainage, with surgical stent insertion, e.g. nephrostomy and ureteric stents being necessary to treat the underlying condition.

Bowel

Enteric abscess can complicate any inflammatory or infective bowel process or result from iatrogenic injury during surgical procedures (Figures 13.4–13.6). Diverticular disease, appendicitis and inflammatory bowel disease are most frequently associated with bowel abscess formation. The main role of percutaneous drainage is temporizing the patient's status to facilitate definitive surgery on an elective basis. The exception to this general rule is in diverticular-related abscess, in which drainage occasionally has a role in treating cases with perforation limited to the mesentery or pelvis without significant faecal contamination.

Periappendiceal abscess may be secondary to perforated/gangrenous appendicitis or ongoing infection after appendicectomy. When a large appendix abscess is present, the preferred management is to treat the patient conservatively by inserting a drainage catheter under CT guidance and perform definitive elective surgery at a later date. In some, limited, instances, drainage may even obviate the need for surgery. Postoperative periappendiceal abscess also responds favourably to percutaneous drainage.

Crohn's abscess is associated with a high level of morbidity and can occur secondary to direct extension from the involved bowel segment, haematogenous spread to a distal site or as a result of anastomotic leak following surgery. Percutaneous drainage may improve morbidity, but, particularly in cases of anastomotic leak, the catheter drainage can continue for an extended period of time until the anastomotic line is completely healed.

Gastrointestinal balloon dilatation and stenting

Oesophagus

Image-guided intervention plays an important role in the management of a wide range of oesophageal pathology (Figure 13.7). A significant number of patients present with non-resectable oesophageal cancer. Palliative treatment therefore has a significant role in the management of advanced oesophageal carcinoma with the aim of reducing the effect of tumour bulk. A wide range of palliative measures including thermal ablation, photodynamic therapy, radiotherapy and oesophageal stenting (including plastic and metal, covered or uncovered stents) are available.

The indications for oesophageal stenting in the setting of malignancy are:

- intrinsic oesophageal compression causing significant dysphagia
- tracheo-oesophageal fistula: a spontaneous malignant fistula can occur secondary to local tumour invasion; since malignant fistulas will

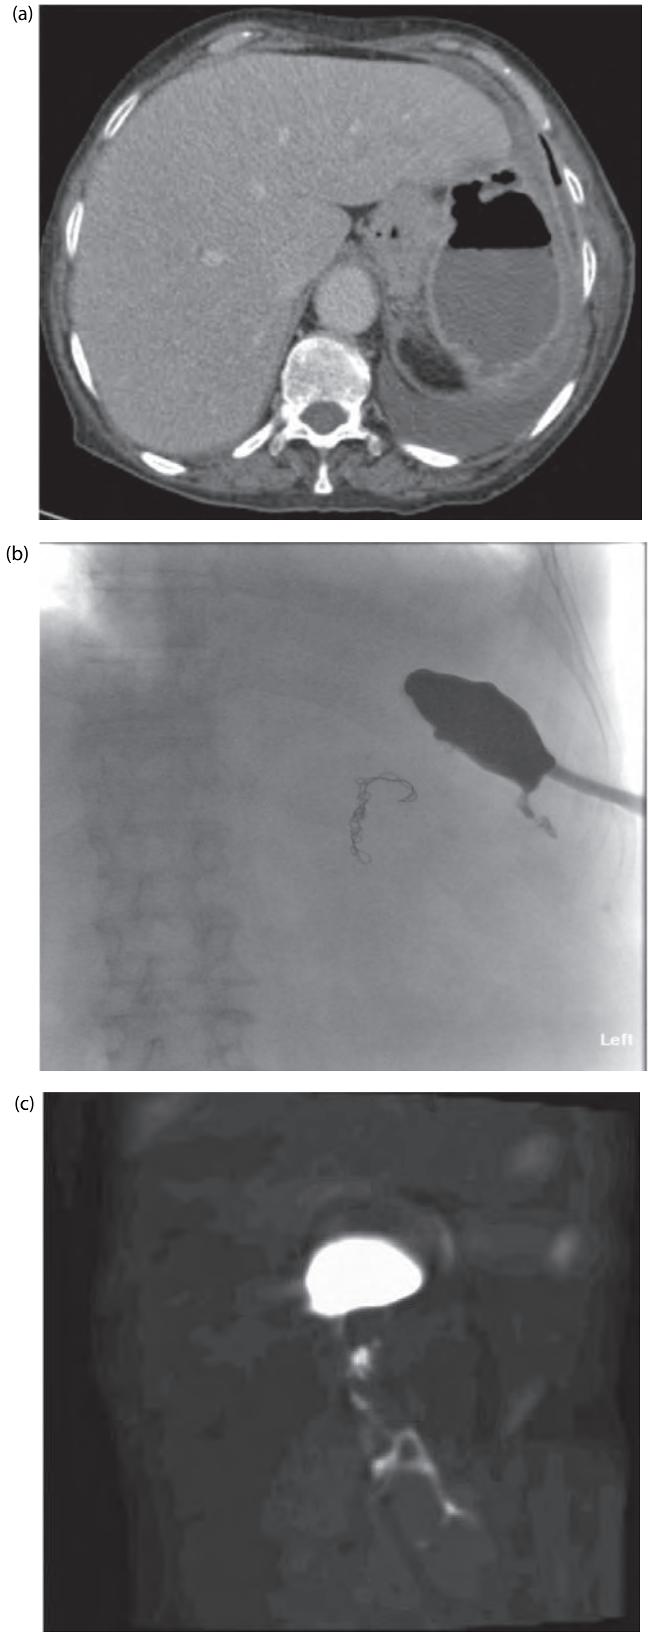

Figure 13.4 (a) CT scan of the abdomen at the level of the liver. There is an abscess collection containing gas in the left subphrenic space. (b) Linogram through the existing drain in the left subphrenic space. It is difficult to establish bowel communication with the abscess cavity. (c) Three-dimensional image obtained from fluoroscopy shows definite communication between the abscess cavity and the descending colon.

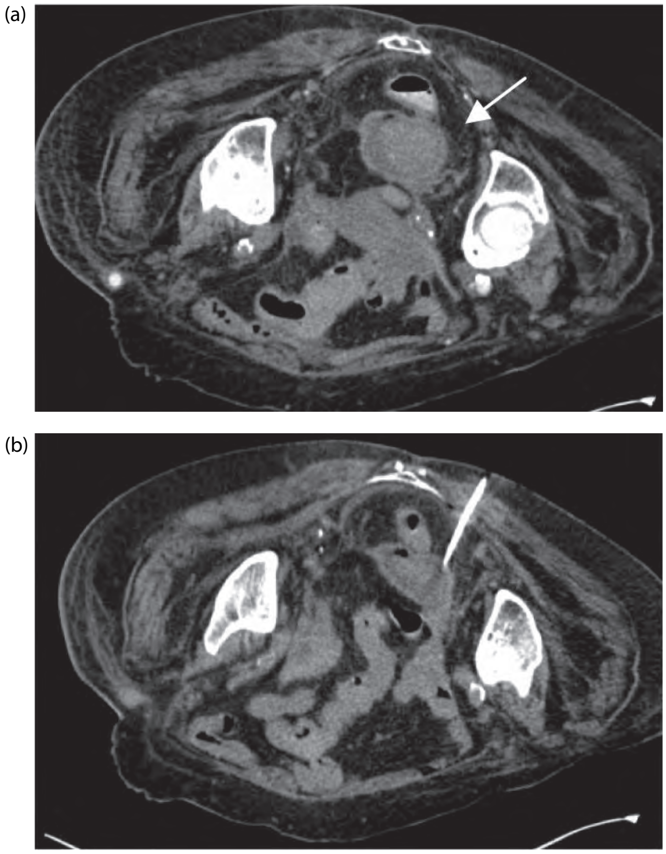

Figure 13.5 (a) Axial CT slice at the sacrococcygeal level shows a prerectal abscess collection (arrow). (b) Axial CT slice at the same level as in (a) shows a drain *in situ* with significant abscess resolution.

not heal spontaneously, self-expandable covered metallic stents are the treatment of choice in those cases

- primary or secondary mediastinal tumours resulting in extrinsic compression
- anastomotic tumour recurrence not responding to balloon dilatation.

Anastomotic stricture and pyloric dysfunction following oesophagectomy and gastric pull-up (Figure 13.8) are relatively common complications, ranging between 27% and 42% and 12% and 13%, respectively. Early diagnosis and treatment is crucial to avoid anastomotic leak, dysphagia, malnutrition and poor quality of life. Balloon dilatation is effective in treating benign stricture and pyloric dysfunction. However, malignant stricture responds better to stenting. In a recent study that involved treating 48 patients with anastomotic stricture after oesophagectomy, radiologically guided balloon dilatation was effective in 98% of benign strictures versus 64% of malignant strictures. In the same study, balloon dilatation was effective in 92% of early pyloric dysfunction but less effective in delayed pyloric dysfunction (63%). In another study that involved 269 patients, anastomotic stricture was noticed in 42% of cases. Endoscopic dilatation was successful in 78% of patients after a median of three dilatation sessions.

In cases of oesophageal leak and fistula, the approach is slightly different. The majority of those cases are secondary to surgery

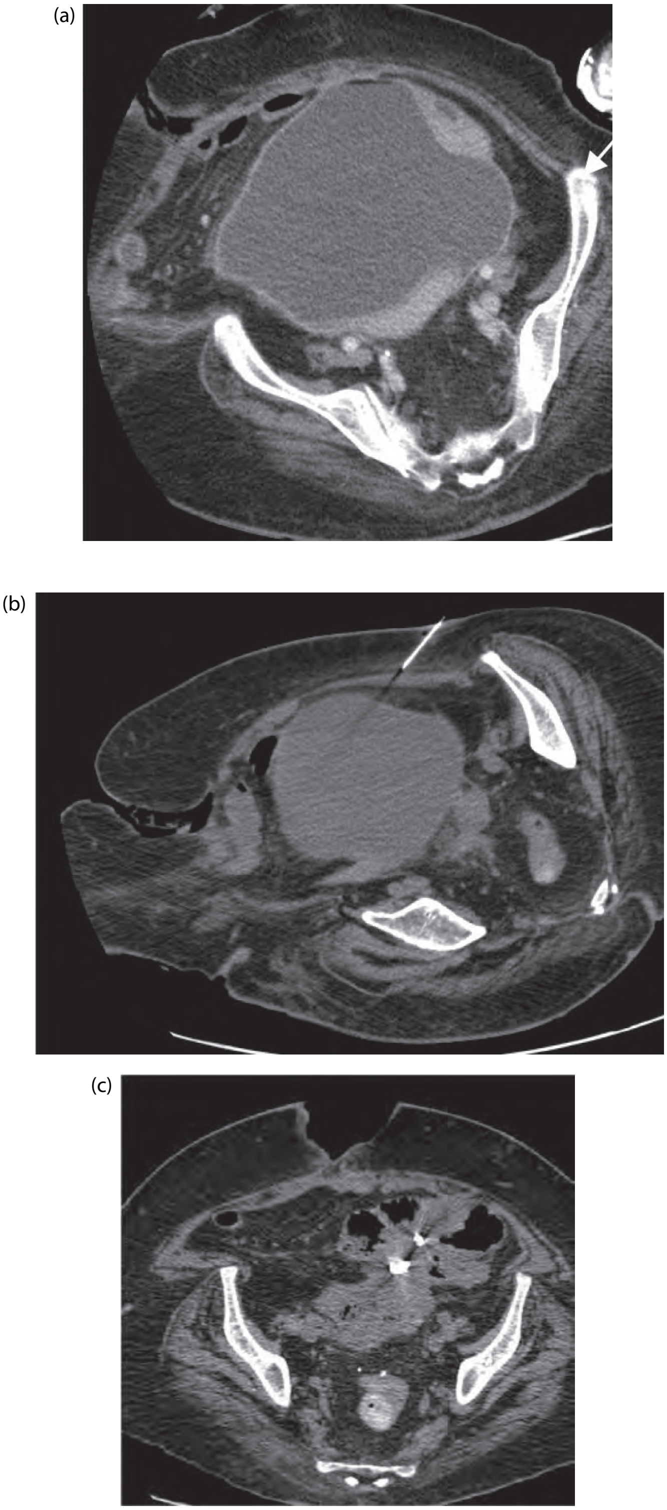

Figure 13.6 (a) Axial CT slice at the level of the pelvis shows a large abscess collection following sigmoidectomy (arrow). (b) Axial CT slice shows the path of image-guided needle insertion through a safe window. (c) Axial CT slice after drain insertion, showing complete resolution of the collection.

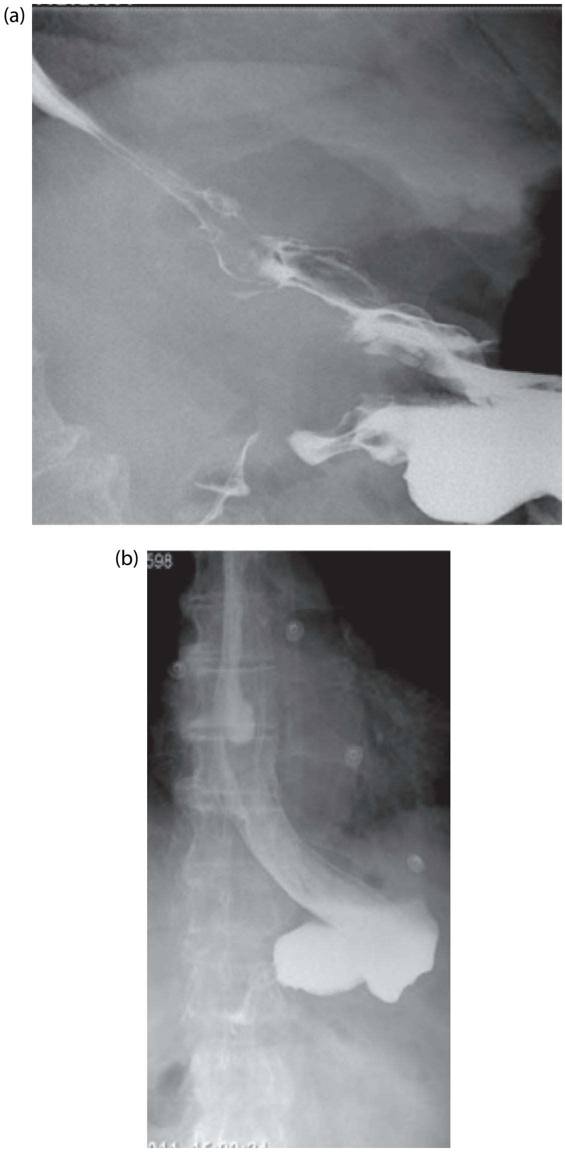

Figure 13.7 (a) Patient with advanced oesophageal carcinoma and grade 3 dysphagia. Barium swallow shows stricture and irregularity of the distal third of the oesophagus and gastro-oesophageal junction. (b) Gastrograffin swallow following oesophageal stenting. There is good flow of contrast through the stent with no hold-up of contrast.

or underlying malignancy. In iatrogenic cases, such as those seen following oesophagectomy and gastric pull-up, the pyloric function must be restored using balloon dilatation if needed. The patient should be nil by mouth and a nasogastric tube inserted to the level above the pylorus to avoid excessive dilatation of the pouch. Most of these patients respond well to these conservative measures. Rarely, repeat dilatation of the pylorus or even stenting of the pylorus could be needed to enhance drainage.

The relative contraindications for oesophageal stenting include recent radiotherapy (in the last 4 weeks), tumour higher than the cricopharyngeal level and severe tracheal compression that could be exacerbated by oesophageal stenting.

The technical success rate of radiologically placed oesophageal stents in improving dysphagia ranges between 90% and 98%. Although stenting has no impact on the survival rate of those patients with advanced disease, it can substantially improve the quality of life.

The complications of radiologically guided oesophageal stenting are generally low. The main complications include migration, perforation, bleeding, chest pain and reflux.

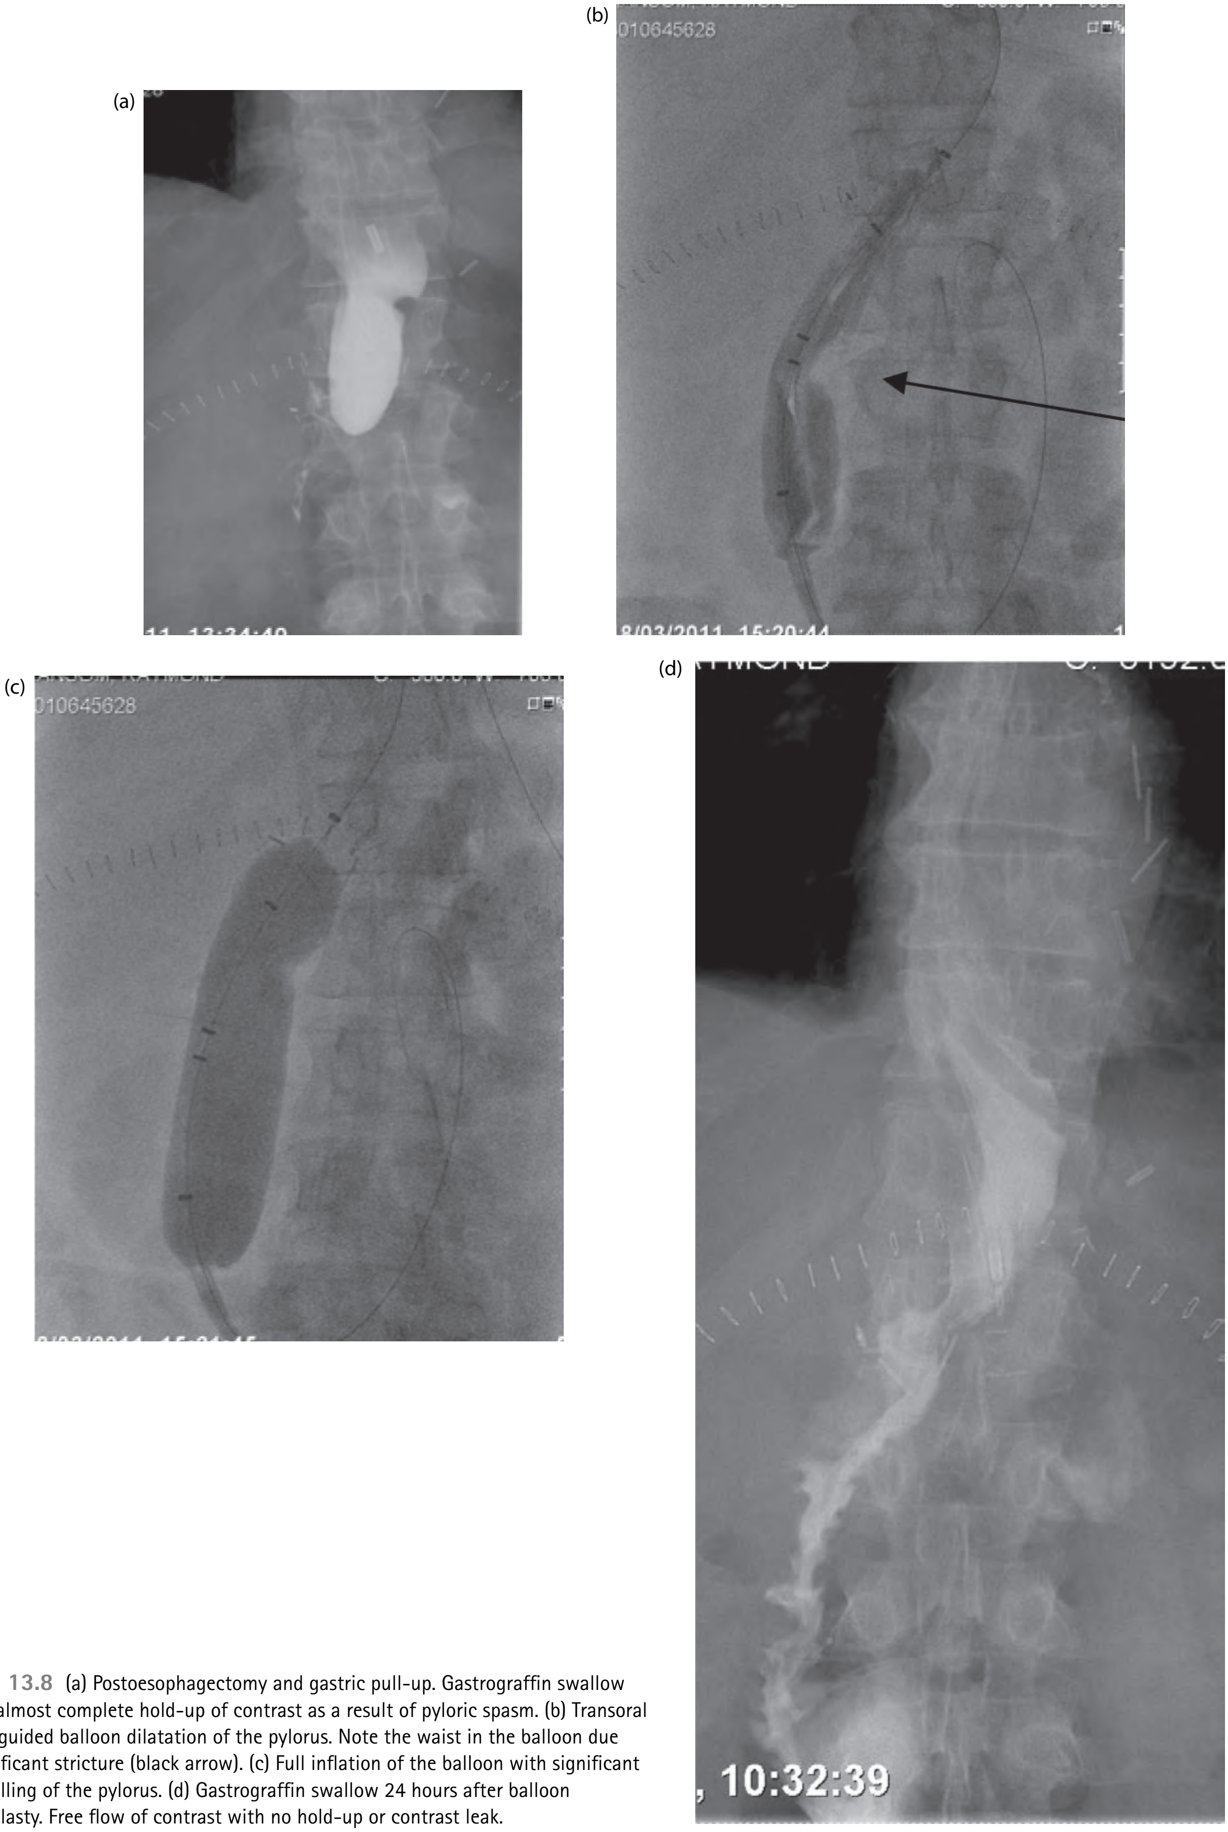

Figure 13.8 (a) Postoesophagectomy and gastric pull-up. Gastrograffin swallow shows almost complete hold-up of contrast as a result of pyloric spasm. (b) Transoral image-guided balloon dilatation of the pylorus. Note the waist in the balloon due to significant stricture (black arrow). (c) Full inflation of the balloon with significant remodelling of the pylorus. (d) Gastrograffin swallow 24 hours after balloon pyloroplasty. Free flow of contrast with no hold-up or contrast leak.

Bleeding can occur in 3–8% of cases. It is generally self-limited. In cases of persistent or heavy bleeding arterial embolization is indicated. Migration can be seen in 0–6% of cases depending on the type of stent, accurate placement and site of the lesion. Self-expandable covered stents are associated with a low incidence of migration. Stents extending into the stomach have a slightly higher chance of migration than stents covering middle oesophageal lesions. Once stent migration happens, restenting using telescopic stents is indicated. The migrated stent can be left *in situ*, if it is causing no abdominal pain or obstruction, or can be removed through a small gastrostomy incision or using endoscopic forceps. Initial chest pain or discomfort is expected in most patients. However, more severe or persistent pain is seen in higher lesions or when large-diameter stents are used. Reflux can be observed in patients with stents crossing the cardia. Antacid and proton pump inhibitors are indicated in those cases.

Once the stent is deployed and the operator is satisfied with its position, the patient is advised to remain nil by mouth for a few hours before resuming clear fluid. The patient should be instructed to start eating well-chewed food, avoid swallowing large pieces of food and drink carbonated drink during the meal to avoid blockage of the stent.

Colon stenting and balloon dilatation

Acute large bowel obstruction (Figure 13.9) can be secondary to a variety of malignant and benign conditions. Colorectal carcinoma is the most common cause of acute large bowel obstruction. Other less frequent malignant causes include metastatic infiltration or infiltration from adjacent malignancy. Benign causes of large bowel obstruction include inflammatory bowel disease and diverticulitis or postradiation stricture.

Patients with acute obstruction have a high mortality and morbidity. The traditional treatment of acute large bowel obstruction is open surgery, usually involving multiple stages. However, surgical intervention is associated with significant mortality and morbidity. In a case–control study comparing the mortality and morbidity between emergency and elective surgery for colon cancer, the mortality was reduced from 34% to 7% and morbidity was reduced from 64% to 24%. The use of metallic stents as a palliative or temporizing measure prior to definitive surgery has become accepted clinical practice. The indications for colorectal stenting are:

- decompression of malignant bowel obstruction to facilitate elective surgery
- palliative decompression of malignant bowel obstruction that is deemed unresectable
- preoperative decompression of benign bowel stricture such as diverticular disease or following radiotherapy
- rarely, in the management of a colonic fistula.

The technical success of stent placement in the colon ranges from 79% to 100%. In a systematic review involving 10 studies and a total of 451 patients comparing colonic stent and open surgery in patients with colon carcinoma, stenting was successful in 92% of cases and was associated with a shorter hospital stay and fewer complications. In a review of 234 patients who had a colonic stent placed for malignant colonic obstruction, the clinical success rate ranged from 75% to 100% with a mean of 90%.

Complications are relatively rare and consist of migration, perforation, bleeding and pain. The overall rate of complication is around 14%. Following successful colonic stent placement, vital signs should be monitored and a plain abdominal film is usually obtained 24–48 hours following the procedure. Stent position and adequate stent expansion are the two important features to look for in the plain film. If stent migration is detected a watchful waiting policy can be taken, as the majority of stents will pass per rectum. Surgery or endoscopic removal is considered if the patient reobstructs. If the stent is inserted for palliative reasons, a stool softener may be helpful to reduce stent obstruction.

Balloon dilatation is reserved for benign strictures such as Crohn's disease and anastomotic strictures. Most patients require one balloon dilatation and the majority of cases respond favourably with a low complication and recurrence rate.

Gastrointestinal bleeding

Lower gastrointestinal bleeding

Lower gastrointestinal bleeding (Figure 13.10) occurs at a rate of approximately 25 cases per 100 000 population per year, with a higher reported incidence among males. Diverticular disease and angiodysplasia are the most common causes of bleeding followed by haemorrhoids, polyps and ischaemic enteritis.

Sigmoidoscopy and colonoscopy represent the first line of investigation and management. The drawback of scoping is the trouble in identifying the exact source of bleeding because of difficulty in visualizing the source of haemorrhage during an active bleed.

Radiological methods such as radioisotopes, angiography and multidetector CT scan allow bleeding points to be identified more readily. Scintigraphy is commonly performed using sulphur colloid or ^{99m}Tc-labelled red blood cells. ^{99m}Tc in particular allows image acquisition over a longer period of time, which can be especially useful for the identification of intermittent bleeding (at rates as low as 0.1–0.5 mL/min) and can increase the sensitivity of subsequent diagnostic angiography. However, the sensitivity and specificity of scintigraphy is highly variable ranging between 24% and 91%.

Percutaneous angiography is performed via a puncture in the femoral or brachial artery. Positive angiography needs active bleeding to occur at a minimum rate of 0.1 mL/min and has sensitivity between 43% and 87%. It is used to demonstrate contrast extravasation, tumour vascularity and/or early draining vein (indicative of angiodysplasia).

With the recent advances in CT technology, there is growing evidence that CT scanning can be helpful in diagnosing the bleeding site, provides information about the underlying pathology, e.g. tumour, and provides information about the arterial anatomy, aiding a quicker and safer angiography. The reported sensitivity, in small series, is around 77%. The limitations of CT scan are the need to give 120 mL of iodinated contrast, radiation and the presence of active bleeding at a rate of 0.5 mL/min.

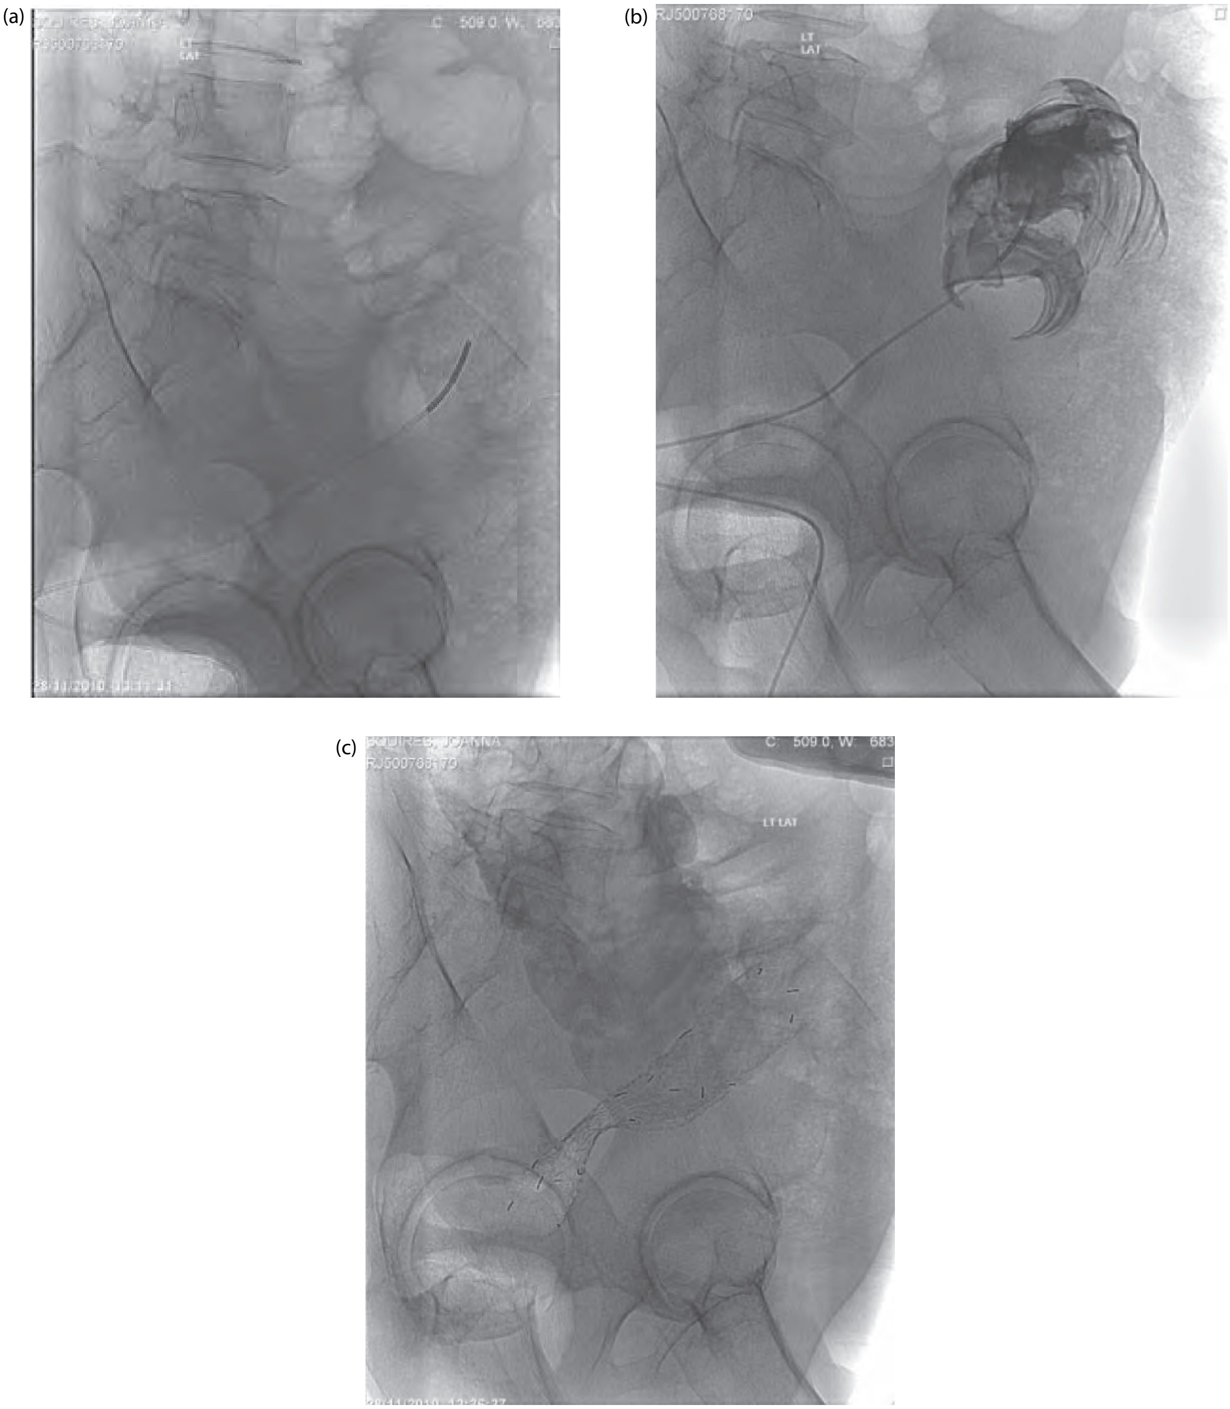

Figure 13.9 (a, b) An 81 year old woman with advanced rectal carcinoma and large bowel obstruction. Lateral fluoroscopy shows that the catheter has crossed the lesion following wire manipulation. (c) A self-expandable stent was deployed across the lesion to relieve the obstruction.

To ensure positive angiography, the patient should be actively bleeding. Bleeding per rectum is probably not the best predictor of active bleeding since the colon has a large capacity to hold blood. Moreover, bleeding has probably stopped when old blood is still passing per rectum. The best clinical indicators of the likelihood of successful angiography are high pulse rate (>100 beats/min), low blood pressure (<90 mmHg) and the need for blood transfusion (5 or more units), i.e. the shocked patient. Nevertheless, elderly patients with limited cardiovascular reserve may not tolerate massive bleeding, with a drastic effect on end-organ perfusion. Therefore, the threshold of performing angiography in this subset of patients should be low. In cases in which active bleeding is uncertain or in patients with chronic low-volume bleeding with negative colonoscopy, angiography is also indicated.

There is no absolute contraindication to visceral angiography, but the relative contraindications include:

- contrast allergy
- renal failure
- coagulopathy.

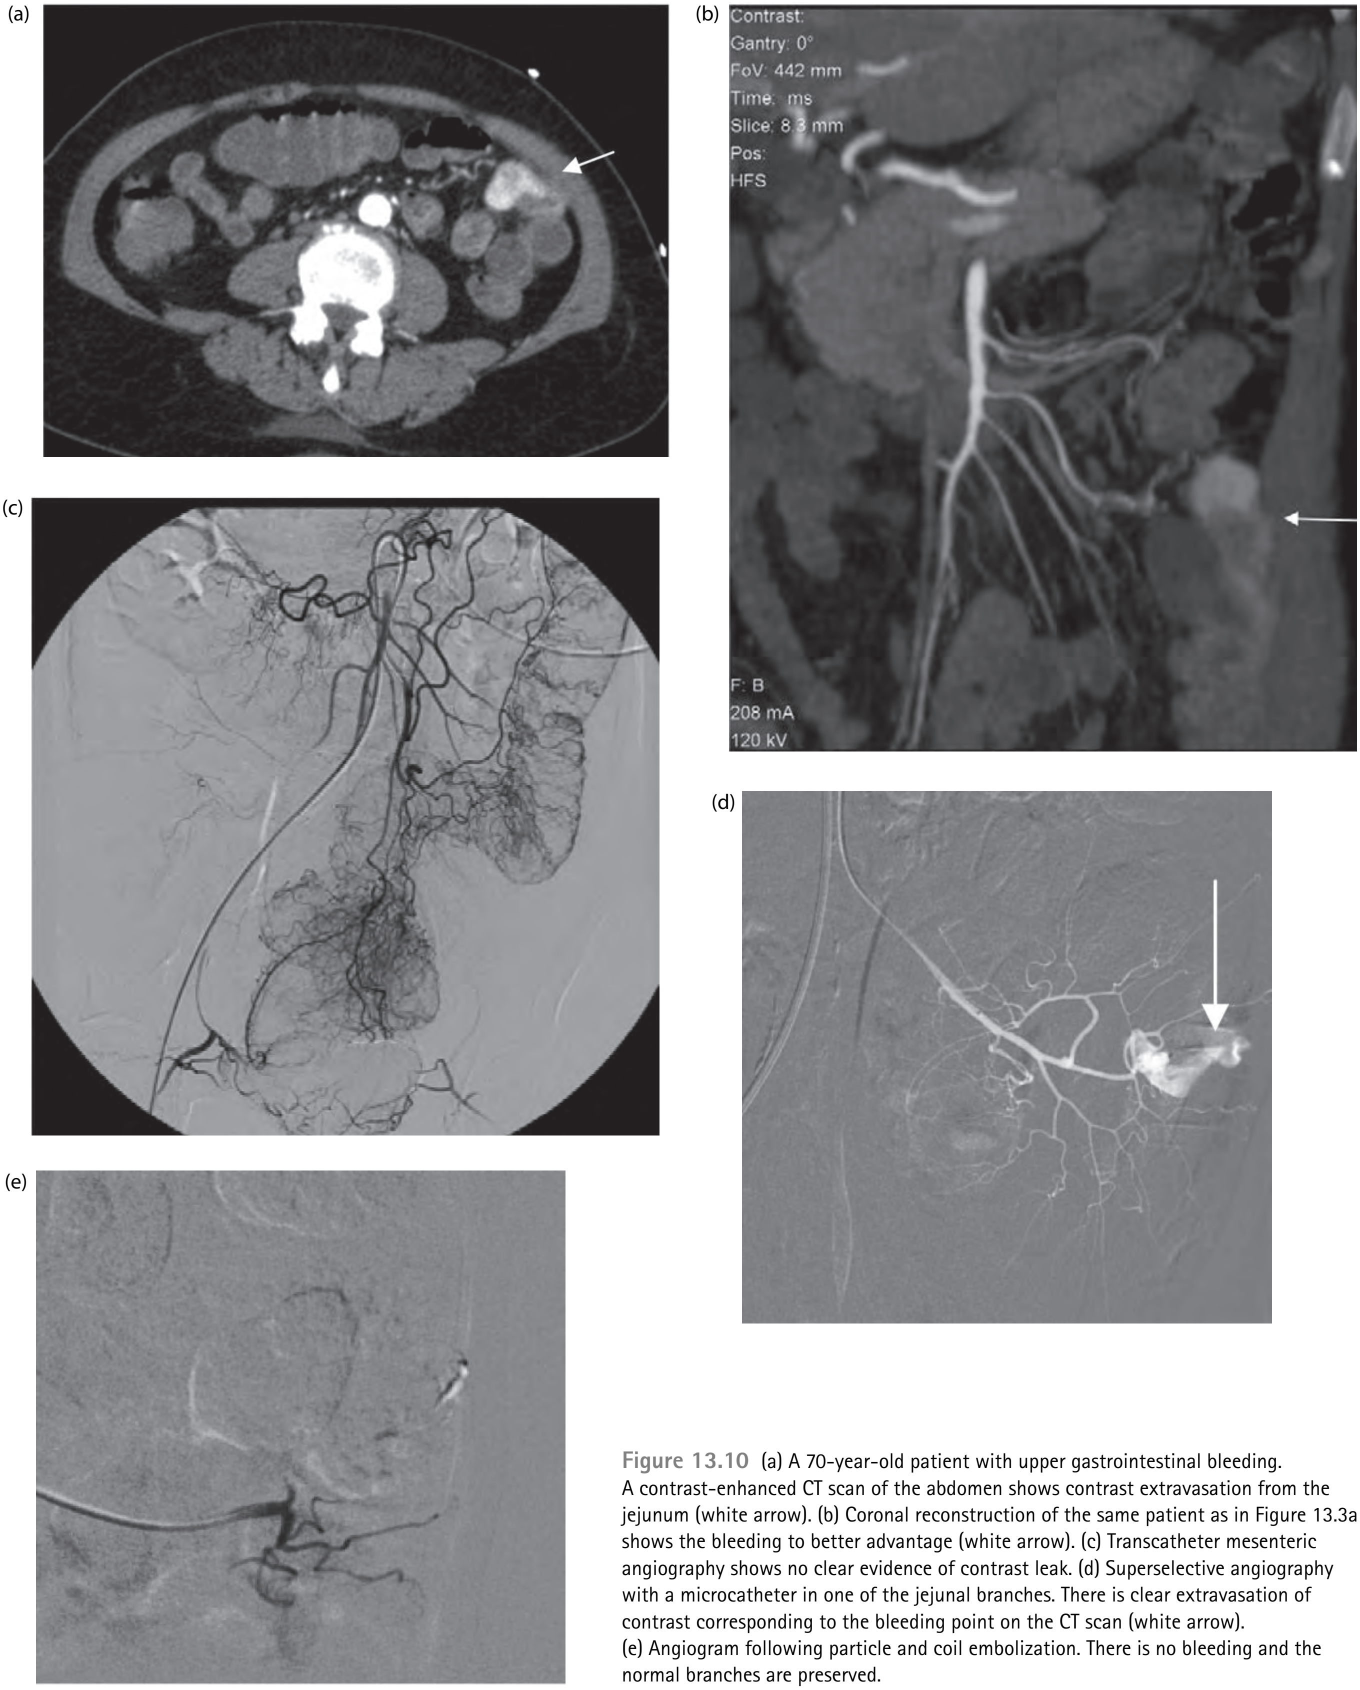

Figure 13.10 (a) A 70-year-old patient with upper gastrointestinal bleeding. A contrast-enhanced CT scan of the abdomen shows contrast extravasation from the jejunum (white arrow). (b) Coronal reconstruction of the same patient as in Figure 13.3a shows the bleeding to better advantage (white arrow). (c) Transcatheter mesenteric angiography shows no clear evidence of contrast leak. (d) Superselective angiography with a microcatheter in one of the jejunal branches. There is clear extravasation of contrast corresponding to the bleeding point on the CT scan (white arrow). (e) Angiogram following particle and coil embolization. There is no bleeding and the normal branches are preserved.

These should be balanced against the benefits gained from angiography such as identification and sealing of the bleeding point. Prophylactic measures such as steroid premedication, adequate hydration and correcting coagulation defects or using a closure device at the puncture site can limit the aforementioned risks.

Gastrointestinal bleeding can be treated using transcatheter embolization. The rationale of this treatment is to decrease the blood flow pressure to the bleeding site to allow clot formation. This can be achieved by using 2.7–3 F microcatheters introduced coaxially through the 5 F selective catheters. This technique allows the embolization process to take place as distal and as close as possible to the extravasation point, together with minimizing the risk of infarction of an adjacent segment of normal bowel. The embolic material used for this purpose includes particles such as polyvinyl alcohol, microcoils and gelfoam particles. The reported technical success of embolization is high, ranging between 73% and 89%. The main reasons for technical failure include small target vessel size, extreme vessel tortuosity, vasospasm and lack of technical expertise. In current practice, transcatheter embolization is accepted as a safe and effective treatment modality. The main causes of rebleeding are failure to achieve the required endpoint of low flow pressure, an unappreciated underlying pathology such as tumour or inflammatory bowel disease and development of collaterals.

The main complication of gastrointestinal embolization is non-target embolization, which could result in bowel infarction or ischaemic stricture. With the advancement in catheter technology, embolic materials and embolization technique, the rate of failed embolization requiring surgical intervention has reduced to around 7%.

Following the embolization procedure, the vascular sheath should be left *in situ* if there is a need for arterial monitoring, uncorrected coagulopathy or a high chance of repeating the procedure. Otherwise, the sheath can be removed and haemostasis is achieved by manual groin compression or by a closure device to the arteriotomy puncture. The patient should be rehydrated, blood products replaced and oxygen administered to minimize the risk of low bowel perfusion and tissue oxygenation. The vital signs, blood counts and abdomen should be monitored regularly for signs of continuous bleeding and/or peritonitis and bowel infarction.

Upper gastrointestinal bleeding

The majority of non-variceal upper gastrointestinal bleeding stops spontaneously. Unlike colonic haemorrhage, endoscopy is the first line of management with adequate injection of the bleeding point producing favourable outcomes. Surgery and embolization are considered in cases that are refractory to endoscopic treatment. Embolization was first performed by Rosch in 1972 and was reserved for high-risk patients. With advancements in catheters and embolic material technology, embolization has now become the second line of management in patients with failed therapeutic endoscopy. As well as being a minimally invasive technique, embolization has the advantage of being suitable for surgically unfit patients and repeatable in cases of persistent bleeding.

Peptic ulcer disease is the most common cause of non-variceal upper gastrointestinal bleeding with the duodenum being the most common site of bleeding. Iatrogenic causes of bleeding such as sphincterotomy, percutaneous transhepatic cholangiogram and live abscess drainage are becoming more frequent.

Non-variceal upper gastrointestinal bleeding is intermittent. Identification of the bleeding site needs the patient to be actively bleeding. Colloid scintigraphy can detect bleeding as slow as 0.1 mL/min whereas red blood cell scintigraphy can detect bleeding at 0.2–0.4 mL/min. Catheter angiography using the current digital subtraction technology can detect bleeding at approximately 0.6 mL/min. Multidetector CT angiography in arterial and venous phases is a promising non-invasive imaging modality with a sensitivity similar to colloid scintigraphy. The advantages of CT scan include repeatability and high sensitivity (which helps in detecting low-flow bleeding together with the ability to plan the next step in management). In cases of failed endoscopy, angiography may need to be considered as an alternative to surgery without the need to wait for full resuscitation as this measure can be taken in the interventional radiology suite. The role of angiography is thus both diagnostic and therapeutic.

There is no absolute contraindication to formal angiography. However, careful management of the access site in patients with severe coagulopathy is important. The sheath could be left in the artery until coagulopathy is corrected with or without the use of occlusion material to seal the puncture hole.

Angiography can detect 40–60% of cases of active non-variceal upper gastrointestinal bleeding. Embolization can control angiographically detected bleeding in 90% of cases with overall clinical success in 50–90% of patients. In a retrospective study of 163 patients with non-variceal upper gastrointestinal bleeding treated by embolization, the total mortality was 33%. Walsh *et al.* found a 17% mortality rate following successful embolization versus 62% if embolization fails.

Specific complications of embolization are rare. Duodenal stricture, ulceration and necrosis are recognized complications. The incidence of complication is higher in patients with a history of previous gastric surgery, radiotherapy or advanced atherosclerosis. Splenic infarction is another rare complication if embolization of the splenic artery is encountered. However, splenectomy in a stable patient is a relatively straightforward surgical procedure should it be required. Liver infarction is expected if there is portal vein thrombosis. Therefore, great care should exercised by the operator in those circumstances.

Postembolization follow-up should continue for at least 30 days to detect late duodenal stricture. If duodenal stricture is expected clinically, radiological confirmation is then advocated with a view to treating symptomatic patients.

Chronic mesenteric ischaemia

Chronic mesenteric ischaemia is a rare condition that usually affects people older than 60 years. Women are typically three times more affected than men. The symptoms of chronic mesenteric ischaemia are usually present when two out of three vessels (coeliac trunk, superior mesenteric and inferior mesenteric arteries) are significantly stenosed (Figure 13.11).

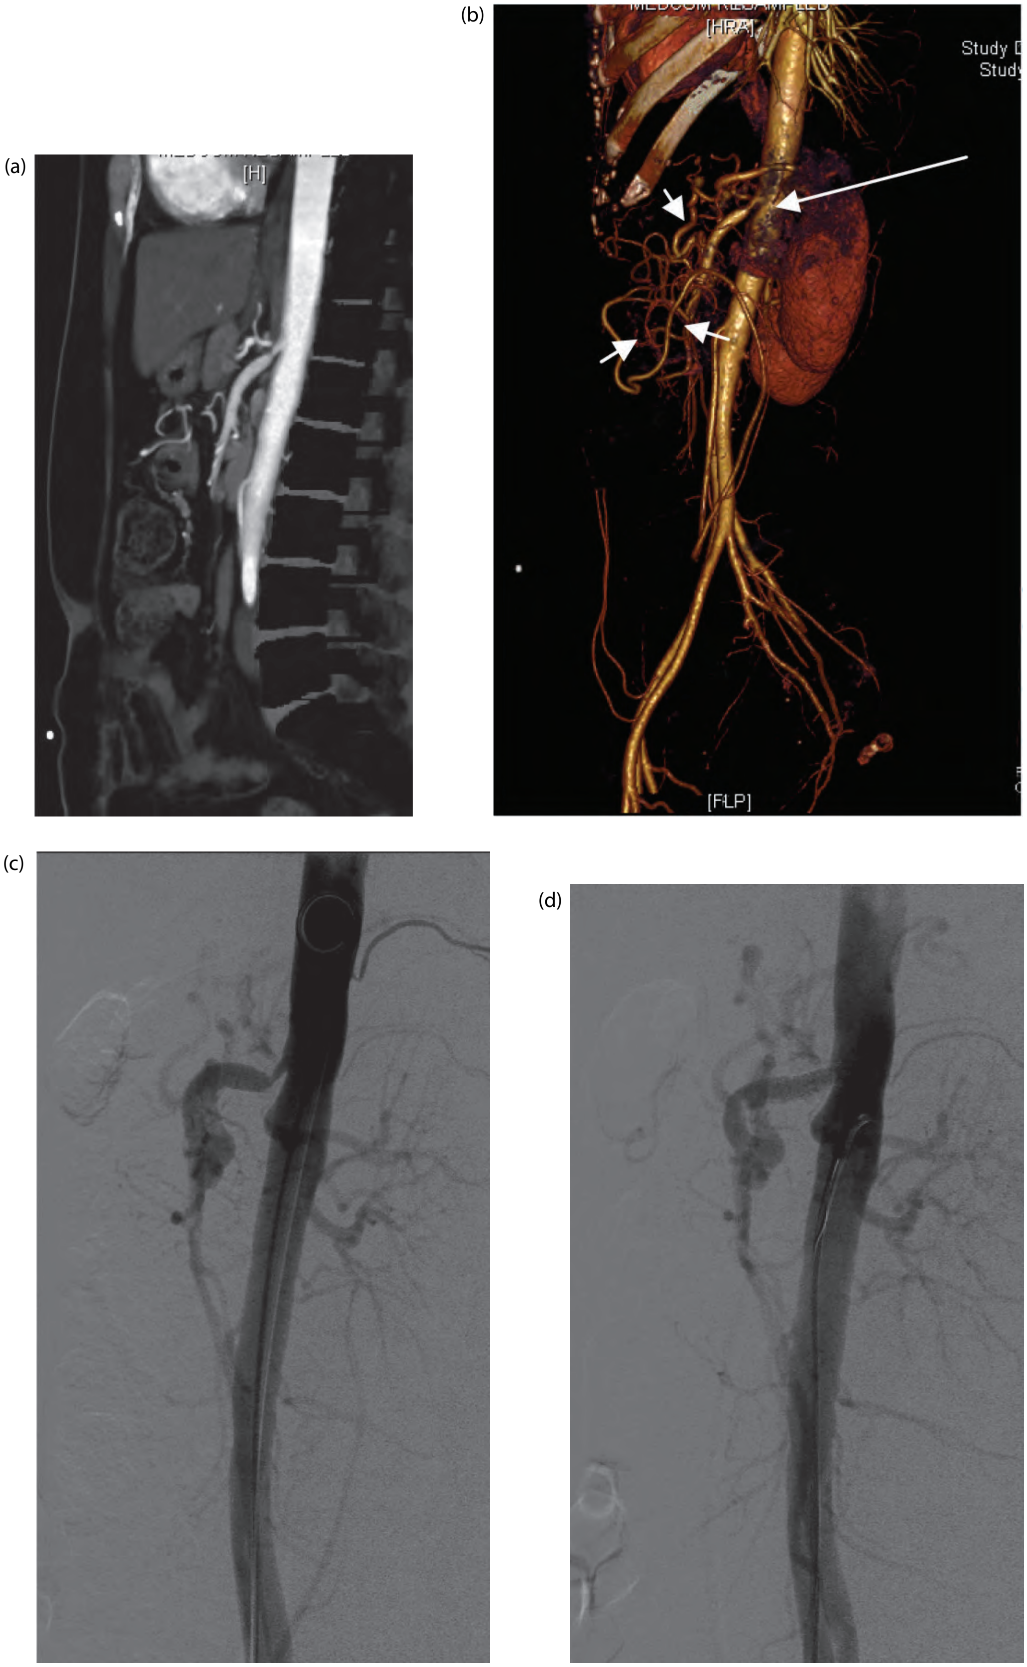

Figure 13.11 (a) Sagittal maximum intensity projection CT angiography shows severe stenosis of the superior mesenteric artery and occluded coeliac trunk at its origin. (b) Volume-rendering CT angiography image shows the stenosis of the superior mesenteric artery (long arrow) and visceral collaterals (short arrows). (c) Catheter angiography confirms the severe stenosis at the origin of the superior mesenteric artery. (d) Catheter angiography following stent angioplasty. Note complete resolution of the stenosis.

However, single-vessel stenosis can sometimes be enough to cause ischaemic symptoms.

Atherosclerosis is the most common cause of mesenteric vessel stenosis. Other causes include Takaysu disease, fibromuscular dysplasia, thrombangitis obliterans and radiotherapy. The majority of patients with visceral artery disease have associated cardiovascular morbidity in other vascular beds.

Clinical diagnosis

Clinically, patients present with postprandial abdominal pain, associated with weight loss, nausea and occasional diarrhoea (which is attributed to villous atrophy). The diagnosis is frequently delayed as weight loss provokes extensive investigations for malignancy in the elderly population, whom it typically affects.

Radiological diagnosis

There are several imaging modalities available to establish the diagnosis of chronic mesenteric ischaemia. CT angiography (CTA) is the most helpful modality. It provides information about the severity of the stenosis, the extent of the disease and assesses the state of the entire aorta as well as the bowel wall. Moreover, it helps the operator to plan the best approach to tackle the lesion in question. CTA is, also, helpful to assess the postoperative complications of open or endovascular treatment. However, CTA with contrast can be nephrotoxic with serious effects on patients with pre-existing poor kidney function.

Magnetic resonance angiography (MRA) is a good alternative to CTA (safe for patients with impaired kidney function) and can provide valuable information regarding the status of vessels and grafts as well as the bowel vascularity. Nevertheless, MRA is inferior to CTA in assessing the patency of stents and presence of atheromatous plaques. Colour Doppler ultrasound has also been used to diagnose visceral artery occlusion or stenosis but this modality depends on operator experience and is known for its poor resolution when compared with CTA or MRA.

Treatment

Patient selection for any intervention is crucial. All non-vascular causes for abdominal pain and weight loss should be excluded both clinically and radiologically prior to intervention. Patients with two or more vessel stenoses can proceed to intervention. Asymptomatic patients with two severely diseased or occluded vessels and awaiting major intestinal surgery may additionally benefit from having at least one vessel revascularized.

Open surgery is considered the traditional treatment of chronic mesenteric ischaemia. Open surgery includes embolectomy and thrombectomy, endarterectomy and bypass grafts. The success rate in relieving symptoms is quite high and 5 year patency rates are reported to be between 75% and 89%. However, this approach is associated with significant morbidity and mortality in comorbid patients. The reported mortality rate ranges from 4% to 17% and morbidity rate from 20% to 33%.

The advances in interventional radiological techniques paved the way for a valid and successful alternative approach to bypass surgery. Percutaneous angioplasty and stenting is a minimally invasive approach with high technical and clinical success. The minimally invasive nature of the procedure allows for early mobility and recovery as well as reduced inpatient stay. The procedure can be performed under local anaesthesia via a femoral or transbrachial approach. Since the first reported case of mesenteric angioplasty by Furrer *et al.* in 1980, several studies have shown good mid- and long-term results of visceral artery stenting and angioplasty. The technical success rate, especially in recent publications, is very high (approaching 100%), reflecting the advances in technology and maturation of operators' experience.

Razavi and Chung (2004) reported their experience in 70 symptomatic patients with 97% technical success and 99% clinical success. The restenosis rate over 3 years was 10%.

In a systematic review of 16 studies including 328 patients, the technical success was 91% and most failures were secondary to the presence of the arcuate median ligament. The reintervention rate for restenosis was 27%, resulting in good primary and secondary assisted patency. However, the authors were unable to analyse the secondary intervention data owing to irregularity in reporting the relevant data. Nevertheless, the review confirmed a very low 30 day mortality rate of 3%.

CHAPTER 14

Trauma and the injured patient

LESLIE KOBAYASHI, RAUL COIMBRA AND DAVID HOYT

General considerations

Trauma remains one of the leading causes of death and disability throughout the world. In the USA, it is the most common cause of death in nearly all age groups under 45 (Figure 14.1). Motor vehicle accidents remain the single most common cause of trauma-related mortality, followed by gunshot wounds and falls.

The classic trimodal distribution of trauma deaths first described by Trunkey in 1983 demonstrates that almost half of all trauma deaths occur in the first hour after injury. Two additional peaks occur within the next 1–4 hours and after the first week of injury. Few patients in the first peak are likely to be saved by the healthcare system, as they die from injury before reaching medical care. In general, survival from these injuries can only be increased by preventative measures. The second peak contains approximately 30% of trauma fatalities and is generally due to haemorrhage. It is this population that constitutes the majority of preventable deaths. The goal of a 'systems' approach to trauma care is to reduce these second peak deaths by increasing efficient and reliable access to medical care following injury. A trauma system operates within a geographical region and provides for rapid transport of victims to specified hospitals within that region. These trauma centres concentrate resources and expertise for treatment of severely injured patients immediately and effectively. The third peak, occurring in days to weeks after injury, is the result of infection and multiorgan failure. Continued understanding of the epidemiology of death and immunosuppression in this peak, as well as quality improvement strategies in the intensive care unit (ICU), may be able to decrease deaths in this peak.

Biomechanics of injury

Injuries occur as a result of energy transfer; this can originate from mechanical, electric, thermal or chemical forces in the environment and results in a physiological imbalance or structural damage in the patient.

The most common type of energy in trauma is kinetic, from the motion of a vehicle, blunt object or bullet. As kinetic energy is equal to one-half mass times velocity squared, the speed of an object, rather than its weight, has the greater impact

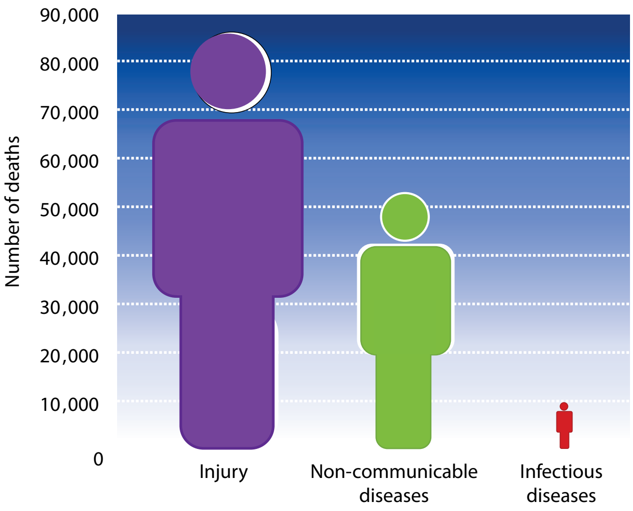

Figure 14.1 Injury deaths compared with other leading causes of death for persons aged 1–44, USA, 2007. (From Web-based Injury Statistics Query and Reporting System (WISQARS); http://www.cdc.gov/injury/wisqars.)

on the overall energy produced, and thus the damage sustained. This is well illustrated by comparing the damage produced by bullets of similar calibre but shot from low- and high-velocity weapons. When the travelling object strikes the patient, force can be imparted by direct contact, or 'impact force', or by cavitation, in which tissue moves away from the point of impact. Two types of cavitation can be created: temporary and permanent. Temporary cavities are created when the surface and structural tissues of the body are stretched but the overall shape of the body is maintained. This is common after blunt trauma. A permanent cavity is created along the lines of an impact force that causes tearing or compression of the tissues, leaving a permanent deformity of the affected tissues that can be identified later. This is often seen after penetrating trauma, in which the site of contact of the knife or bullet to the body is readily seen.

Body tissue properties such as elasticity and viscosity are also important in determining the amount of damage sustained. Relatively elastic tissue such as muscle will sustain less injury than denser, less elastic tissue such as the spleen or liver. Damage is also proportional to the rate of energy transfer, with a similar force applied over a shorter time causing more damage, again emphasizing the importance of the velocity of the objects involved. Also important is the surface area over which force is applied. Equal force applied over a smaller surface area also results in increased damage.

Blunt

Examples of blunt trauma include falls, motor vehicle collisions, pedestrians struck by vehicles, blunt assaults and sports-related injuries. Blunt trauma is the most common type of injury in the USA, with motor vehicle accidents and pedestrians struck by cars being the two most common mechanisms.

Motor vehicle accidents

Several factors influence the severity and pattern of injuries sustained after a crash. The size of the vehicle, the position of the occupant, use and type of restraint devices, the type of accident and the body habitus of the occupant all influence the injury patterns seen. When a vehicle strikes another object three collisions occur: first, the vehicle strikes the object; second, the occupant strikes the vehicle or restraint device; and, third, the internal organs strike the body cavity wall, other organs, ligaments or bone.

Frontal impact

Frontal impact occurs when the vehicle is abruptly stopped from moving forward. This rapid deceleration can result in the occupant moving up and over, or down and under the vehicle. The down and under path can result in lower extremity and pelvic fractures. The upper torso may then rotate forward, striking the vehicle, resulting in abdominal or thoracic injuries. The up and over path results in the occupant being launched over the dashboard or steering column. This results in head and facial trauma. As the torso then strikes the vehicle, compression and shear injuries can result in solid organ injuries, rupture of hollow viscous or bucket handle injury, cardiac contusion and aortic injury.

Lateral impact

In the lateral impact the vehicle is struck from the side, displacing it laterally. This can cause injury when passenger space intrusion impacts the occupant, resulting in rib, pelvic and lower extremity fractures; lung contusions; and solid organ injury. If restraints are involved the body is restrained while the head is free to continue travelling in the direction of the impact, causing flexion/rotation injuries such as spinal fracture, aortic disruption and blunt cerebrovascular injury.

Rollover and ejection

Crashes with rollover and ejection are particularly worrisome because of the potential for high-energy transfer and severe injury. During rollover the vehicle and occupant undergo multiple impacts in rapid succession, occurring at multiple different impact angles, and any type of injury is possible. Ejection also implies a high-energy transfer and rapid deceleration as the victim impacts the vehicle during exit and then impacts the ground; this can result in severe head, neck, facial and torso injuries. Victims of both ejection and rollover should be taken to the nearest trauma centre after stabilization and assumed to have life-threatening injuries until proven otherwise.

Pedestrians struck

Being struck by a vehicle is associated with very-high-energy transfer, and these patients should be considered to have multisystem trauma and transported to the nearest trauma centre for evaluation.

There are three impacts when a pedestrian is struck: first, the bumper strikes the lower extremities, the legs are displaced from under the torso; the second impact occurs when the torso then rolls up onto the bonnet of the vehicle; the third impact occurs as the victim falls away from the car. The victim can be propelled a significant distance through the air in some cases before striking the ground. Fractures of the lower extremities, pelvis, ribs and spine are common, as are injuries to the head and face. The pattern of injury will also depend on the type of vehicle, with passenger cars producing mostly lower extremity and pelvis injuries whereas trucks and vans cause more abdominal and thoracic injuries. Children are smaller and struck anatomically higher than adults with relatively few lower leg and more femur and pelvic fractures and torso injuries. Additionally, children are more likely to be dragged or fall underneath the vehicle, where they can then be run over. Significant closed head and spinal injury should be presumed until proven otherwise.

Penetrating

Penetrating trauma is categorized by the energy level imparted by the source of injury into low, medium and high velocity. Knife or ice-pick wounds are generally low energy and cause trauma only by direct laceration. Handguns and rifles can be low, medium or high energy, and cause injury by direct laceration, crushing of tissues during penetration, and temporary and permanent cavitation. The energy level is determined by the muzzle velocity of the projectile (Table 14.1). Low-energy weapons are those with muzzle velocities of less than 335 m/s. Medium-energy weapons have velocities of 335–610 m/s. High-energy weapons have velocities of greater than 610–760 m/s.

Table 14.1 Weight of projectile, muzzle velocity and approximate maximum kinetic energy of frequently used firearms

Description (calibre)	Projectile weight (g)	Muzzle velocity (feet/s)	KE (feet/lb × 10^2)
Pistols			
0.22 short	29	1000	0.5
0.38 special	158	870	1.8
9 mm Luger	125	1150	2.6
0.45	250	860	2.8
0.357 magnum	158	1430	5.0
0.44 magnum	240	1470	8.1
Rifles			
0.22 long	40	1150	0.8
5.56 mm M-16	55	3250	9.1
Winchester	170	2200	12.8

KE, kinetic energy

Higher velocity weapons tend to cause more tissue destruction because of the larger temporary cavity formed and the effects of fragmentation. Studies of high-velocity bullets demonstrate that the temporary cavity created is approximately 10–20 times the diameter of the projectile.

Common shapes of bullets include round-nose, wadcutter and semi-wadcutter. Bullets can be partially or fully jacketed, referring to the hard copper or alloy covering that will prevent fouling of the rifled barrel. Partially jacketed bullets have a soft exposed nose and are referred to as soft points. Bullets can also have hollowed out points (hollow points); both hollow and soft points will expand when striking tissue, causing tumbling, fragmentation and a wider impact zone, leading to more tissue damage. Fragmentation is a major cause of tissue destruction and occurs when the bullet breaks up after impact with the resulting pieces creating their own paths through the tissue. Alternatively, other parts of the body such as teeth or bone fragments can also become missiles, causing damage to surrounding tissues.

Shotguns are slightly different from handguns and rifles. The calibre is measured in gauge; the lower the gauge number, the wider the internal diameter of the gun. The bullets for shotguns range from single slugs with rifling grooves to numerous steel pellets. These pellets are close together at the muzzle but rapidly spread out as the distance from the gun increases. At close range shotguns are highly destructive, but they cause less injury as the range increases. Close range wounds should be inspected for embedded shotgun shell wadding or part of the shell, as these are potential sources of infection.

Metabolic response to trauma

Metabolism is the complex system of interrelated biochemical reactions and physiological responses required to maintain life. Traumatic injury is one of many stimuli that trigger a set of metabolic changes known as the stress response. The stress response is the body's damage control system, intended to maintain homeostasis on a cellular and systemic level, and to provide substrate for repair of injury. This response involves a set of hormonal and inflammatory signals that produces a hyperdynamic and hypermetabolic state, and mobilizes the immune response promoting haemostasis, wound healing and infection control. The systemic inflammatory response syndrome describes the pathological extension of the stress response.

Severity and type of injury determine the intensity and character of the stress response. The physiological response, described as the 'ebb and flow' phenomenon, is characterized by an early hypovolaemic hypoperfusion state with elevated oxygen consumption, and decreased urine output and blood pressures. During this time the inflammatory and hormonal mediators begin to accumulate. As the patient stabilizes a hyperdynamic state develops. This can take 12–24 hours and is characterized by increased cardiac output, oxygen delivery, tachycardia and fever with restoration of haemodynamic parameters. As oxygen delivery normalizes anaerobic metabolism diminishes, allowing clearance of lactate and base deficit. During this hyperdynamic state, carbohydrate, protein and fat metabolism are significantly altered. Hyperglycaemia, protein catabolism and lipolysis are prominent. The underlying purpose of these changes is the mobilization of energy and substrate for survival and wound healing. Glucagon, cortisol and catecholamines are the primary hormonal mediators of the stress response.

Fluid and electrolyte conservation

Decreases in fluid volume from haemorrhage lead to multiple signals directed at restoring circulating volume. Decreased atrial pressure releases atrial natriuretic peptide (ANP). Aortic and carotid body receptors trigger a neural response relating lower pressures. These inputs work through the hypothalamus and lead to release of antidiuretic hormone (ADH). The renin–angiotensin system is also activated and aldosterone is released. Aldosterone, ADH and ANP then work on the renal tubule to conserve sodium and water.

Hypermetabolism

The hyperdynamic state requires a great deal of energy; this results in an increase in basal metabolic rate (BMR). BMR can be predicted based on age, sex and body size. BMR can be measured using monitoring of respiratory gas exchange. Oxygen consumption in litres per unit time multiplied by 4.8 estimates the BMR in kilocalories per unit time. Metabolic rate is markedly increased in the postinjury patient. Severely injured patients may have a BMR that is 1.5 times normal.

Hyperglycaemia is common and is proportional to the type and severity of injury. In the ebb phase hyperglycaemia and hypoinsulinaemia are present. Later insulin levels rise but hyperglycaemia persists. Glucagon, epinephrine (adrenaline), norepinephrine (noradrenaline), vasopressin and angiotensin II are secreted in response to stress and promote glucose mobilization and production. These signals are also responsible for muscle catabolism. Usual controls of hyperglycaemia are lost and exogenous glucose and insulin no longer suppress hepatic gluconeogenesis. The stress response also increases peripheral insulin resistance, particularly in the skeletal muscle.

Following injury a catabolic state exists and muscle breakdown exceeds production. Nutrition with supplemental protein can help attenuate this response but will not prevent it. Skeletal muscle serves as the primary reserve pool of amino acids that are mobilized for gluconeogenesis in the liver. Glutamine is mobilized preferentially, and serves two unique purposes: it is utilized by gut enterocytes as an energy source and by the kidney for ammonia production. It is also used by fibroblasts and endothelial and immune cells.

The stress state is also lipolytic, and this state is not attenuated by exogenous nutritional sources, it is thought to be perpetuated by continued high sympathetic tone and catecholamine levels. Again, elevation in free fatty acids is proportional to injury severity. These high levels of fatty acids promote pathways of prostenoid production with resultant immunosuppressive effects. It is thought that limiting fat intake to 2 g/kg body weight per day may help to avoid this effect. In addition, modification of the specific fatty acid composition of dietary fat may be of value in modifying the immune response.

Oxygen and energy metabolism are also altered. Normally oxygen delivery exceeds consumption by a ratio of 5:1. This reserve is diminished in the stress state owing to decreased delivery from hypovolaemia, hypoxia and acute blood loss anaemia, and increased consumption from the hypermetabolic state. At the mitochondrial level there is uncoupling of oxidative phosphorylation, which can lead to a reliance on anaerobic pathways despite adequate oxygen delivery.

Because of the hypermetabolic state early nutritional support is essential to the care of the injured patient. Although catabolism is not completely eliminated, full nutritional support is essential for promotion of wound healing, prevention of infection, maintenance of lean body mass, and as a substrate for liver metabolism. Enteral nutrition is also essential to maintain gut mucosal integrity. Enteral nutrition is cheaper than parenteral nutrition, does not require central venous access, is physiological and serves as a trophic factor for enterocytes. There is a growing body of evidence to suggest that specific nutritional factors such as glutamine, arginine and omega-3 fatty acids are immunomodulators and that manipulating their concentrations in enteral feeds may allow the physician to alter the inflammatory response, immune system and nitrogen balance.

Mediators of the stress response to injury

Immune response after injury is complex and still poorly understood. Local tissue damage results in release of chemical signals that trigger local and systemic inflammation. This causes capillary leak, leucocyte infiltration, and local production of free radicals which can result in ongoing tissue damage. Systemically leucocyte demargination and mobilization from the bone marrow and spleen result in leucocytosis with a bias towards immature cell types, known as a 'left shift'. The leucocyte-produced cytokines involved in mediating inflammation include interleukin (IL) 1, IL-2, tumour necrosis factor (TNF) α and interferon (IFN) α.

TNF-α, or cachectin, so named because of its catabolic effects, can also be released by Kupffer cells. It is responsible for fever; anorexia; promotion of proteolysis, skeletal muscle wasting and negative nitrogen balance; tachypnoea; and tachycardia. TNF-α is also responsible for neutrophil release, margination and activation; as well as release of oxidants, superoxide, lysozyme and arachidonic acid metabolites. It is also responsible for increased vascular permeability, procoagulant effects and fibroblast proliferation needed for wound healing. At high levels it can also be associated with hypotension, organ failure and death.

IL-1 is released by macrophages and monocytes. It is similar to TNF-α and causes fever, is chemotactic for neutrophils, and increases endothelial permeability and catabolism. IL-1 stimulates release of IL-2 and IL-6 and shifts the liver to production of acute phase proteins. IL-2, produced by T-lymphocytes, stimulates cell-mediated immunity. It can be suppressed in trauma patients, and the degree of suppression has been correlated with mortality. In contrast, IL-6 is increased in trauma. It is released by fibroblasts and activated B-lymphocytes and promotes fibroblast, β-cell and hepatocyte proliferation.

IFN-α is produced by helper T-cells and macrophages. It is a priming agent for macrophage function, and increases production of other cytokines such as TNF-α, thus promoting the cascade. Other mediators include the leukotrienes, which are products of the lipoxygenase pathway or arachidonic acid metabolism. Produced in the vascular tissue and lung parenchyma by macrophages, mast cells and neutrophils, they serve as chemoattractants and smooth muscle vasoconstrictors. Prostenoids are also products of arachidonic acid metabolism and act as vasodilators, vasoconstrictors and platelet activators.

Specific organ system changes

Every organ system is affected by the stress state. The central nervous system is heavily involved in the response to injury; anxiety, pain and even ICU psychosis can lead to ongoing stimulation of the neurohumoral arm of the stress response. Cortical function may deteriorate as a result of regional ischaemia, accumulation of metabolic by-products or pharmacological agents. The lung is usually the first organ to fail. Carbon dioxide production is increased requiring increased minute ventilation; in addition, the lung is vulnerable to inflammatory effects of the postinjury state. Alveolar damage can trigger a self-perpetuating inflammatory process as the lung is rich in immune cells; this can result in the acute respiratory distress syndrome (ARDS). The liver undergoes major changes in response to injury as well. Hepatic blood flow is diminished; despite a diminished blood supply, hepatic activity is increased with gluconeogenesis, recycling of lactate through the Cori cycle, ureagenesis, and shifting of protein synthesis away from albumin towards acute phase proteins such as C-reactive protein, fibrinogen and caeruloplasmin. If these severe metabolic demands continue the liver becomes overwhelmed and cholestasis and steatosis can develop; if unchecked, frank liver necrosis may result. Gut function and mucosal integrity are diminished as blood flow is redirected away from the splanchnic system towards vital organs such as the heart and brain. In the early stages preservation of intravascular volume is key; oliguria results. As the stress response develops the kidney also needs to increase clearance of metabolic by-products to keep up with their increased production because of the body's hypermetabolic, catabolic and anaerobic state. Higher renal blood flow is required to meet these demands, and if not available because of hypovolaemia/hypotension acute tubular necrosis and azotaemia may result. In addition, circulating cytokines and inflammatory mediators as well as exogenous nephrotoxic agents may cause direct damage to renal tubular cells.

Modification of the stress response

Since cytokines are associated with many deleterious systemic effects, blockade of cytokine production or specific cytokine receptors has the potential to control the stress response. A number of cytokine blockade strategies have been attempted. Antibody to TNF-α has been used successfully to blunt the inflammatory response but has resulted in increased mortality in some trials. Other cytokine antibodies have been trialled alone or in combination with no clear success to date. Cyclo-oxygenase inhibition using non-steroidal anti-inflammatory compounds has the potential to inhibit the inflammatory cascade and has been met with some limited success. Early local and regional anaesthetic techniques have been found to limit the inflammatory response to surgical trauma and may be similarly beneficial in the injured trauma patient. Exogenous insulin and glucose control may be useful in attenuating catabolism; however, tight glucose control does not appear to be more beneficial than moderate control in trauma patients.

A recent area of intense research has been the use of beta-blockade in the injured patient. There is a growing body of evidence to suggest that administration of beta-blockers, particularly in the head-injured patient, may block the catecholamine surge associated with the stress response and decrease multisystem organ dysfunction and improve mortality.

Prehospital care and transport

Prehospital response

The prehospital response describes the systematic approach to the delivery of prehospital care to the injured patient. This system, referred to as emergency medical services (EMS), is usually organized on a local governmental level. The major goals of an EMS system are to provide rapid access by well-equipped vehicles, appropriate field management and rapid transport to an appropriate hospital. The EMS system is organized into three phases: the prospective phase, immediate phase and retrospective phase. The prospective phase encompasses funding, education of personnel, purchase of equipment and vehicles, and development and maintenance of treatment protocols. The immediate phase is initiated when the EMS system is activated, such as through a 999 call, and proceeds through assessment, triage, treatment and transport. Hospital personnel are notified of the situation and anticipated arrival using the MIVT (mechanism, injuries, vital signs, treatment) algorithm. The retrospective phase consists of review of every call after completion to ensure proper medical care was provided and for quality improvement.

Triage

Patients can be categorized into three groups based on their injuries: those that are rapidly fatal; those that are potentially fatal; and those that are not fatal. The first group constitutes approximately 5% of all patients, and are unlikely to benefit from prehospital care; the third group is the most common, representing 80% of all patients, and are unlikely to be harmed by delays in treatment. The second group, approximately 7–15% of patients, consists of those who have potentially fatal injuries. It is these patients who are most likely to benefit from diversion to a mature trauma centre and require most rapid transport.

Many triage protocols exist for identification of these patients. Such protocols aid in determining the optimal distribution of patients to hospitals in the area based on victim factors and the resources of the area such as number of, and distance to, specialty trauma centres. The American College of Surgeons Committee on Trauma (ACS-COT) has a protocol for this in *Resources for the Optimal Care of the Injured Patient*.

Outside of mass casualty and disaster management situations, categorization of traumas is generally based on patient acuity. Prior to the patient's arrival as much data from prehospital personnel should be gathered as possible. The components that determine level of acuity include clinical factors and mechanism of injury (MOI). Clinical criteria include physiological derangements of heart rate, blood pressure and level of consciousness. Clinical criteria have been repeatedly validated as useful triage tools. Scoring systems such as the Revised Trauma Score (RTS) (Table 14.2) are widely used in the field to quickly calculate the injury severity and predict the patient's medical needs. The RTS uses blood pressure, respiratory rate and the Glasgow Coma Scale (GCS) (Table 14.3) to calculate a coded

Table 14.2 Revised trauma score components

Glasgow Coma Scale	Systolic blood pressure (mmHg)	Respiratory rate	Coded value
13–15	>89	10–29	4
9–12	76–89	>29	3
6–8	50–75	6–9	2
4–5	1–49	1–5	1
3	0	0	0

Coma score: (responsiveness sum = 3–15 (E + M + V)).

value. MOI criteria in isolation have a very low predictive value in identifying severely injured patients. However, penetrating mechanisms such as stab wounds and gunshot wounds to the trunk or neck should be considered high-level traumas, as should blunt mechanisms that indicate significant force, such as falls over 4.5 metres, automobile versus pedestrian, and high-speed motor vehicle crashes. Other triage criteria such as age, associated medical conditions, environmental conditions and EMS personnel judgement should also be used during triage. Elderly patients in particular have multiple comorbidities, higher morbidity and mortality than their younger counterparts, sustain more severe injuries with minor mechanisms, and are therefore more likely to benefit from transfer to specialized trauma centres.

Because any triage system will not be perfect they should be evaluated routinely to ensure over- and undertriage rates are at acceptable levels. Undertriage occurs when a patient is not felt to have a serious injury but actually does; this can result in potentially preventable morbidity and mortality. Overtriage occurs when a patient is felt to have sustained a serious injury but actually has not; this can result in overutilization of finite resources. The ACS-COT has determined an acceptable undertriage rate to be ≤5%, while the acceptable overtriage rate may vary from 25% to 50%.

Methods of transport

Several options for transport exist including ground, helicopter or fixed wing flight, with the goal of transport to move patients quickly and safely. In the urban setting there appears to be no significant advantage for flight over ground transportation; rather, the main benefit of flight transport is for long-distance travel. However, air transport has unique complications relating to the patient; these include expansion of gases within body cavities such as pneumothoraces, and in potential spaces such as tissues with gas gangrene or penetrating eye injuries. Air can also expand within equipment such as air splints and endotracheal cuff balloons. Additionally, the space within most air transport vehicles is significantly smaller than that within ground transport vehicles.

Interhospital transfer

There are four ACS-designated trauma centre levels. Although all four levels are maximally committed to care of the trauma victim they are distinguished from each other by available resources and personnel capable of caring for the acutely injured. It is imperative for the initial treating physician to recognize that some trauma victims may require diagnostic or therapeutic modalities beyond the scope of the receiving hospital. The need for transfer is based on patient status, injuries and comorbidities. Injuries that will require prompt treatment by surgical subspecialty services are best treated at designated trauma centres. Examples include damage to the central nervous system; major chest injuries; severe abdominal or pelvic injuries; complex or open fractures; or patients requiring revascularization. Multitrauma patients and those at the extremes of age may also benefit from transfer.

Transfer agreements with designated trauma centres should be present in all hospitals with limited resources for injured patients. Transfer agreements are established protocols between hospitals that ensure rapid and efficient passage of pertinent patient information prior to actual patient transport. This should include patient identification, history and physical examination findings, diagnostic and therapeutic procedures performed and their results. The accepting trauma physician may also suggest possible diagnostic or therapeutic manoeuvres prior to transfer such as intubation or insertion of a nasogastric tube, Foley catheter or thoracostomy tube. It also allows for mobilization of resources such as operating theatre or ICU beds at the receiving hospital. The physicians involved should also discuss the mode of transportation, accompanying personnel and equipment that may be needed for optimal transfer. Derangements in the patient's physiological status should be identified and stabilized as best as possible prior to transfer.

Transfers do have the potential for instability and these risks must be balanced against the benefits of a higher level of care. Risks can be minimized with the use of proper equipment, personnel and planning. In addition to the medical aspects of interhospital transfers, physicians must comply with certain federal and local legal regulations.

Assessment of the injured patient

Prehospital phase

Care of the injured patient begins in the prehospital setting with a tightly integrated emergency medical response system designed to provide immediate access to life-saving medical care. In most locations, this involves a first response team of paramedics who provide basic life-support measures, external compression of bleeding, splinting and spine stabilization within minutes of a traumatic event. Often, these prehospital personnel can also perform advanced procedures, including intravenous access, intubation and pleural decompression. The patient is stabilized and rapidly transported to a trauma centre, where resuscitation is continued and injuries are identified and treated expeditiously.

Hospital phase

The transfer of patient care from prehospital to in-hospital teams should occur in an organized fashion with a report that rapidly details the mechanism of injury, obvious injuries, the patient's vital signs, and treatments provided by prehospital providers (MIVT). The report becomes the formal mechanism by which transfer of care occurs. Assessment and treatment then follow a logical sequence based on clinical judgement and the principles of the Advance Trauma Life Support (ATLS) programme developed by the ACS-COT. A team approach involving physicians, nurses, technicians and trained paramedical personnel allows resuscitation to occur while ongoing evaluation is conducted.

The team must have a captain responsible for organizing the team efforts and performing the primary survey. He or she should rapidly determine the nature of diagnostic tests or interventions required by the patient, and the order in which those activities should be performed. Various tasks can be accomplished simultaneously by different team members, all of which should be co-ordinated by the team leader.

Preparation for patient arrival

Prior to patient arrival it is essential that monitoring devices, warmed intravenous fluids, blood products, multiple intravenous access devices, and Vacutainers for blood samples should be immediately available. Adjunctive devices – suction canisters, intubation and ventilation equipment, urinary and nasogastric catheters, splinting or casting material, pelvic binders and surgical instrument trays – should also be easily accessible.

Personal protective gear (PPG) should be donned by all members of the treatment team. Precautions should include occlusive gown, gloves, face shield or at a minimum eye protection, a mask and surgical cap if any sterile procedures are anticipated, and shoe covers. PPG is worn not only for the protection of the patient but also for the protection of the staff from blood-borne infection, which ranged from 1.4% to 1.9% for HIV and from 3% to 8% for hepatitis C in recent studies of trauma patients.

Primary survey

The primary survey consists of the ABCDEs (airway, breathing, circulation, disability and exposure/environment). This ABCDE sequence has been derived to address life-threatening injuries most rapidly; as such, airway obstruction, which causes death in 1–5 minutes, is first, while less rapidly lethal problems such as hypoxia and hypotension are second and third. Upon arrival patients are visually surveyed for injuries; devices such as non-invasive blood pressure cuffs, pulse oximetry and electrical cardiac monitors are used to obtain vital signs; large-bore intravenous access is established; and the patient is completely disrobed. Adjuncts to the primary survey include plain radiographs of the chest and pelvis, and focused assessment with sonography for trauma (FAST), including views of the abdomen and pericardium.

During evaluation of the ABCDEs full spinal precautions should be maintained, and resuscitation should be ongoing. A type and cross-match should be the first priority in obtaining blood samples. Blood should also be drawn to obtain haematological, chemical and coagulation profiles, and arterial co-oximetry. Pregnancy tests should be done in all females of childbearing age.

Airway

The clinician must assess whether the airway is patent, whether it is protected and whether there is an evolving injury that may have an impact on future patency of the airway. The patient who responds when questioned has an adequate, protected airway. The patient who is unconscious or who demonstrates respiratory insufficiency is at risk for aspiration, hypoxia and hypercarbia, and requires definitive airway control.

The evaluator should perform simple manoeuvres such as the jaw thrust or chin lift, and suctioning of the mouth and oropharynx to clear the airway, and high-flow supplemental oxygen should be provided. Supplements such as the nasal trumpet and oral airway can be considered. During this time, any interventions require an awareness of the possibility of cervical spine injury.

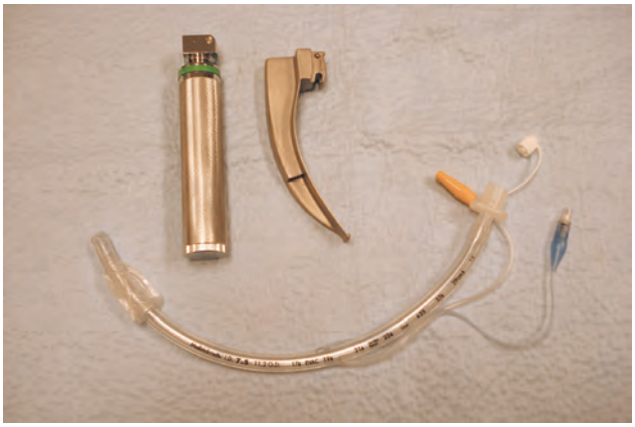

Figure 14.2 Airway tools: laryngoscope and endotracheal tube.

If there continues to be evidence of respiratory insufficiency after these manoeuvres, or if the patient remains unable to protect the airway, definitive control with endotracheal intubation or cricothyroidotomy is necessary (Figure 14.2). Intubation in the comatose patient can generally be accomplished without sedating or paralysing medications. Increased muscular tone and biting make sedating and paralytic agents necessary, as does intubation of the conscious patient. In these cases rapid sequence intubation (RSI) is utilized. RSI is a technique of administering boluses of a sedative with/without a paralytic agent while using cricoid pressure to prevent aspiration with little or no preoxygenation, again to prevent gastric insufflation and aspiration. It is important to obtain a very quick neurological assessment prior to intubation: if 5–10 seconds can be spared, an assistant should ask the awake patient to move his or her limbs, briefly assess sensation and perform a pupillary examination. In the comatose patient response to painful stimuli should be ascertained and a rectal and pupillary examination should be performed. Once intubation is accomplished, appropriate positioning of the endotracheal tube (ETT) should be confirmed clinically, with a carbon dioxide detector, and radiographically. Care should be taken to rule out right mainstem intubation.

In some cases traditional orotracheal intubation can be difficult or impossible; in these cases conversion to a surgical airway should occur immediately. Cricothyroidotomy is the preferred surgical airway in adults. The patient's neck is exposed while maintaining strict cervical spine immobilization, the cricothyroid membrane is palpated between the thyroid and cricoid cartilages, a vertical midline incision is made in the skin, the membrane is exposed and divided in the transverse direction, and the ETT or tracheostomy tube is placed into the airway.

In certain patients the airway may be patent upon initial inspection but may be in danger of becoming compromised. These high-risk patients and those who require prolonged transport may benefit from elective placement of a definitive airway. Finally, agitated and combative patients or those with acute alcohol or drug intoxication may be unable to protect their airway and should be promptly intubated as well.

Breathing

After establishing a controlled airway it is necessary to ensure adequate gas exchange. Life-threatening conditions that should be diagnosed on primary survey include tension pneumothorax (Figure 14.3), open pneumothorax or sucking chest wound (Figure 14.4), massive haemothorax (Figure 14.5) and flail chest (Figure 14.6). These should be identified by absence of breath sounds on clinical examination in most cases and treated with tube thoracostomy, pain control and mechanical ventilation.

Once the most immediately life-threatening injuries have been addressed, adjuncts to the breathing assessment such as arterial blood gas and plain radiographs can be obtained. Arterial blood gas is especially important in the head-injured and comatose patient as significant hypercapnia may be present and is difficult or impossible to assess clinically. Chest radiograph (CXR) is an essential adjunct to the primary survey and can aid in diagnosis and treatment of both airway and breathing problems. It can be used to assess correct positioning of definitive airways and chest tubes and to detect simple pneumothorax, haemothorax, pulmonary contusion and broken ribs. CXR can also reveal a widened mediastinum, which may indicate thoracic aortic injury; sternal or thoracic spinal fracture; and an enlarged cardiac silhouette, which might indicate the presence of pericardial fluid.

Circulation

After airway and breathing complications are addressed, circulation is the next priority. Blood pressure, pulse, skin perfusion, urine output, mental status and central venous pressure are clinically useful indicators of haemodynamic condition. The goal

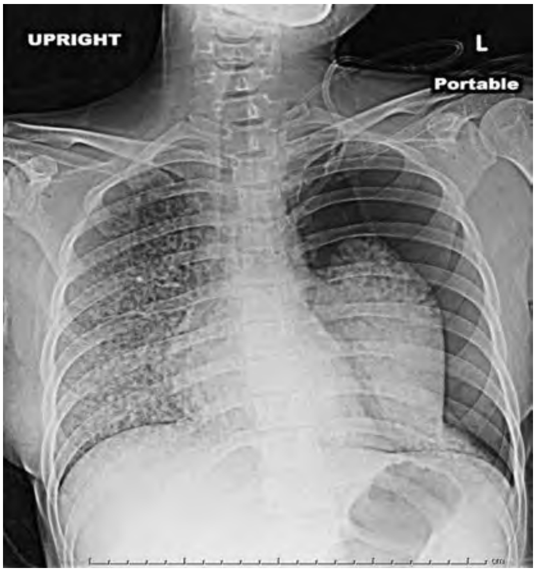

Figure 14.3 Chest radiograph demonstrating tension pneumothorax; note the deviation of the trachea and heart away from the pneumothorax to the contralateral side.

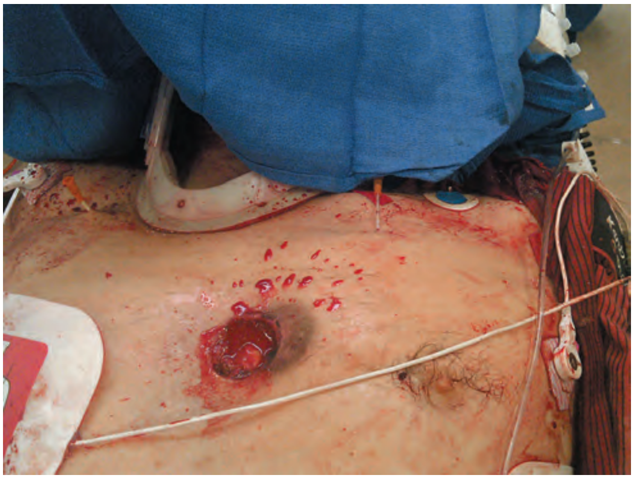

Figure 14.4 Sucking chest wound from close range shotgun blast.

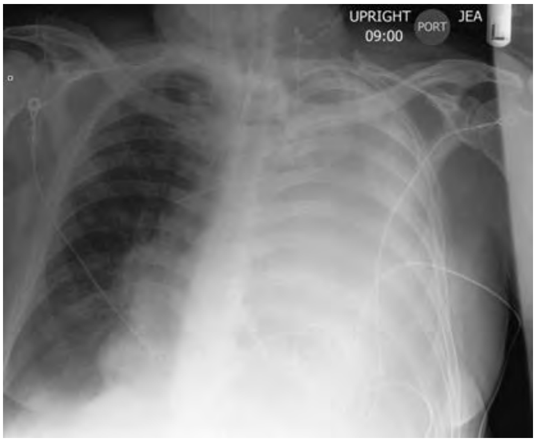

Figure 14.5 Chest radiograph demonstrating massive haemothorax of the left chest; note the deviation of the mediastinal structures to the contralateral side.

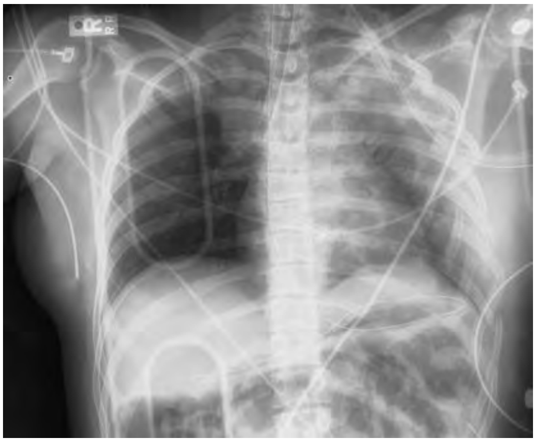

Figure 14.6 Chest radiograph demonstrating flail segment of the left lower ribs with associated haemothorax causing increased opacification of the left hemithorax.

is to determine whether the patient is in shock. It should be kept in mind that elderly patients often lack the intrinsic ability to mount a sympathetic response to haemorrhage or may be on beta-blockers, preventing normal tachycardia, and be in a state of occult hypoperfusion with apparently normal vital signs.

Types of shock include cardiogenic, redistributive, obstructive and hypovolaemic. Hypovolaemic shock due to blood loss is the most common cause and should be assumed to be the source of hypotension in all trauma patients. However, both types of obstructive shock should be rapidly ruled out in all hypotensive trauma patients. These are tension and cardiac tamponade. Cardiac tamponade results from external compression of the heart by blood or fluid resulting in hypotension. Clinical indications of tamponade include restlessness, inability to lie supine, distended neck veins, muffled heart sounds and pulsus paradoxicus. Diagnosis can be confirmed with pericardial ultrasound, which is highly sensitive and specific, nearing 100% in most studies. If tamponade is confirmed, treatment is emergency surgery. If no surgeon is present pericardiocentesis can be used to temporize the patient until transfer to a surgeon can occur.

Haemorrhagic shock is classified according to severity, amount of blood lost and extent of organ failure (Table 14.4). Areas where significant blood loss can occur include external loss and bleeding into the chest, the abdomen, the pelvis or retroperitoneum, and the extremities. Ongoing fluid requirements or lack of response to resuscitation indicates significant haemorrhage and necessitates immediate measures to identify and control the source of bleeding. Sources of external bleeding should be controlled with direct pressure or tourniquets, and fractures should be splinted. Bleeding into the chest is diagnosed primarily with CXR or after chest tube placement. Pleural effusion, appearance of elevated hemidiaphragm, and white-out of the affected lung field are all indications of haemothorax and should be treated with immediate placement of a thoracostomy tube. Evidence of significant abdominal trauma on physical examination includes seat belt signs, abdominal wall haematomas or lacerations, or abdominal distension. Haemoperitoneum may also cause peritonitis and significant abdominal pain. Patients with peritonitis should be taken urgently for laparotomy regardless of their haemodynamic status. Patients without peritonitis should undergo FAST. FAST consists of four ultrasonographic views: the pericardium (subxiphoid or parasternal), hepatorenal fossa, splenorenal fossa and around the bladder. FAST is easily accessible, can be performed in less than 2 minutes and is portable, repeatable, inexpensive and non-invasive. A positive FAST (Figure 14.7) in a hypotensive patient is an indication for immediate laparotomy. However, an equivocal or negative FAST, especially in the hypotensive patient, cannot reliably rule out intra-abdominal bleeding. In the unstable patient, if the FAST is negative or equivocal, diagnostic peritoneal aspiration (DPA) should be performed. Aspiration of 10 mL of blood or more is considered positive. If no blood returns consideration can be given to diagnostic peritoneal lavage (DPL). If gross blood or succus is noted, this is a positive finding if at least 75% of the infusate is returned. If >100 000 red blood cells (RBCs)/mm^3 (blunt) or 1000 RBCs/mm^3 (penetrating), >500 white blood cells (WBCs)/mm^3 or food particles are found this is also considered a positive finding necessitating laparotomy. If FAST and DPA are negative in patients with abdominal trauma, retroperitoneal and pelvic bleeding are potential sources of haemorrhage. Clinical examination includes palpation of the pelvis for lateral and anteroposterior stability. A stable pelvis on examination with full active range of motion of both hips nearly excludes significant pelvic fracture. In comatose patients this may not be possible, and the mainstay of diagnosis is plain film of the pelvis (PXR). If pelvic fracture is diagnosed on clinical examination or PXR and hypotension is present the pelvic ring should be reapproximated using an external compression device; these include pelvic binders, external fixators and sheets. The placement of stabilization devices closes the pelvic ring, decreases pelvic volume and tamponades bleeding.

Table 14.4 Classification of shock in adults based on initial presentation (for a 70 kg man)

	Class I	Class II	Class III	Class IV
Blood loss (mL)	≤750	750–1500	1500–2000	≥2000
Blood loss (% blood volume)	≤15	15–30	30–40	≥40
Pulse rate	<100	>100	>120	>140
Blood pressure	Normal	Normal	↓	↓
Pulse pressure	Normal or ↑	↓	↓	↓
Capillary refill	Normal	Delayed	Delayed	Delayed

Improvements in prehospital care have resulted in more frequent transport of patients *in extremis* to trauma centres. Rapid assessment of these patients is required to decide who will benefit from aggressive resuscitative efforts. Resuscitative thoracotomy or emergency department thoracotomy (EDT) is performed to address cardiovascular collapse. It allows evacuation of haemothorax/pneumothorax, release of tamponade, repair of cardiac and intrathoracic vessel injuries, evacuation of air embolus, clamping of hilar injuries, cross-clamping of the aorta, and performance of open cardiac massage (Figure 14.8). In general, EDT is indicated for patients with witnessed arrest with cardiopulmonary resuscitation (CPR) <5 minutes

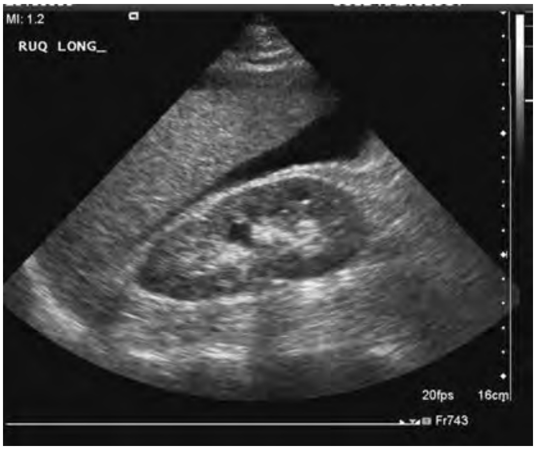

Figure 14.7 Positive focused assessment with sonography for trauma: the dark strip represents free fluid in Morrison's pouch between the liver and the right kidney.

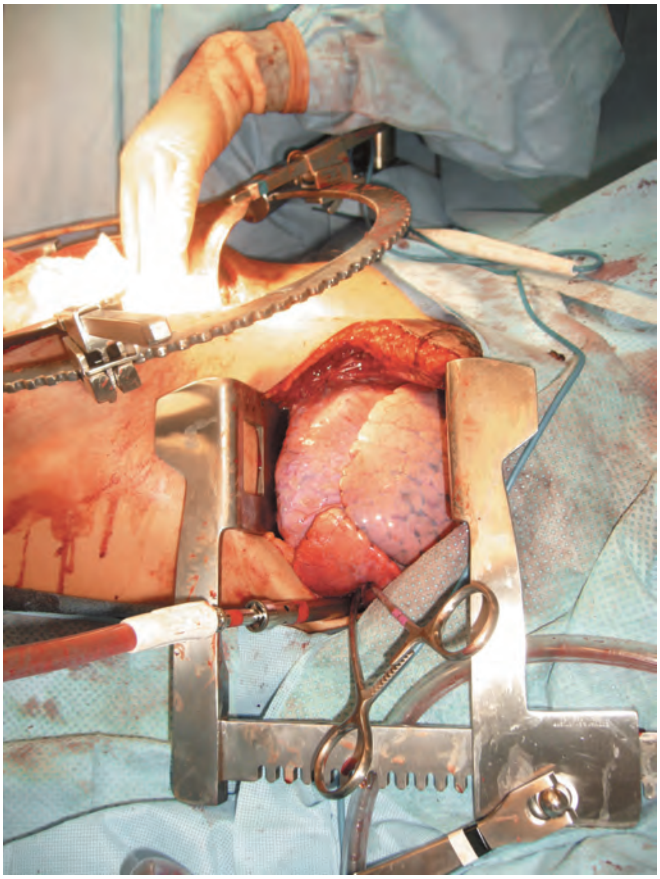

Figure 14.8 Resuscitative thoracotomy with aortic cross-clamp in place.

following penetrating thoracic trauma, witnessed arrest upon or after arrival following blunt trauma if signs of life were present in the field, and persistent hypotension due to tamponade or intrathoracic haemorrhage. Outcomes are best with penetrating cardiac injury, followed by penetrating non-cardiac thoracic trauma. Outcomes following penetrating and blunt abdominal trauma are poor. Outcomes in children are similar to adults, and indications for paediatric EDT are similar to those for adults.

Resuscitation strategies

Treatment of shock begins with immediate insertion of two large-bore intravenous lines, ideally placed during the prehospital phase; however, placement of such lines should not delay transport. If peripheral access is impossible an intraosseous or central line can be inserted. Intraosseous lines can be placed into the tibia, humerus, sternum or clavicle. The rate of infusion and the range of medications that can be infused through an intraosseous line are excellent and comparable to peripheral venous lines. As with any invasive procedure, complications from intraosseous insertion do occur, including compartment syndrome, osteomyelitis and fracture; however, complication rates are very low. Central venous catheters are also an option. Locations for central lines include jugular, subclavian and femoral. Care should be taken to avoid placement of central lines when significant vascular injury proximal to the access site is suspected. Other choices for venous access include saphenous vein cutdown at the ankle or groin, or cutdowns to the cephalic or basilic vein in the antecubital fossa.

Resuscitation should begin with infusion of 2 litres of warmed crystalloid if hypotension is present. If the systolic blood pressure fails to improve, O-negative packed RBCs (PRBCs) should be transfused. However, in selected patients with penetrating torso trauma a strategy of permissive hypotension may be beneficial. A study in which patients were randomized to traditional or delayed resuscitation revealed a significant survival benefit in patients with delayed fluid resuscitation, as well as fewer complications and shorter hospital lengths of stay. However, few studies have been able to replicate the positive effects of delayed resuscitation. At this time, there is still active debate as to the benefit of permissive hypotension and the mainstay of treatment of haemorrhagic shock remains active fluid resuscitation and immediate source control.

When transfusion of large volumes of blood is necessary the optimum ratio of PRBCs to fresh frozen plasma and platelets is also an area of active research. Massive transfusion is variably defined, but is generally accepted to be any patient requiring >10 units of PRBCs within the first 24 hours of hospitalization. In these cases, dilution of fibrinogen, platelets and clotting factors occurs as whole blood is lost, and is replaced with only PRBCs and crystalloid. Both military and civilian studies reveal decreased mortality in a step-wise fashion with increasing plasma to red cell ratio, with optimal results approaching a ratio of 1:1. Protocolizing transfusion and transfusion ratios has increased in popularity recently. The goal of massive transfusion protocols (MTPs) is to standardize the replacement of platelets and clotting factors in the optimum ratio to red cells to prevent coagulopathy, but avoid increased risks of multisystem organ dysfunction and increase efficiency of transfusion. MTPs are helpful in reducing time to transfusion, which results in faster blood/component replacement and may decrease crystalloid volumes. Reduced times to transfusion of first blood products exclusive of the transfusion ratio has also been associated with decreased mortality.

An adjunct to a balanced transfusion strategy is the use of pharmacological agents to treat coagulopathy, including recombinant human factor VIIa and prothrombin complex, which contain factors II, VII, IX and X. There is some evidence that use of these agents may result in decreased transfusion requirements and lower rates of transfusion-related organ failure among certain trauma patients.

Disability

After securing the airway and restoring oxygenation, ventilation and adequate circulation, the patient's neurological status should be ascertained. This consists of the GCS score (Table 14.3), pupillary examination and gross determination of movement and sensation. The neurological examination should be deferred until restoration of adequate oxygenation, ventilation and circulation as any derangements can render the examination inaccurate. Other factors that may alter the GCS score and pupillary examination include intoxication with drugs or alcohol, hypothermia and hypoglycaemia. After restoration of oxygenation and circulation, any pupillary abnormalities or alterations in GCS score should be presumed to be the result of traumatic brain injury until advanced imaging has definitively ruled it out. Patients with a GCS score of ≤8 or lateralizing signs are very likely to have an intracranial mass lesion requiring prompt surgical intervention.

Any patients with presumed brain injury should undergo CT scan of the head as soon as possible after the primary survey is completed. Patients with a GCS score of ≤8 and any two of age >40, hypotension or lateralizing signs are at significantly increased risk of intracranial hypertension, and should undergo placement of an intracranial pressure-monitoring device regardless of CT findings. In patients with presumed or confirmed brain injury neuroprotective resuscitation should begin as soon as possible. This includes mild hyperventilation to a $P\text{aCO}_2$ of 32–35 mmHg, circulating blood volume, avoidance of hypotonic solutions and maintenance of adequate oxygenation.

Full spinal precautions must be maintained with protection and immobilization of the entire spine throughout the evaluation process. Previously in patients with definite evidence of blunt spinal cord injury a steroid bolus followed by continuous infusion for 24–72 hours was recommended. However, a growing concern over limitations of the studies these guidelines were based on and failure of subsequent studies to demonstrate a definite benefit to steroid administration have led to the removal of the recommendations for the use of steroids in spinal cord injury from the 8th edition of the ATLS manual.

Exposure

In order to complete the primary survey the patient must be fully disrobed to reveal all injuries, and log-rolled maintaining full spinal precautions to assess the back and perineum. After complete visual inspection, the patient should be covered as quickly as possible with warm blankets to prevent hypothermia.

Interestingly, several studies of victims of non-traumatic cardiac arrest and patients undergoing cardiac or neurosurgical procedures have shown significant improvements in outcome with induction of mild to moderate hypothermia with core temperatures of 32–34°C. However, results in trauma patients have shown a significantly higher rate of multisystem organ dysfunction and mortality. Traumatic brain injury, in particular, has shown no benefit in survival or neurological outcome with therapeutic hypothermia. At this time hypothermia should still be considered detrimental in both the adult and paediatric trauma population.

Secondary survey

The secondary survey is a quick but comprehensive head-to-toe physical examination. The secondary survey may include simple or advanced imaging such as extremity plain films or CT scans. The secondary survey also includes a brief directed history, which should follow the AMPLE model of allergies, medications, past illnesses/operations, last meal, and events/environment related to the injury. The history should be directed at detection of pre-existing conditions or medications that may alter management of life-threatening injuries. The history should also include information from the prehospital providers regarding the mechanism of injury, which can help the physician to judge those areas of the body that may have sustained the greatest energy transfer so that subsequent investigations can be directed appropriately.

The head and neck examination should include inspection and palpation to detect lacerations, haematomas, fractures and tenderness, otoscopic evaluation to detect haemotympanum, and assessment of all cranial nerves. Any lacerations should be rapidly closed with sutures or staples to prevent ongoing blood loss. The primary adjuncts to the head and neck assessment include radiographs of the cervical spine and CT scans of the head, face and neck. CT of the neck can also be performed with intravenous contrast to assess the soft tissues and carotid and vertebral arteries with high sensitivity.

The majority of the thoracic examination is undertaken in the primary survey, when physical examination and CXR will detect most injuries. The two major exceptions are thoracic aortic injury and thoracic spine fracture. Both may present with widened mediastinum and back pain. Patients with aortic injury may also have loss of aortic contour, apical capping, tracheal or nasogastric tube deviation, and loss of the aortopulmonary window on CXR. Any patient with significant external evidence of thoracic trauma should undergo electrocardiogram (ECG) and CT scan of the chest with intravenous contrast. Patients with ECG changes may have blunt cardiac injury and should be monitored with telemetry for at least 24 hours. The CT scan of the chest will reliably diagnose spinal fracture, give additional information on parenchymal lung injury (contusion, laceration, occult pneumothorax), and is now the screening examination of choice for thoracic aortic injury.

The abdomen and pelvis should be inspected and palpated during the secondary survey. A rectal examination should be performed. If the prostate is noted to be high riding, in the presence of urethral bleeding or perineal/scrotal haematoma, a retrograde urethrogram should be performed to rule out urethral injury prior to Foley catheter placement. If there is evidence of injury, a suprapubic catheter can be placed. As stated previously, unstable patients may undergo DPA/DPL as an adjunct to the primary or secondary survey. In stable patients an adjunct to the secondary survey is a CT scan of the abdomen and pelvis. CT scan of the abdomen and pelvis with intravenous contrast can detect fractures of the thoracolumbar spine and pelvis, free fluid or air in the peritoneal cavity, and solid organ injury. Additionally, in the presence of concerning pelvic fractures or gross haematuria, delayed phase images can be obtained to examine the urinary collecting system. CT scan of the abdomen and pelvis cannot be relied upon to detect hollow viscous injury. Some signs of hollow viscous injury on CT scan include free fluid without solid organ injury, focally thickened bowel wall and free intraperitoneal gas; however, these signs are neither sensitive nor specific. The gold standard for detection of hollow viscous injury remains laparotomy or serial observation.

The patient should also be log-rolled while maintaining full spinal precautions to inspect the back, spine and posterior head and neck for wounds, crepitus and any tenderness to palpation.

A complete musculoskeletal survey should also be performed during the secondary survey; all joints should be assessed for passive and active range of motion, long bones should be assessed for instability, the limbs should be examined for external signs of trauma or violation of the joints, and a sensory examination of all dermatomes should be performed to assess for peripheral nerve injury. A complete assessment of all peripheral pulses should also be performed. If any asymmetry is noted, and in cases of obvious fracture or deformity even if pulses are present in the affected limb, an ankle–brachial index (ABI) or brachial–brachial index (BBI) should be performed after reduction of fractures to rule out occult vascular injury. The blood pressure should be taken below the level of injury and compared with the systolic blood pressure in the unaffected upper extremity. If the ABI or BBI is >0.9 occult arterial injury is unlikely; if it is <0.9 further imaging should be obtained. Ultrasound and CT angiography are commonly used modalities. Extremities must be monitored frequently for the development of compartment syndrome. Compartment pressures should be measured if any symptoms such as pain out of proportion to examination or with passive range of motion or signs such as oedema or tense compartments develop. Elevated compartment pressures are an indication for emergency fasciotomy.

Once the secondary survey has been completed, if the decision to transfer the patient to another facility has been made, transfer should not be delayed for adjunctive imaging, and an appropriate level of transport care should be determined and arranged.

Specific injuries

Soft-tissue injuries of the neck

The neck is an anatomically complex region that acts as a conduit for multiple structures, including vital components of the vascular, neurological, respiratory and digestive systems. The neck is enveloped by the platysma and the superficial fascia, and by the deep cervical fascia, which includes the pretracheal and prevertebral planes. The space between the pretracheal layer and the prevertebral layer is called the visceral compartment, where all the vital structures are located. Clinically, the neck is divided into three surgical zones (Figure 14.9). Zone 1 is bounded by the clavicles and cricoid cartilage; zone 2 lies between the cricoid cartilage and the angle of the mandible; finally, zone 3 extends from the angle of the mandible to the base of the skull. Zone 1 and 3 injuries are difficult to expose surgically and are typically investigated with imaging and panendoscopy. All zone 2 injuries historically underwent mandatory operative exploration. More recent experience has shown good outcomes with a policy of selective operative management. Currently, the primary determinant of operative versus conservative management is clinical presentation. Regardless of location of injury, patients with hard signs of vascular or aerodigestive injury require surgical exploration; those with soft signs should undergo imaging; those with no signs of injury may be observed or discharged.

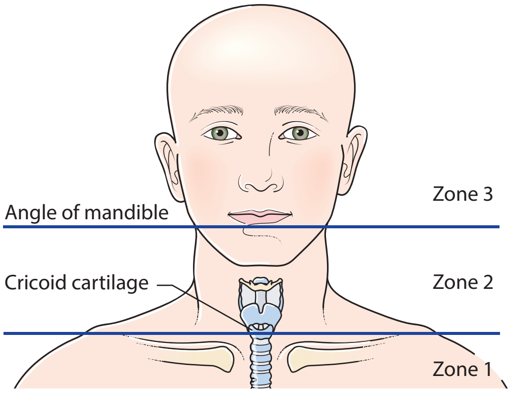

Figure 14.9 Classification of the zones of the neck.

Initial evaluation

The propensity of respiratory compromise in patients with vascular or tracheal injuries makes the early establishment of a secure airway a priority. Approximately 10% of patients with neck injuries will have some degree of airway compromise. Haematoma, laryngeal fractures, soft-tissue swelling or intraluminal bleeding may cause upper airway obstruction. Many patients with blunt injuries will have major associated craniofacial trauma, requiring intubation for airway management. Endotracheal intubation is mandatory in patients with significant obstructive signs and should be considered as a prophylactic measure when injuries are deemed capable of producing obstruction. Direct laryngoscopy may not be tolerated well in the awake patient, and medications used in rapid sequence intubation may convert an urgent airway into an emergency airway. Direct laryngoscopy may also be technically challenging owing to distortion of the airway from overlying soft-tissue damage. Because of this, the operating theatre has several advantages over the emergency department for airway management in patients with neck injury. It is a controlled environment, may have more access to advanced airway equipment, and conversion to a surgical airway can occur with the aid of extra personnel, equipment, better positioning, improved lighting and sterile technique. Despite meticulous planning, the establishment of a surgical airway is often necessary in patients with significant neck injury. Cricothyroidotomy is a good option for the unstable patient, but should only be used if endotracheal intubation fails in the stable patient. Additionally, preservation of as much intact airway as possible is important if there is a tracheal injury.

Patients in hypovolaemic shock should be resuscitated and obvious external haemorrhage from cervical wounds should be controlled by direct external pressure. Overlooked occult haemorrhage from seemingly innocuous penetrating neck wounds is a dangerous pitfall. Wounds at the base of the neck may produce massive internal bleeding into the mediastinum or pleural space, or into an adjacent tracheal wound. Massive haemorrhage from these injuries can occasionally be controlled by direct pressure, or by insertion of Foley catheters in the wound tract to tamponade bleeding (Figure 14.10), while arranging

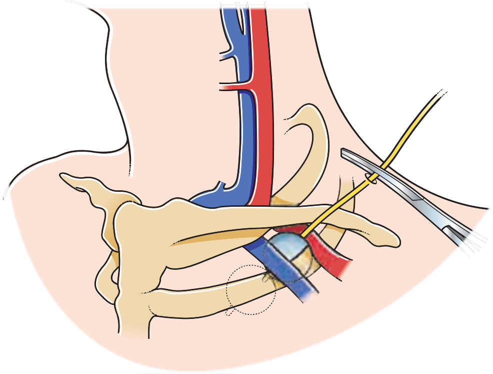

Figure 14.10 Balloon tamponade of a zone 1 neck injury with Foley catheter. (From Asensio JA, Demetriades D (eds) *Techniques in Complex Trauma Surgery*. Philadelphia, PA: W.B. Saunders, 2003.)

transport to the operating theatre. Immediate anterolateral thoracotomy or sternotomy for proximal vascular control should then be performed for vascular control and repair.

After securing the airway and ensuring ventilation and circulation are intact all patients should be assessed for hard and soft signs of injury. All patients with neck injuries should be visually inspected, including the oropharynx, and the neck should be auscultated for bruits and palpated for thrill or crepitus. All patients should also undergo a careful neurological evaluation, including cranial nerves, particularly VII and IX–XII, and motor and sensory examinations. All findings should be clearly documented, particularly if operative management is likely. Hard signs of injury include expanding or pulsatile haematoma, bruit/thrill, active bleeding, hypotension, air bubbling through the wound, stridor, unexplained focal neurological deficits and airway compromise (Table 14.5). Soft signs include small volume haemoptysis or haematemesis, dysphagia, dysphonia, subcutaneous emphysema and isolated nerve injury. Unstable patients and those with hard signs of injury should be taken for operative exploration. For clinically stable patients with soft signs of injury, invasive and non-invasive studies (radiographs, contrast radiographs, arteriography, CT, endoscopy) may serve several purposes. They may be used for localization of a known or suspected lesion and aid in planning the operative approach. They may also be used to exclude potential injuries. In the case of arteriographic embolization, the procedure may also be therapeutic.

Table 14.5 Indications for operative intervention in the management of neck injuries

Type of injury	Indication
Vascular	Hypotension/shock Active external bleeding Large or expanding haematoma Lack of distal pulse Bruit/thrill Significant haemothorax or haemomediastinum
Aerodigestive	Massive subcutaneous emphysema Air bubbling from the wound Large haemoptysis or haematemesis Stridor
Neurological	Hemispherical deficit or hypoperfusion

Chest films are routinely obtained in all trauma patients. Occult haemorrhage into the chest, associated pneumothorax or cervical soft-tissue air can be seen on radiographs. Neck films may also be useful for detecting foreign bodies (e.g. glass) and in the assessment of gunshot trajectories. Arteriography can be performed when vascular injury is suspected and has been found to be very accurate. The reliability of arteriography in excluding mediastinal vascular injuries has been questioned, however, owing to the size and orientation of the aorta and great vessels, and arteriography is ill suited for detection of venous injuries. CT angiography (CT-A) of the neck is fast becoming the initial diagnostic examination of choice. CT-A gives information on both arterial and venous vasculature, bony structures, soft tissue and most importantly the tract of injury in penetrating trauma. If the tract of injury is far from vital structures, work-up can be considered complete. CT-A of the neck is diagnostic for vascular injuries with sensitivities approaching 100%. It is less accurate for evaluation of the aerodigestive tract; however, if the tract is suspicious, oesophagoscopy, bronchoscopy and contrast oesophagography can be performed. In patients with wounds superficial to the platysma or with complete absence of any clinical signs no further evaluation is generally required.

The use of contrast oesophagography in the evaluation of cervical oesophageal injuries is controversial, as the sensitivity is not as high as it is for the intrathoracic oesophagus in which effluent from a laceration or perforation tends to be less contained. Several investigators have found the incidence of missed injuries associated with this method to be as high as 50%. Sensitivity can be increased by distending the oesophagus with water-soluble contrast under slight pressure through a proximally placed nasogastric tube. Similarly, oesophagoscopy has not proven to be a reliable means of excluding injury, with a reported sensitivity in several small studies of only 40–50%. Using a combination of oesophagoscopy and oesophagography however, may increase sensitivity to 75–85%.

Penetrating neck injuries

Zone 1 injuries occur at the base of the neck and do not allow easy accessibility from an operative standpoint. Injuries in zone 1 may involve proximal carotid, subclavian or innominate vessels, and patients are at risk for exsanguinating haemorrhage, which may be occult if the blood tracks into the chest or mediastinum. Asymptomatic patients can be evaluated by CT-A or angiography. Most studies suggest that asymptomatic zone 1 patients with negative imaging may be safely managed non-operatively. However, as many as 39% of patients with zone 1 vascular injuries present with unexplained shock. The management strategy for symptomatic or unstable zone 1 injuries consists of early operative exploration. A variety of incisions have been used to gain exposure and vascular control for thoracic inlet injuries (Figure 14.11a,b). The operative approach will be determined by the specificity of localizing signs, preoperative arteriography or associated intrathoracic injuries. Transverse clavicular incisions are used for access to distal subclavian injuries. Injuries to the mid-portion of the subclavian vessels

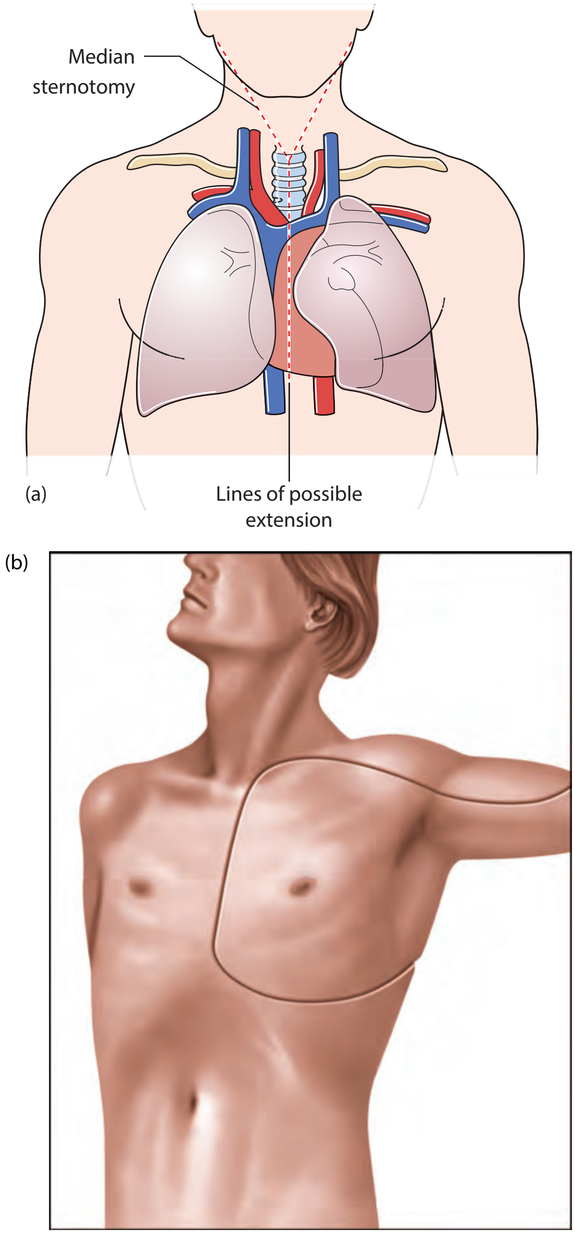

Figure 14.11 Operative approaches for injuries to the neck. (a) Anterior sternocleidomastoid incision with optional mediastinal extension excellent for zone 1 and 2 injuries. (b) Trapdoor with modification to include extension to left thoracotomy, another option for zone 1 injuries particularly the left subclavian artery and vein. (From Hoyt *et al.*, *Surg Clin North Am* 2001;**81**:1299–330.)

will usually require either a clavicular osteotomy or resection of the clavicle to obtain adequate exposure. Proximal access to right subclavian or innominate vessels is best obtained through a median sternotomy with supraclavicular lateral extension for additional exposure. Left proximal subclavian injuries will generally require a posterolateral thoracotomy for control. 'Trap door' or 'book' incisions combine an anterior thoracotomy with a median sternotomy and supraclavicular extension for wide exposure to left-sided and aortic arch injuries. More distal carotid injuries can be best approached via an anterior sternocleidomastoid incision.

It is injuries to zone 2 that have generated the greatest controversy regarding their management. Exploration of the vital structures in this location is relatively simple surgically and can generally be accomplished via a standard anterior sternocleidomastoid incision. The historical policy of mandatory exploration of all injuries in zone 2 that penetrated the platysma resulted in a significant number of negative explorations, and careful retrospective review of patients with positive and negative explorations found that physical examination findings were quite sensitive in detecting patients likely to benefit from exploration. Current recommendations are for immediate exploration for all patients with hard signs of injury (Table 14.5); CT-A with adjunctive angiography, oesophagography, bronchoscopy and oesophagoscopy on a case-by-case basis based on location and tract of injury on CT-A for patients with soft signs of injury; and observation for completely asymptomatic patients.

Zone 3 injuries may involve the petrous or cavernous portions of the internal carotid artery, the vertebral artery or deep branches of the external carotid artery. Wide exposure of this area and distal vascular control may be difficult to obtain. Routine exploration as a diagnostic manoeuvre may be both hazardous and inaccurate; because of this, arteriography is the diagnostic method of choice for zone 3 injuries. Similar to zone 1 injuries, arteriography is sensitive and specific, and can be therapeutic for these relatively inaccessible injuries. Additionally, the intracranial circulation can also be assessed in patients with dense neurological deficits.

Specific injuries

Vascular

The repair of most arterial injuries can be accomplished by lateral arteriorrhaphy, primary reanastomosis or graft interposition. Ligation is rarely indicated for major vessels except in cases of inaccessible lesions, or in damage control situations. Vertebral artery ligation is generally tolerated without sequelae; ligation of the carotid is also generally tolerated in patients with an intact circle of Willis. Injury to major veins should be repaired if possible, although ligation does not lead to significant morbidity. The risk of venous air embolism, however, is of great concern. Suspected venous injuries should be managed with gentle pressure on the wound and exclusion of the injury with proximal and distal control as soon as possible. The patient should be in the Trendelenburg or at the least supine position until repair or ligation are complete to increase vascular pressure and reduce the risk of air embolus.

Tracheal

Most tracheal injuries can be closed primarily; mucosal approximation should be performed carefully with fine absorbable sutures to avoid intraluminal granulation tissue. Injuries of the thyroid or cricoid cartilage can be closed with sutures or plates. Tracheal rings and cartilage can be reapproximated using non-absorbable extramucosal sutures. All repairs should be buttressed with healthy tissue; this is of paramount importance if there is a concomitant oesophageal injury, as prevention of a tracheo-oesophageal fistula is necessary. Buttressing can be done with one of the strap muscles, or the sternocleidomastoid.

Oesophageal

Intraoperative oesophagoscopy and insufflation of a nasogastric tube with air or dye can aid in the diagnosis of suspected oesophageal injury. Oesophageal injuries should be widely explored to ensure the entire mucosal defect is seen. Once the full extent of injury has been identified it can be repaired in one or two layers with absorbable suture. As with tracheal injuries, all oesophageal repairs should be buttressed with healthy tissue, and wide drainage is highly recommended. If there has been significant delay in treatment or severe tissue destruction, the repair can be protected with a T-tube, or diversion can be performed with a proximal cervical oesophagostomy. More distal oesophageal injuries may be primarily repaired if diagnosed early, but late repair of intrathoracic oesophageal injuries should not be attempted. These injuries are best treated by wide drainage and oesophageal diversion and exclusion. Injuries in the thoracic and abdominal oesophagus can freely contaminate the peritoneal, mediastinal and thoracic cavities, leading to sepsis and death in 20–42% of cases. In contrast, mortality for cervical perforations ranges from 0% to 20%, with the majority of studies demonstrating zero mortality.

Conservative management is an acceptable strategy in selected patients. Indications for non-operative management include contained perforation, absence of distal obstruction, cervical or thoracic location, and minimal systemic signs of infection. Medical management consists of fasting, antibiotics and strict monitoring. Follow-up imaging is performed in 7–10 days to assess for healing

Blunt neck injuries

Blunt neck injuries are caused frequently by a direct blow to the thyroid or cricoid cartilage as the result of either motor vehicle or 'clothes-line' accidents. Severe injuries may also follow acceleration–deceleration forces, significant flexion–extension of the cervical spine or inadequate use of seat belts. Injuries to the larynx, trachea or oesophagus may result. Severe injuries may not be obvious on initial examination. Patients may present with airway obstruction, hoarseness, dysphagia, subcutaneous air, laryngeal deformities, blood in the aerodigestive tracts, haematoma or soft tissue swelling. Airway obstruction usually requires placement of a surgical airway. In the presence of severe laryngotracheal trauma a cricothyroidotomy often is not feasible, and tracheostomy will be required. In stable patients the first-line diagnostic test is a CT scan of the neck with contrast. The CT will allow adequate visualization of the skeletal, soft-tissue and vascular structures of the neck. The weakness of CT is its lack of sensitivity for aerodigestive injury; if suspicious physical examination or CT findings are present, bronchoscopy with oesophagoscopy or oesophagography may be indicated.

Signs of major vascular injury from blunt trauma may be more subtle than those associated with penetrating trauma. Injuries are frequently missed, or present in a delayed manner with a developing neurological deficit; however, blunt cerebrovascular injury is rare even in centres with aggressive screening policies. Injuries can occur as a result of severe hyperextension and rotation, direct force to the vessel or by injury from adjacent fractures. The majority of patients have minimal to no symptoms at presentation, but the risk of subsequent stroke may be high in the absence of treatment. Indications for screening in asymptomatic patients include seat belt sign, GCS score >8, presence of diffuse axonal injury, basilar skull fracture, cervical spine fracture, Le Fort II or III fractures, near hanging injury, direct blow to the neck and hyperextension injuries. Angiography has been the historic gold standard for diagnosis of blunt cerebrovascular injury; however, CT-A with multichannel (16–64) detectors is fast becoming the primary screening and diagnostic modality. CT-A has the benefit of being quick, widely available and easy to perform, and does not require the presence of a specially trained angiography team. It also avoids the morbidity associated with an arterial puncture and allows adequate visualization of the cervical spine and soft tissues. Studies have shown detection rates similar to angiography. Sensitivity ranges from 83% to 100%, with negative predictive values of 92–98%.

Injuries are graded using the Denver Grading Scale. Grade I injuries are small intimal tears or haematomas affecting <25% of the vessel lumen. Grade II injuries are intimal disruptions affecting ≥25% of the lumen. Grade III injuries are pseudoaneurysms. Grade IV injuries are complete vessel occlusions and grade V are vessel transections. The optimal type and duration of treatment for blunt cerebrovascular injury remains controversial; options include anticoagulation, antiplatelet therapy, surgical repair and endovascular coils or stents. Grade I/II injuries have a low risk of bleeding and treatment consists of anticoagulation or antiplatelet agents. Both methods appear to have equivalent efficacy. The majority of these low-grade injuries will heal, and repeat imaging is indicated as antithrombotic therapy can be discontinued after healing. Grade III injuries are less likely to resolve with antithrombotic therapy alone, and, although the risk of rupture is low, the risk of thromboembolic complications without treatment can be high. Surgery should be considered for all accessible lesions. Endovascular therapies are available and placement of stents or coils may decrease the risk of enlargement; however, there is no evidence that they are superior to antithrombotic agents alone in stroke prevention. Stents used for carotid artery injuries in particular have been associated with greater complications than antiplatelet/anticoagulant therapy, and are not currently recommended. Grade IV lesions (occlusions) are unlikely to resolve with antithrombotic therapy, and neither medical nor surgical treatment is likely to reverse symptoms if already present. Follow-up imaging is not recommended for grade IV lesions as they are unlikely to change with time. Grade V lesions (active extravasation) require surgery or endovascular intervention.

Complications of cervical trauma

Massive haemorrhage leading to hypovolaemic cardiac arrest and complications arising from spinal cord injuries are the leading causes of mortality in patients with cervical trauma. Missed injuries, involving the oesophagus, may lead to fistula formation, abscess and occasionally to mediastinitis. Undiagnosed vascular injuries have produced late sequelae, including arteriovenous fistula and false aneurysms. Glottic or subglottic stenosis may complicate laryngeal and tracheal injuries.

Chest trauma

Anatomy

The chest and its contents can be divided into four anatomical zones: the chest wall, the pleural space, the lung parenchyma and the mediastinum. The chest wall consists of the bony thorax and the associated musculature. Injuries to the chest wall consist primarily of fractures of the ribs and sternum as well as soft-tissue injuries. The pleural space is a virtual space between the lung and the chest wall. Although it is normally empty, the pleural space can become filled with air (pneumothorax) or blood (haemothorax) as a result of injury. In addition, alteration of the normally negative intrapleural pressure will cause collapse of the lung and ventilatory compromise. The lung parenchyma and airways can become compromised by laceration, contusion, obstruction, haematoma and pneumatocele. The mediastinum contains the heart, aorta, great vessels, trachea, proximal bronchi and oesophagus. Injuries within the mediastinum have the potential to involve many critical structures, and require an aggressive diagnostic and therapeutic approach.

Initial management

The initial management of patients with suspected chest injury should follow the ABCDEs; a primary survey should be done to identify immediate life-threatening injuries. As mentioned above the major thoracic injuries that should be identified and addressed during the primary survey include tension pneumothorax, massive haemothorax, open pneumothorax and flail chest in the breathing section; and pericardial tamponade in the circulatory section.

Tension pneumothorax and massive haemothorax may both present with haemodynamic compromise and absence or diminished breath sounds on the affected side, and tracheal deviation away from the side of injury. Tension pneumothorax/haemothorax and open pneumothorax should all be treated with immediate chest tube placement. Pericardial tamponade may also present with profound hypotension, distended neck veins and muffled heart sounds, and is generally the result of penetrating trauma to the cardiac box. This box is bordered by the clavicles and costal margins superiorly and inferiorly, and bilaterally at the mid-clavicular line. Diagnosis can be confirmed with pericardial views on FAST, although if the bloody effusion decompresses into the left chest a false-negative FAST is possible. For this reason negative FAST cannot definitively rule out pericardial effusion in the presence of a left haemothorax. Rapid thoracotomy or median sternotomy to release the tamponade and repair the cardiac defect are life saving and should be performed immediately.

Once the primary survey is complete, the secondary survey should focus on visual inspection of the chest for deformities, contusions, lacerations and penetrating wounds. Radio-opaque markers should be placed at all wound sites prior to imaging. The location and direction of penetrating injuries can aid in the determination of structures at risk for injury. However, it is important to be aware that structures within the chest may be damaged by penetrating wounds outside the boundaries of the thorax.

Palpation of the chest can reveal areas of tenderness and deformity as well as crepitance. These may be indicative of rib or sternal fractures. Marked crepitance is indicative of subcutaneous emphysema, which can result from major bronchial injury, pulmonary parenchymal injury or oesophageal injury. Auscultation of the chest allows assessment of breath sounds; decreased breath sounds are suggestive of pneumothorax/haemothorax, or possible mainstem bronchus intubation.

The CXR can yield a wealth of useful diagnostic information and should be obtained as early as possible in the resuscitation. The radiograph should be examined carefully in its entirety for evaluation of the bony thorax, soft tissues of the chest wall and mediastinum, lung parenchyma, airways, and cardiac and mediastinal silhouette. It should also be repeated if interventions occur such as intubation or nasogastric or thoracostomy tube or central line placement, or if the clinical course alters significantly. An arterial blood gas should be performed as well to assess for hypoxia, hypercarbia, acid–base status and toxins such as methaemoglobinaemia or carboxyhaemoglobin. Other more involved diagnostic studies of the chest are required in special circumstances. These may include CT-A, angiography, FAST ultrasound and formal echocardiogram. These may be necessary for the diagnosis of thoracic or great vessel injury, thoracic spinal fractures and blunt cardiac injury.

Injuries to the chest wall

Rib fracture

By far the most common injury sustained after blunt chest trauma is rib fracture (Figure 14.12). In older patients, rib fractures can occur after a relatively minor injury because of decreased bone density and loss of chest wall compliance. The primary manifestation of rib fractures is pain. Pain can cause significant complications owing to splinting and poor inspiratory effort, including alveolar derecruitment, hypoxia, respiratory distress, airway obstruction and pneumonia. The use of bedside pulmonary function tests including forced vital capacity (FVC) and maximum inspiratory force can give an objective estimate of the patient's degree of ventilator compromise. Tidal volume of $<5\,\mathrm{mL/kg}$, FVC $<10\,\mathrm{mL/kg}$ or maximum inspiratory force of $<30\,\mathrm{cmH_2O}$ are indicators of ventilatory compromise. Additionally non-invasive continuous capnography, which can be used to follow the trend of expired carbon dioxide, can help to detect hypoventilation early.

Initial attempts at pain control using oral or parenteral analgesics are appropriate, but additional measures must be aggressively pursued in those patients who do not respond to initial therapy. Adjuncts can include topical pain patches with local anaesthetic, intercostal nerve blocks, and epidural or spinal anaesthesia.

Rib fractures may also serve as a marker for more serious injuries. Historically, fracture of the first rib has been a hallmark of very-high-energy transfer and has been associated with major chest, abdominal and vascular injury. Fractures of the lower ribs are associated with solid organ injury, with a 20% incidence of splenic injury associated with fracture of the tenth to twelfth ribs on the left side.

Flail chest

Flail chest occurs when three or more contiguous ribs are fractured in two or more locations resulting in a segment of chest wall that can move independently (Figure 14.13). This will result in paradoxical motion with negative-pressure ventilation. Additionally, a large amount of force is required to create a flail segment and may also cause underlying pulmonary contusion. Many physiological changes occur with a flail chest: the paradoxical motion can decrease total lung capacity and functional residual capacity, pain associated with rib fractures can result in splinting and atelectasis, and most importantly the associated contusion can lead to ventilation–perfusion mismatch. These changes ultimately culminate in increased shunt fraction, resulting in hypoxia. While the mechanical injury to the chest wall undoubtedly contributes to respiratory morbidity, the underlying pulmonary contusion is by far the most important determinant of respiratory status. The majority of patients do not require mechanical ventilation, but, when necessary, mechanical ventilation is associated with worse prognosis and a variety of complications. The need for intubation and mechanical ventilation is determined by the patient's clinical appearance, ability to ventilate adequately and the degree of pulmonary dysfunction. Pain control and pulmonary toilet are essential in preventing complications associated with flail chest. Several studies have demonstrated the superiority of epidural anaesthesia for pain control, prevention of pneumonia and decreased need for mechanical ventilation. Increasing age is associated with worsened outcomes, with some studies suggesting that ages as low as 45 years are associated with increased complications and mortality. Thus adequate analgesia and pulmonary toilet are of paramount importance in the management of the elderly patient with thoracic trauma and strong consideration should be given to ICU admission.

Some patients with large flail segments have very severe chest wall deformity and subsequent loss of volume in the affected hemithorax. Chest wall reconstruction and mechanical stabilization of the flail segment is advocated by some for highly selected cases. There is some evidence to suggest that plating, wires or other means of mechanical stabilization may contribute to weaning from mechanical ventilation and pain control. However, evidence is limited and definite indications for surgical stabilization are lacking.

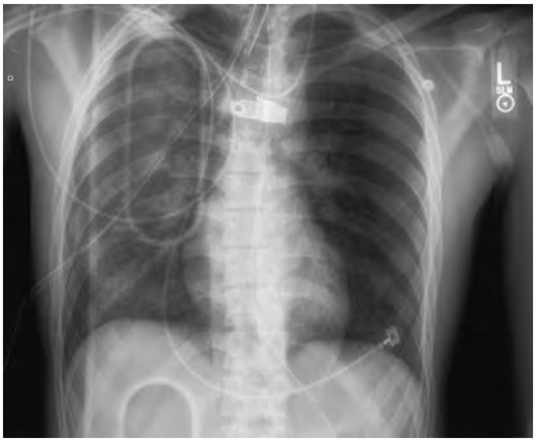

Figure 14.12 Chest radiograph demonstrating multiple posterior rib fractures of the right chest.

Sternal fracture

The majority of sternal fractures (Figure 14.14) are sustained as a result of the use of shoulder restraints, especially in older patients with decreased bone density. Under these circumstances, the sternal fracture is often an isolated injury and is rarely associated

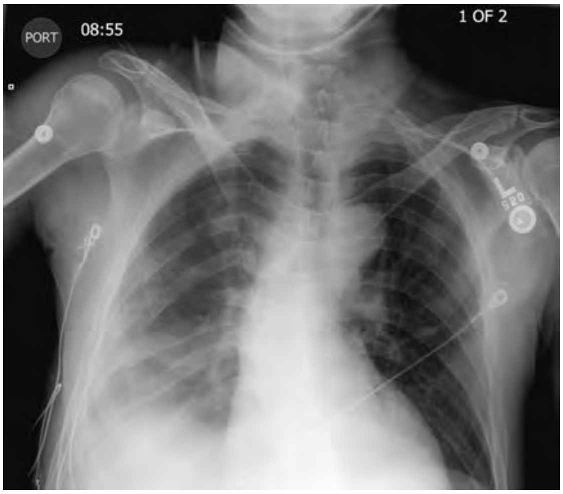

Figure 14.13 Chest radiograph demonstrating a posterior flail segment of the right chest with associated haemothorax and right lower lobe contusion.

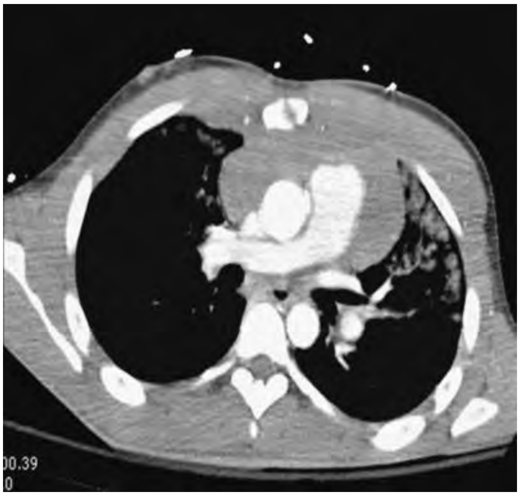

Figure 14.14 Axial CT images of a sternal fracture with associated mediastinal haematoma.

with significant intrathoracic injury. The need for additional evaluation in patients with sternal fracture should be based on the overall circumstances, not the mere existence of the fracture. Treatment of the sternal fracture itself is generally conservative with an emphasis on pain relief. Fewer than 25% of patients with a complete fracture of the sternum will require operative fixation.

Injuries to the pleural space

Pneumothorax

Pneumothoraces occur when air escapes from the injured lung, or enters through a penetrating wound and collects in the pleural cavity (Figure 14.15). Pneumothorax can be either simple or present with tension physiology. Tension pneumothorax is the most rapidly life threatening of breathing problems. It occurs when air continues to accumulate in the pleural space, creating pressures above atmospheric. This can result in mediastinal shift away from the site of injury and cause markedly decreased venous return to the heart and resultant hypotension. Tension pneumothorax can be recognized by hypoxia, tachypnoea, hyper-resonance, absence of breath sounds on the side of injury and deviation of the trachea away from the side of the injury, distended neck veins and hypotension. If tension pneumothorax is suspected emergency decompression must be performed. ATLS recommends needle decompression with a large-bore needle placed in the second intercostal space in the mid-clavicular line. However, placement of a needle in the fifth or sixth intercostal space at the anterior axillary line corresponding to the level of the inframammary crease is frequently easier and further removed from vital mediastinal structures. Needle decompression should be followed by the placement of a chest tube for more permanent decompression of residual air and drainage of any blood that may be associated with the now simple pneumothorax. Simple pneumothoraces are generally successfully treated with placement of tube thoracostomy as well. Occult pneumothoraces (seen on CT scan but not on CXR) or small asymptomatic pneumothoraces may be observed and can resolve spontaneously. However, expectant management should not be pursued in patients on positive-pressure ventilation as the risks of expansion and creation of tension physiology are significantly elevated, and the time required for air leaks to seal can be greatly prolonged.

Open pneumothorax, or sucking chest wounds, occur when a defect in the chest wall is full thickness and large enough for air to communicate between the thoracic cavity and the environment. If the wound is sufficiently large, intrapleural pressure remains equal to atmospheric pressure. Attempts at spontaneous ventilation will result only in movement of air in and out of the body wall defect. No significant ventilation of the lung is possible and respiratory compromise is severe. The wound should be grossly decontaminated and an occlusive dressing should be applied and secured on three sides. A chest tube should be placed to relieve the associated pneumothorax immediately.

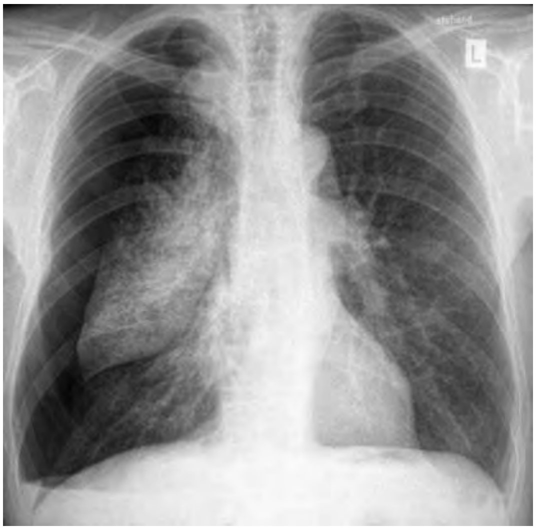

Figure 14.15 Chest radiograph demonstrating right simple pneumothorax; note that the mediastinal structures remain in the midline despite significant lobar collapse.

Haemothorax

Massive haemothorax may also present with tension physiology. Hypotension may be a result of decreased preload from tension physiology as well as from massive blood loss. Distended neck veins may or may not be present, and obstruction due to tension physiology increases venous pressure causing distension; however, severe associated intravascular volume depletion may counteract this effect. Simple haemothorax can present with diminished breath sounds, dullness to percussion and effusion or blurring of costophrenic angles on CXR (Figure 14.16). Treatment for both massive and simple haemothorax is immediate placement of a chest tube. The majority of lacerations to the lung involve low-pressure vessels of the pulmonary circulation and bleeding can be expected to stop after placement of the chest tube and re-expansion of the lung. Injuries to the intercostals or internal

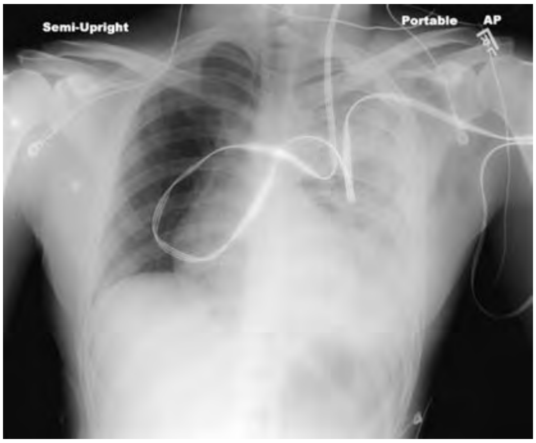

Figure 14.16 Chest radiograph demonstrating left haemothorax with near white-out of the left chest; this is typical of images taken with the patient supine as the blood layers evenly over the posterior thoracic wall.

mammary arteries, however, can lead to massive haemorrhage, especially if the vessels are only partially transected. Blood loss >1000–1500 mL defines a massive haemothorax and is an indication for operative exploration. Additional indications for thoracotomy include continued blood loss of ≥200 mL/h for longer than 4 hours and massive air leak. Every effort should be made to collect shed blood in a sterile fashion so that it may be autotransfused.

Retained haemothorax can complicate the hospital course of 3–8% of patients with haemothorax. It can occur as a result of delay in presentation, diagnosis or treatment; thoracostomy tube malposition, migration or occlusion; and may result in empyema or fibrothorax. Treatment options include open drainage, video-assisted thoracoscopic drainage and intrapleural thrombolysis. Intrapleural thrombolysis can lead to radiographic resolution in up to 90% of cases.

Technique of tube thoracostomy

The initial therapy in most patients with haemothorax/pneumothorax is tube thoracostomy. The tube should ideally be placed rapidly but in a controlled and sterile fashion. The arm is abducted if possible, the chest is rapidly prepared with Betadine or chlorhexidine and the insertion site is anaesthetized if time permits and the patient is awake. The ideal insertion site is in the fourth or fifth intercostal space along the mid-axillary line. This generally corresponds to the inframammary fold in females and the nipple in males. This site is chosen to avoid injury to the diaphragm and to allow easiest access to the thoracic cavity through a minimal amount of muscle and soft tissue. It is important to palpate the entry site carefully to ensure no injury to the diaphragm has occurred, that the thoracic cavity has been entered and that there are no significant adhesions in the area. Entry should meet no resistance, and the tube is generally advanced 10–15 cm such that the last drainage hole is within the thorax. The tube should then be securely sutured and taped in place with an occlusive dressing and attached to a closed drainage system that has been prepared for autotransfusion. A postprocedure CXR is mandatory both to confirm placement of the tube and to ensure the desired therapeutic effect. Persistent haemothorax/pneumothorax (Figure 14.17) should be treated with a second chest tube, but should also raise the question of the need for a thoracotomy to control bleeding or address airway injury.

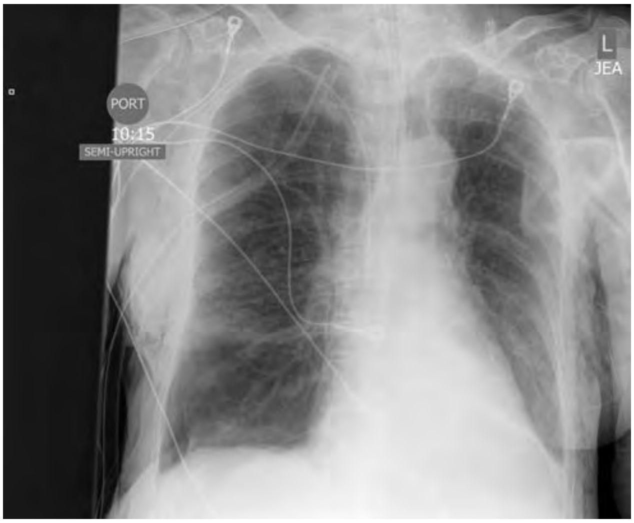

Figure 14.17 Chest radiograph demonstrating small residual subpulmonic pneumothorax after chest tube placement.

Pulmonary parenchymal injuries

Pulmonary laceration

Simple lacerations of the lung parenchyma are common after penetrating trauma but uncommon after blunt trauma. Laceration can result in leakage of air or bleeding, resulting in a pneumothorax/haemothorax (Figure 14.18). Initial treatment of either is with a tube thoracostomy to drain any air or blood and re-expand the lung. The majority of bleeding will cease spontaneously as the lung vasculature is a low-pressure system, and the lung is rich in tissue thromboplastin. The majority of air leaks are small and will close spontaneously. Chest tube placement is the definitive management in the majority of cases.

Air leak may be prolonged or exacerbated by positive-pressure ventilation. The treatment is generally weaning from mechanical ventilation and extubation, which generally allows healing and resolution of the leak. In the case of massive air leaks tracheobronchial injury should be investigated. If the air leak is large enough effective alveolar ventilation can be lost. If this is the case selective bronchial intubation beyond the injury, or of the unaffected lung, can be used to decrease leakage and improve ventilation. In extreme cases split lung ventilation with a double-lumen ETT and two separate ventilators can be used to allow independent lung ventilation.

Parenchymal injury requiring extensive lung resection and pneumonectomy following trauma is rare but can result in severe cardiac dysfunction and high mortality. In fact morbidity and mortality increase in a stepwise fashion as the extent of pulmonary resection increases. Reasons for this include increasing injury severity and more associated injuries. However, several studies have shown that the extent of resection remains an independent predictor of mortality even after correcting for

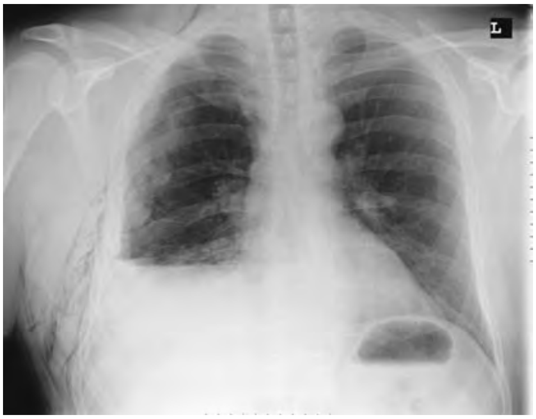

Figure 14.18 Chest radiograph demonstrating a right haemopneumothorax due to a stab wound. Note the air–fluid level in the lower chest and the associated subcutaneous emphysema.

these factors. This may be due to increased right heart strain/failure following traumatic lung resection. In contrast to patients undergoing lung resection for non-traumatic reasons, e.g. when chronic lung disease has resulted in minimal blood flow to the diseased lung preoperatively, trauma patients generally have normal pulmonary vasculature. After resection the sudden decrease in the pulmonary vascular compliance owing to parenchymal resection acutely increases right heart afterload causing strain and failure. As the right heart fails there is decreased left heart preload, resulting in decreased cardiac output. There are case reports using pulmonary vasodilating agents such as nitroglycerin, nitroprusside, alprostadil, epoprostenol and nitric oxide to treat right heart failure following traumatic resection and pneumonectomy. However, treatment is primarily supportive, and mortality remains high: 62% following pneumonectomy, 35% following lobectomy and 22% following wedge resection.

Pulmonary contusion

Pulmonary contusion is a common finding following chest trauma. Contusions occur most commonly after blunt thoracic trauma, with falls and motor vehicle crashes accounting for the majority of injuries in the civilian population. Among military combatants the shock wave produced by high-velocity weapons and blasts also commonly results in severe pulmonary contusion. Contusion results from haemorrhage and oedema formation in the injured lung parenchyma. Contusion can result in decreased lung compliance, diminished alveolar function, vasoconstriction in the injured lung, increased secretion production, and decreased secretion clearance. A significant shunt can occur and result in significant hypoxia. Decreased compliance can also increase the patient's work of breathing, causing respiratory fatigue and failure and increased ventilator support requirements in the intubated patient. The diagnosis of pulmonary contusion is generally made on the basis of mechanism of injury, arterial hypoxaemia and CXR or CT scan findings. Parenchymal damage generally becomes radiographically apparent within 4–6 hours of injury, peaks at approximately 72 hours after injury and usually resolves within 7 days. However, the period of time needed for return of adequate lung function may vary from 1 day to several weeks depending on the severity of injury, inflammatory response, concomitant injury and comorbid conditions, as well as the presence or absence of complications such as ARDS and pneumonia.

Plain films and CT scans are the mainstay of diagnosis (Figure 14.19a,b). CXR may demonstrate an ill-defined area of infiltration in the area of injury; however, it may take some time for the complete extent of injury to manifest, with only 47% of lesions detected at admission and 92% present at 24 hours. CT scan may be more sensitive than plain radiographs, particularly in the initial period following injury, in delineating the extent of contused lung. Scoring systems aimed at predicting the extent of pulmonary dysfunction and contusion-related complications are generally more accurate when using CT findings than when using plain radiographs. However, newer generation CT scanners may be overly sensitive and differentiating true contusion from atelectasis, aspirated contents and haemothorax may be difficult; therefore, diagnosis should be made by correlating radiographic findings with clinical symptoms. Lesions deemed 'occult contusions', i.e. those seen on CT but not visible on CXR, are generally asymptomatic and self-limited.

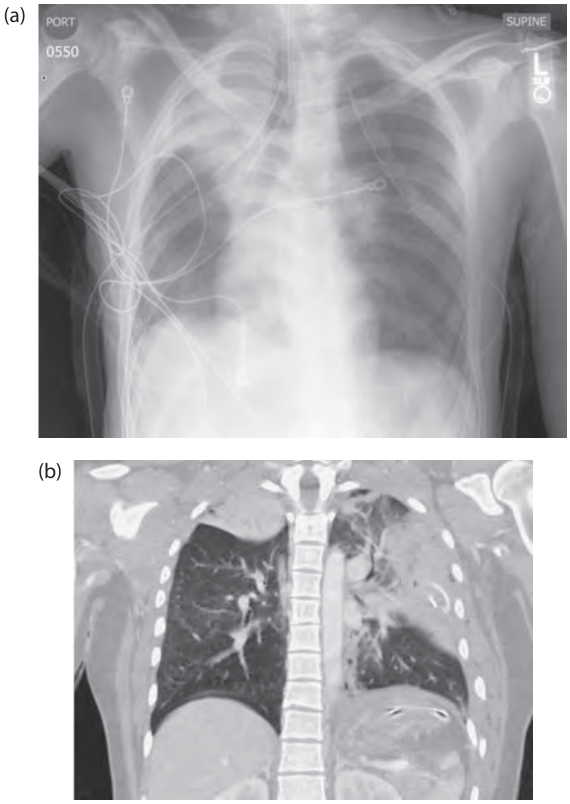

Figure 14.19 (a) Chest radiograph demonstrating a right upper lobe contusion. (b) Coronal CT demonstrating bilateral lung contusions.

The treatment of pulmonary contusions is mainly supportive with supplemental oxygen and aggressive pulmonary toilet. In selected patients non-invasive positive-pressure ventilation may be helpful in improving oxygenation, and avoiding intubation in up to 82% of patients; however, any patients who manifest signs of respiratory failure should be intubated immediately. For patients with severe hypoxaemia due to unilateral lung injury the use of a rotating bed or dependent positioning of the uninjured lung may improve ventilation–perfusion mismatch and improve oxygenation. The use of rotating beds has also been associated with decreases in ventilator days and associated pneumonias. Decreased capillary endothelial integrity in the injured lung makes judicious fluid management in the patient with pulmonary contusion essential. There is some evidence to suggest a role for replacement of surfactant in patients with severe contusions; however, there is no role for prophylactic antibiotics or steroids in the treatment of pulmonary contusions.

Injury to the large airways

The incidence of major tracheobronchial injury in most trauma centres is low. This is the result of a combination of high scene mortality and a tendency for some injuries to remain relatively asymptomatic in the acute period. In general, penetrating injuries occur in the cervical area, while the majority of blunt injuries occur within 2.5 cm of the carina. Patients present in one of two ways, depending on the location of the bronchial rupture.

Patients in whom the bronchus ruptures into the pleural cavity will present with pneumothorax and air leak after chest tube placement. Other symptoms can include massive subcutaneous or mediastinal emphysema and haemoptysis. If the bronchial rupture occurs within the mediastinum the presentation can be much less acute. Respiratory distress in this group is uncommon; symptoms may include haemoptysis, mediastinal emphysema (Figure 14.20) and occasionally subcutaneous emphysema. These types of injury generally heal without intervention; however, they may present in a delayed fashion with symptoms due to strictures in the area of injury.

Patients with suspected injury should be evaluated with bronchoscopy. Treatment depends on the extent and location of the injury as well as the patient's overall clinical condition. Patients with concomitant oesophageal injury should all undergo repair. Patients with persistent symptoms following adequate pleural drainage and intubation distal to the site of injury may require repair. Injuries involving the membranous portion of the trachea are more likely to heal than injuries involving the cartilaginous portion. Injuries involving less than one-third of the circumference of the trachea or major bronchus can be observed. Injuries greater than one-third require repair to prevent stricture formation.

Injuries to mediastinal structures

Blunt thoracic aortic injuries

Blunt thoracic aortic injury is primarily the result of sudden deceleration injuries, and injuries primarily occur in areas where the aorta is fixed. The most common site of injury is in the descending aorta just distal to the origin of the left subclavian at the site of the ligamentum arteriosum; this site accounts for >90% of injuries. Other locations include the aortic root, where the aorta is fixed to the heart, and the diaphragmatic hiatus. Unfortunately, the majority of patients with thoracic aortic injury do not reach the hospital alive: 80–90% die prior to hospital arrival. Of those patients surviving to evaluation, thoracic aortic injury is present in approximately 0.3–2.8%. Patients generally fall into one of two categories. The first group presents with haemodynamic instability due to free rupture of the haematoma and time to treatment is a key factor in outcome: 30% die within 6 hours, 50% within 24 hours and 90% at 10 weeks if thoracic aortic injury is not treated. The second group consists of patients who are haemodynamically stable, and often asymptomatic; these patients generally have small contained pseudoaneurysms (Figure 14.21) with a low risk of rupture and will respond well to medical management and delayed treatment. However, because these patients are generally asymptomatic, screening and diagnosis of thoracic aortic injury may be difficult. Currently, CXR is the primary screening examination. Abnormalities associated with thoracic aortic injury include widened mediastinum (>8 cm), apical capping, left pleural effusion, loss of the aortopulmonary window, depression of the left mainstem bronchus, deviation of the trachea or nasogastric tube to the right, and widening of the right paratracheal stripe. However, CXR is non-specific, and all patients with abnormalities on CXR should rapidly undergo further imaging to definitively diagnose their injuries. Options include traditional angiography, CT-A, echocardiography and MRI/magnetic resonance angiography (MRA).

While specificity is excellent, ranging from 98% to 100%, the sensitivity of aortography ranges widely, from 38% to 92%. The majority of missed injuries appear to be intimal tears and small intramural haematomas, which are more likely to be diagnosed by echocardiography or CT-A. Access site complications include thrombosis, haemorrhage, dissection, pseudoaneurysm and arteriovenous fistula. Systemic complications include anaphylaxis and contrast-induced nephropathy, which can be as high as 62% in high-risk populations.

In contrast to angiography, CT-A is widely available, can be performed at any time, is fast and avoids arterial puncture. Similar to the use of CT-A in blunt cerebrovascular injury, CT-A is increasingly replacing traditional angiography for the diagnosis of thoracic aortic injury. A comparison of trauma practices

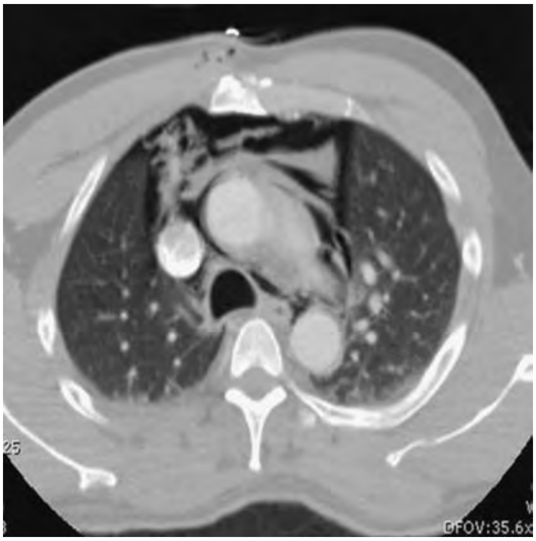

Figure 14.20 Axial CT scan demonstrating pneumomediastinum.

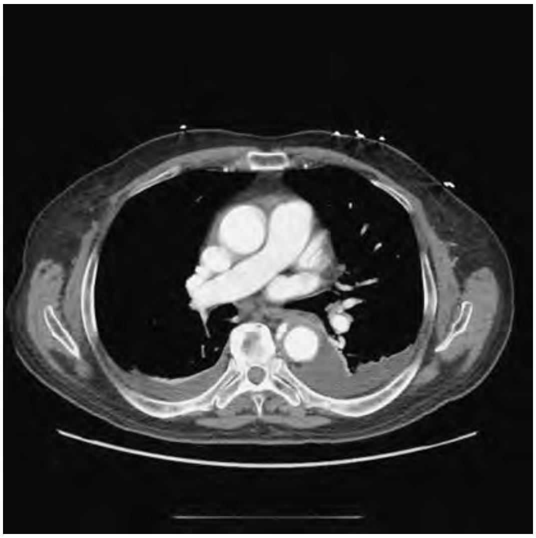

Figure 14.21 Axial CT scan with thoracic aortic pseudoaneurysm; note the associated contained haematoma.

from the time periods 1994–6 and 2005–7 revealed an increase in the use of CT scan for diagnosis of thoracic aortic injury from 34.8% to 93.3%. Modern series reliably report sensitivity between 95% and 100%. Specificity with modern technology ranges between 94% and 99.8%.

In patients with haemodynamic instability or who require emergency surgery, transoesophageal echocardiography may be the ideal diagnostic modality. It is portable, fast and repeatable, and does not require intravenous contrast. Sensitivity can be as high as 98–100%, but can vary widely based on operator experience. An alternative to transoesophageal echocardiography is intravascular ultrasound. This technique involves insertion of an ultrasound probe intravascularly into the aorta. It has excellent diagnostic accuracy, with sensitivity of 92–100% and specificity nearing 100%. In a study comparing intravascular ultrasound, transoesophageal echocardiography and angiography among patients with blunt chest trauma, intravascular ultrasound outperformed both transoesophageal echocardiography and angiography. Drawbacks of transoesophageal echocardiography include invasiveness and the need for specialized equipment. There are also risks of oesophageal injury and airway compromise. Intravascular ultrasound requires arterial puncture with the attendant risks of access site complications such as haematoma, fistula, pseudoaneurysm and dissection.

Contrast-enhanced MRA (CE-MRA) is performed with intravenous gadolinium and produces images of a high quality with fewer respiratory and cardiac artefacts than traditional MRI. CE-MRA can be used for diagnosis with a sensitivity and specificity between 98% and 100%. CE-MRA has the ability to create detailed three-dimensional reconstructions that are of great value in preoperative or prestent planning. CE-MRA has the benefit of avoiding ionizing radiation and iodinated contrast. However, CE-MRA requires lengthy examination times outside of a monitored critical care setting, and potentially lengthy transport times. CE-MRA may not be available in many centres, and may not be operational at night, on holidays or weekends. Because of this, it is still ill-suited to the acute trauma work-up.

Patients with thoracic aortic injury historically all underwent emergency open repair via a left thoracotomy. Recently, conservative management with blood pressure and heart rate control have allowed many patients to be temporized until open or endovascular treatment can be undertaken after other life-threatening injuries are addressed and normal physiology has been restored. Medical management consists of tight blood pressure and heart rate control with beta-blockers and vasodilators. In cases of minor injury and in patients with prohibitive operative risk, medical management may be the definitive treatment. However, the majority of patients undergo either open or endovascular repair. Open repair is associated with significant mortality and morbidity, the most significant of which is paraplegia, occurring in 1.6–14.0% of patients. Because of the difficulties and dangers of open repair the use of endovascular techniques has significantly increased in popularity. There have been several studies of thoracic endovascular aortic repair demonstrating a technical success rate of 92–100% with mortality of 0–17.9%. In comparison with open repair, studies have shown a significant decrease in mortality, blood loss, transfusion requirements, paraplegia rates, operating theatre times and length of stay. Complications, including access site dissection, fistula and pseudoaneurysm, and systemic, such as CIN, pneumonia, heart attack and stroke, occur in 0–15% of cases. Endoleaks also occur in 0–15% of patients and may require additional intervention. The majority are type I endoleaks; this is likely to be related to the technical difficulty in achieving a good proximal seal in the aortic arch. The majority of type I leaks are diagnosed at the time of the original procedure and treated. However, long-term outcomes are unknown and several studies have demonstrated an increased need for secondary interventions among thoracic endovascular aortic repair patients compared with those undergoing open repair.

Penetrating thoracic aortic injuries

Injuries to the thoracic aorta and great vessels are more commonly due to penetrating mechanisms. In these circumstances the diagnostic problems are considerably more clear-cut. Those patients presenting with initial haemodynamic instability and a penetrating wound to the chest require urgent thoracotomy. In stable patients CT has proven to be an excellent and cost-effective screening examination. Patients with transthoracic or transmediastinal gunshot wounds are at risk for vascular, aerodigestive and spinal injuries. CT scan can determine which patients require surgery and which require additional more invasive imaging, such as angiography, oesophagoscopy, oesophagography or bronchoscopy. Studies reveal conclusive results in 82.9–100% of cases.

The approach to major vascular injuries in the thorax may involve significant blood loss; therefore, adequate preparations should be made, including initiation of the MTP and having large-bore intravascular access and warming equipment available. Proximal and distal control may require cross-clamping of the descending aorta, with the associated risk of spinal cord ischaemia. Partial bypass techniques have greatly improved over the past several years and should be used within the trauma setting whenever practical. Under most circumstances, systemic heparinization is not required. Primary repair of the injury should be attempted when feasible, but intercostal vessels should not be sacrificed to gain mobility owing to the increased risk of spinal cord ischaemia. Dacron interposition grafts can be used if defects are too large for primary repair. In patients with severe physiological derangement, temporary intravascular shunts may be used as a damage control technique. Chest tubes, nasogastric tubes and commercially prepared vascular shunts can all be used depending on the diameter of the injured vessel. The shunts should be secured proximally and distally with silk ties or umbilical tape. Patency appears to be adequate without the use of systemic heparinization, although maximum dwell times are unknown.

Blunt cardiac injuries

The incidence of blunt cardiac injury varies widely from 8% to 71% owing primarily to the wide spectrum of the disease, which ranges from mild asymptomatic contusion to free wall rupture, and a lack of consensus on a gold standard diagnostic test. Blunt cardiac injury can be divided into abnormalities of conduction and those of structure.

The most commonly seen electrical abnormalities are non-specific ST–T wave changes. The most common clinically significant electrical disorders are tachyarrhythmias, of which atrial fibrillation is the most likely. Haemodynamically significant arrhythmias are rare and treatment is similar to arrhythmias of non-traumatic aetiology with medications or cardioversion. There are no data to support the use of prophylactic antidysrhythmics.

Structural lesions include blunt cardiac rupture, valvular or papillary muscle rupture, coronary artery injury and myocardial contusion. Structural lesions are best diagnosed with echocardiography, which has an excellent sensitivity and specificity. Few patients with blunt cardiac rupture remain alive long enough to present to the hospital. The right chambers are most commonly injured because of their more vulnerable location directly beneath the sternum. If patients reach the hospital alive the most common presentation is haemorrhagic shock or tamponade. Treatment is swift diagnosis and open cardiac repair but subsequent mortality remains high. Patients with suspected cardiac rupture should be supported with volume resuscitation with early initiation of MTPs. Needle pericardiocentesis may be useful only as a temporizing measure if there are no immediate surgical capabilities. Valvular or papillary muscle rupture is rare after blunt injury but can be progressive, making prompt surgical intervention the most appropriate treatment. Blunt coronary artery injury is also very rare, representing <2% of blunt cardiac injuries. Direct impact may result in thrombosis, dissection or vessel rupture. Coronary rupture may present with shock, tamponade or haemorrhage; treatment is immediate operative repair, or ligation if tolerated. Occlusion or dissection present similarly to acute myocardial infarction. Treatment includes medical management, percutaneous intervention and operative revascularization.

Contusions are the most common structural abnormality. The majority of cardiac contusions are asymptomatic and have no long-term consequences. However, patients with haemodynamic instability should be admitted to the ICU, with intubation, invasive cardiac monitoring and urgent echocardiogram. Treatment of cardiogenic shock associated with blunt cardiac injury should include replacement of intravascular volume, inotropic agents and occasionally placement of an intra-aortic balloon pump. In stable patients with suspicion of blunt cardiac injury diagnostic tests include creatine phosphokinase-MB (CK-MB), troponin I (Tn-I), echocardiography and ECG. There is level I evidence to support the use of ECG in diagnosis of blunt cardiac injury, and it is recommended that all patients with suspicion of blunt cardiac injury undergo at least an admission ECG. If this is normal there is little risk of blunt cardiac injury. However, addition of biomarkers of cardiac injury such as CK-MB or Tn-I can increase sensitivity and specificity to 100% and 71%, respectively.

If blunt cardiac injury is diagnosed, patients should be admitted for observation. The majority of haemodynamically significant complications occur in the first 24–48 hours. If they are appropriately monitored and managed the vast majority of patients recover quickly with no long-term cardiac dysfunction. In the immediate period studies have shown that, if early surgery is required for other injuries, general anaesthesia can be used safely, although consideration should be given to intraoperative haemodynamic monitoring with transoesophageal echocardiography or pulmonary artery catheters.

Penetrating cardiac injuries

Penetrating cardiac trauma is rare, accounting for only 0.16% of trauma admissions overall. Even with modern trauma systems only 10–15% of victims of penetrating cardiac trauma reach the hospital alive. Stab wounds have a better outcome than gunshot wounds and account for the majority of survivors of penetrating cardiac injury. Predictors of good outcome include the presence of a sinus rhythm upon entry to the pericardium, absence of exsanguination and presence of tamponade. Negative predictors include emergency department thoracotomy and atrial injury (Figure 14.22), and wounds producing large defects in the pericardium. Lastly, longer prehospital times and patients requiring >3 minutes of CPR have higher mortality.

The highest risk for injury to the heart occurs within the cardiac box – the area bordered by the clavicles, costal margin and mid-clavicular lines. However, every penetrating injury to the chest should be suspected of cardiac injury until proven otherwise. Hypotension is the most common clinical finding; however, Beck's triad (hypotension, distended neck veins, distant cardiac sounds) may not be present because of significant intravascular volume depletion associated with haemorrhage. Anxiety, restlessness and pulsus paradoxicus are all also associated with tamponade.

In the unstable patient with multicavitary trauma, or in those with thoracic trauma who are stable, FAST has become the diagnostic method of choice. With reported sensitivity and specificity nearing 100% in diagnosing pericardial effusion, a positive cardiac FAST can be seen as an absolute indication for operation. However, false-negative results can occur, particularly in the presence of significant pneumothorax/haemothorax allowing decompression of a potential effusion into the left hemithorax. Given the widespread dissemination of FAST, invasive testing such as pericardiocentesis and subxiphoid

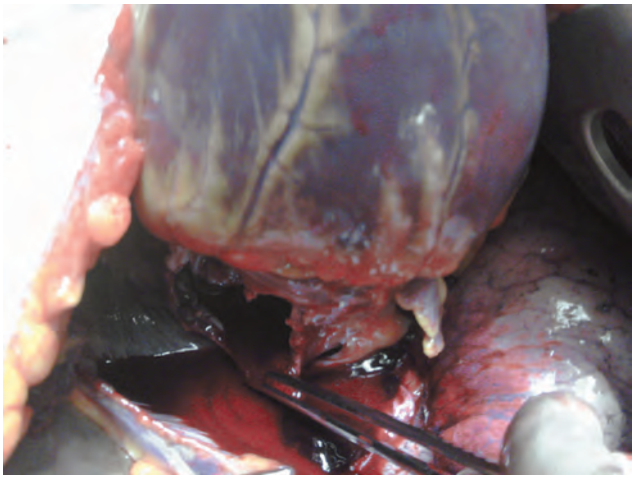

Figure 14.22 Postmortem photograph depicting a large right atrial laceration due to a gunshot wound to the chest.

window have few indications in a hospital environment and should only be considered when FAST is not available. In contrast, a transdiaphragmatic window during laparotomy for associated injuries is useful for rapidly ruling out cardiac injury. It is easily performed, has excellent sensitivity and specificity, and is associated with a very low rate of complications. If the pericardial fluid is bloody, the laparotomy can be extended into a median sternotomy to address the cardiac injury rapidly.

Keys to management include early recognition, aggressive resuscitation and rapid repair. Patients with a perfusing rhythm and positive FAST should be transferred to the operating room for median sternotomy immediately. However, many patients arrive *in extremis* or full cardiac arrest and there is no time for transfer to the operating theatre. These patients should undergo immediate resuscitative thoracotomy. Resuscitative thoracotomy has an overall survival rate of 7.4%; the best outcomes, with 19.4% survival, are seen with thoracic stab wounds. In the presence of cardiac arrest, the thoracic aorta should be clamped in order to improve coronary and cerebral circulation. Once the cardiac injury is identified, active bleeding is controlled by finger compression and then sutured. Injuries close to the coronary vessels should be repaired with horizontal mattress sutures underneath the vessel. Injuries to the posterior wall of the heart can be exposed by slowly lifting the apex of the heart. Overly rapid or aggressive elevation can result in severe arrhythmias or complete arrest. Following repair, if necessary, the heart is resuscitated with open cardiac massage, intravenous fluids, intravenous or intracardiac epinephrine, and internal defibrillation.

All survivors should undergo serial postoperative echocardiographic evaluation. Penetrating injuries may lacerate the septum, resulting in atrial septal defects, ventricular septal defects, or damage to valve leaflets or papillary muscles. These internal injuries may be missed at the time of operation, and are often asymptomatic. Progression of injury may also cause focal dyskinesia or cardiac pseudoaneurysm in the postinjury period. Myocardial oedema and haematoma may prevent flow through atrial septal defects or ventricular septal defects, and wall motion abnormalities may take weeks to develop; therefore, it is essential to repeat evaluations a few weeks after injury.

Injuries to the oesophagus

Because of its protected location in the posterior mediastinum, blunt injury to the thoracic oesophagus is exceedingly rare. When it occurs, blunt rupture of the oesophagus is usually seen in the distal third just above the gastro-oesophageal junction, similar to Boerhaave syndrome. The injury is probably produced by sudden increases in the intraoesophageal pressure owing to blunt upper abdominal trauma in the presence of a full stomach.

Penetrating injuries are more common and may occur at any level. One must conduct a thorough search for injury to the oesophagus if a penetrating wound has a trajectory that is in proximity to the thoracic oesophagus. There is a high incidence of major associated injury with either blunt or penetrating mechanisms.

Specific signs and symptoms due to perforation of the oesophagus are few and generally the patient's complaints are related to associated injuries. As noted, early diagnosis is the single most important factor in determining ultimate outcome. Findings on CXR include pneumomediastinum, widened mediastinum, air in the prevertebral space or left pleural effusion. The best initial study is contrast oesophagography, although this test does have a significant false-negative rate; adjunctive flexible oesophagoscopy can add to the sensitivity. Early operative repair is the key to successful therapy. Mediastinal contamination and eventual sepsis lead to prohibitively high mortality rates in patients whose operative repair is delayed beyond 12–24 hours.

The upper two-thirds of the thoracic oesophagus are best approached through a right thoracotomy whereas injuries confined to the lower third may be more easily accessible from the left. The general operative principles are to attempt surgical closure when possible and establish wide mediastinal drainage. Extensive tissue destruction, massive mediastinal contamination or delay in surgery may preclude primary repair and constitute indications for exclusion.

Abdominal and pelvic injuries

The abdomen encompasses a large area of the body from the diaphragm superiorly to the infragluteal fold inferiorly, including the entire circumference of this region. Abdominal injuries are generally classified into blunt or penetrating based on mechanism. This breakdown can be useful to the surgeon because the types of injury, presentation and management are quite different. Approximately 25% of all abdominal trauma patients will require a laparotomy at some point during their hospital stay.

Blunt trauma accounts for >80% of all abdominal trauma, resulting in a rate of intra-abdominal injury of approximately 18%. The incidence of blunt trauma is increasing owing to the increasing rate of automobile and motorcycle accidents. The car remains the cause of the majority of blunt abdominal trauma. Solid organ injury is more common than hollow visceral injury following blunt trauma, with the liver being the most commonly injured organ. Given the success of selective non-operative management of solid organ injury, the need for laparotomy following blunt trauma is low. Blunt abdominal trauma requires exploratory laparotomy in only 4% of cases but accounts for 78% of trauma admissions. Mechanisms of injury in blunt abdominal trauma include direct blunt force against bony surfaces such as the spine or pelvis, acceleration/deceleration injury, 'burst' injury and laceration from broken rib, pelvis or spine fragments.

Penetrating trauma accounts for approximately 20% of trauma admissions. The liver and small bowel are the most commonly injured organs. Surgical exploration is more frequently required following penetrating trauma, with 15% of posterior stab wounds, 50% of anterior stab wounds and 60–75% of gunshot wounds requiring laparotomy. In general, higher velocity mechanisms result in worse outcomes, such that gunshot wounds are worse than stab wounds and military wounds are worse than civilian wounds. While injury following low-velocity penetrating trauma results only from direct laceration, injury following medium- and high-velocity mechanisms can occur as a result of laceration, cavitation or blast. Injuries to both thoracic and abdominal cavities occur in 25% of patients with penetrating trauma as the wound may traverse the diaphragm.

Failure to recognize occult abdominal haemorrhage and to successfully control bleeding leads to significant morbidity, and such injuries account for approximately 10% of traumatic deaths that occur annually in the USA. Additionally, failure to appropriately manage abdominal injuries accounts for the majority of preventable deaths following trauma. Trauma to the abdomen is often associated with multisystem injuries, particularly the central nervous system, chest and musculoskeletal system, and these concomitant injuries may obscure signs and symptoms of abdominal injury. Because of this, the need for repeated assessment of the patient suspected of having intra-abdominal injury cannot be overemphasized. The trauma surgeon must take responsibility for overall treatment and provide consistent serial examinations.

Significant intra-abdominal injury can follow iatrogenic causes, including endoscopy, CPR, peritoneal dialysis, paracentesis, biopsy and contrast enema. The principles of diagnosis and treatment are no different from other traumatic injuries.

Anatomical considerations

A practical knowledge of the contents of the abdomen is important. Abdominal injuries can be divided into intraperitoneal, pelvic and retroperitoneal injuries. Examination of the true abdomen and intraperitoneal structures is relatively straightforward. Blood and enteric contents from both hollow visceral and abdominal vascular injury often cause peritoneal irritation and severe pain prompting operative exploration. In the absence of peritonitis, the FAST examination or DPA/DPL can be useful for detecting intraperitoneal free fluid in the hypotensive patient, thus identifying the abdomen as a source of significant haemorrhage. In contrast, injury to the pelvis and retroperitoneal structures can be a diagnostic challenge. Bleeding into both the pelvis and retroperitoneum is often asymptomatic, even when large volumes have been lost, and is undetectable by FAST as well as by DPA/DPL. Damage to the retroperitoneal portions of hollow viscous structures will likewise often be asymptomatic, or present with vague non-specific findings such as tachycardia or failure to clear a base deficit. Because of this a high level of clinical suspicion and judicious use of adjunctive imaging such as CT scanning, urethrography, and angiography are necessary to avoid delays in diagnosis and treatment.

Diagnosis

A history should be obtained from the patient if possible, and from the paramedics in the MIVT format. Information on the type of weapon involved in assaults and the types of vehicle, location of the patient, presence or absence of restraints and vehicle damage in accidents and even images of the scene can be useful to the clinician.

Upon arrival, ATLS protocols should be followed and blood samples should be drawn for basic studies, most importantly type and cross-match. This is then followed by the abdominal examination as a part of the complete secondary survey. The key objective of the physical examination is to determine whether operative exploration is necessary. Absolute indications for surgery include peritonitis, hypotension with evidence of intraperitoneal haemorrhage and evisceration. Unfortunately, outside of these findings, physical examination can be non-specific. Bleeding may be retroperitoneal, and the physical examination may be benign even in the presence of significant haemorrhage. Alternatively, associated injuries to the abdominal wall, overlying ribs and pelvis may result in significant pain and tenderness on examination even in the absence of any intra-abdominal organ injury.

Abdominal assessment should be systematic and orderly. The abdominal wall should be inspected for seat belt signs, abrasions, ecchymoses, lacerations, wounds and foreign objects. Particular care should be taken if a seat belt sign is found, as the presence of an abdominal seat belt sign is associated with a significant increase in intra-abdominal injuries. In adults the presence of a seat belt sign increases the risk of intra-abdominal injury two- to eightfold. This is further increased in paediatric patients, in whom rates of intra-abdominal injury can be increased as much as 12-fold in the presence of a seat belt sign. Hollow visceral, particularly the duodenum, and mesenteric injuries are markedly increased and the threshold to operate on a patient with free fluid and a seat belt sign should be very low. Pancreatic injury is also increased, particularly among paediatric patients. However, the seat belt sign is not associated with increased mortality.

In all cases, but particularly with penetrating mechanisms, care should be taken to inspect the groins, axillae and back to ensure no additional injuries are missed. The abdomen should be palpated to assess for peritoneal signs or rigidity and localized tenderness. In blunt injuries, the pelvis should be assessed for stability, tenderness and range of motion of the hips. If pelvic fracture is suspected the perineum and urethral meatus should be inspected and a rectal examination performed to rule out distal genitourinary injury. In the absence of signs/symptoms of urethral injury a Foley catheter should be placed to assess for haematuria and resuscitation status. A nasogastric tube should be placed as well to decompress the stomach and evaluate for bleeding. Both gastric and urinary bleeding are indications for laparotomy following penetrating trauma.

The abdominal examination may be supplemented by diagnostic imaging methodologies including FAST, plain radiographs, DPA/DPL and CT scan. Prior to any imaging all penetrating wounds should be marked with radio-opaque clips. Plain radiographs or CT scan can then be taken to delineate the trajectory of the bullet or path of the knife and allow for an intelligent assessment of the likelihood of associated injury. Additionally, wounds can be packed with Betadine-soaked gauze, again in order to delineate the tract of injury.

Choice of imaging is determined by the clinical condition of the patient. Unstable patients with isolated abdominal trauma should proceed directly to the operating theatre; however, those with blunt or multicavitary penetrating trauma may have multiple sources of haemorrhage and it is necessary to identify the correct cavity for exploration prior to transfer to the operating theatre.

FAST remains the most rapid, non-invasive and repeatable modality for determining the presence of free fluid in the abdomen. The purpose of the FAST examination is to identify the presence of free fluid in the peritoneal cavity; however, at least 200–300 mL of blood must accumulate before it can be reliably seen on FAST. While the reported sensitivity of FAST varies from 67% to 80%, the specificity and accuracy are consistently reported to be 98–100%. Therefore, although a positive study is reliable, a negative FAST does not exclude intraperitoneal haemorrhage. A positive FAST in the hypotensive blunt trauma patient warrants immediate exploratory laparotomy. If the FAST is negative or indeterminate in hypotensive patients, DPA or DPL may be of use.

First introduced in 1965, DPL has a sensitivity of 90–95%, specificity of 99–100% and accuracy of 92–98%. Many surgeons perform DPA only and do not add lavage if the aspiration is negative because it is unlikely that blood detected by lavage and not by DPA or FAST is responsible for significant hypotension. The false-positive rate for DPL is higher in patients with pelvic fractures and, similar to FAST, DPL is unreliable in detecting injury to retroperitoneal organs. Patients with a positive DPA, defined as aspiration of ≥10 mL of blood or aspiration of succus, or a grossly positive DPL (drainage of bloody or blood-tinged effluent) should be taken immediately for surgical exploration. In stable patients, if the returning lavage fluid is not frankly positive, microscopic analysis can be performed; a positive result is generally considered as a RBC count >100 000/mm^3, WBC >500/mm^3, amylase >200 units or the presence of bile or faecal material.

When performing a DPA, proper technique is essential to avoid iatrogenic injury and to obtain the best sensitivity. First, a Foley catheter should be placed to decrease risk of bladder injury, a nasogastric tube should be inserted to avoid gastric injury, and the abdomen should be prepared in a sterile manner. The infraumbilical site should be used if there is no evidence of pelvic fracture or pregnancy; if either is present or suspected, the supraumbilical position should be chosen. An incision approximately 1 cm long should be created sharply, then a needle inserted aiming towards the pelvis until a pop is felt as the fascia is breached. A wire is then inserted and the needle removed. Seldinger technique is then used to thread a catheter over the wire into the peritoneal cavity. A syringe is used to aspirate the catheter. If the aspirate is negative and lavage is desired, the syringe is removed leaving the catheter in place, valveless tubing is attached to the catheter and 1 litre of sterile saline for adults or 10 mL/kg for paediatric patients is infused. The tubing should not be disconnected at any point, and once the fluid bolus has infused the tubing should be lowered below the patient to allow gravity to assist in removal of the infusate into a vacuum bottle or empty saline bag. It is important to remember that DPL is only considered adequate if ≥75% of the infusate is returned. DPA/DPL are contraindicated in patients with previous laparotomy, and may be technically difficult in the pregnant or morbidly obese patient.

In the stable patient with evidence of significant abdominal trauma FAST has little value, as a negative scan cannot reliably exclude injury and a positive scan does not necessarily require laparotomy. DPA/DPL may have a role in the stable patient who is unevaluable owing to a depressed level of consciousness, spinal cord injury or intoxication, or in those who will be unevaluable owing to general anaesthesia for surgical treatment of concomitant injury. In stable patients without peritonitis who have a reliable abdominal examination and who are not distracted, intoxicated or anaesthetized, serial abdominal examination has proved a reliable means of excluding surgical abdominal injury, particularly in the patient with abdominal stab wounds. In stable patients with high-velocity penetrating trauma or blunt trauma, serial abdominal examinations should be supplemented with CT scan.

Advantages of CT scan include high sensitivity and specificity – up to 90–100% for solid organ injury; ability to evaluate the entirety of the abdomen, retroperitoneum and pelvis; excellent delineation of tract of injury following penetrating trauma; and high sensitivity for detection of intraperitoneal fluid. CT is also non-invasive, and can be used to reliably predict patients with solid organ and pelvic injury who may benefit from angioembolization. Additionally, when genitourinary injury is suspected because of the location of wounds or haematuria, delayed images can be easily obtained and used to evaluate the urinary collecting system. Disadvantages include cost, radiation and contrast exposure, need to remove the patient from a monitored, therapeutic setting, and poor sensitivity for hollow viscous and diaphragm injury. When present, some indications of hollow viscous injury include bowel wall thickening, mesenteric thickening/haematoma, free fluid without solid organ injury and pneumoperitoneum (Figure 14.23). The presence of any of these findings warrants surgical exploration. However, absence

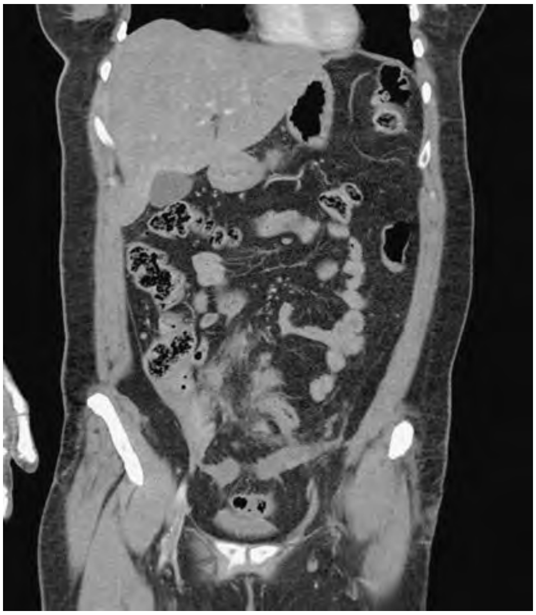

Figure 14.23 Coronal CT revealing free fluid in the pelvis as well as within the mesentery of the small bowel with inflammatory changes of the small bowel mesentery near the right lower quadrant;, these findings are concerning but not diagnostic for hollow viscous injury. At laparotomy the patient was found to have a full thickness mesenteric laceration with active bleeding and an associated antimesenteric small bowel injury.

of these signs does not definitively exclude hollow visceral injury and patients with significant mechanisms of injury require serial abdominal examinations and a high index of suspicion should be maintained by the clinician. Should any deterioration in vital signs, laboratory values or abdominal examination occur, there should be a low threshold for surgical exploration. Patients with negative CT scans and no clinical deterioration can generally be safely discharged after 24–48 hours of serial observation.

Plain films of the abdomen are rarely used, but may be beneficial in cases of impalement to delineate the tract of injury prior to operation and in cases of multiple projectiles, such as shotgun and multiple gunshot wounds, to look for the distribution of foreign bodies (Figure 14.24). Plain films may occasionally reveal pneumoperitoneum (Figure 14.25), which is another indication for surgical exploration.

Priorities of treatment

It is the job of the trauma surgeon to integrate various specialties that may be called upon to participate in the care of the multiply injured patient. This requires aggressive resuscitation and prioritization of injury work-up and treatment; often, two or more teams may be required to work simultaneously, e.g. in patients with both intra-abdominal and intracranial injury. The trauma surgeon should be aware of what other treatment teams are doing and participate in the decision to alter goals of care from definitive care to damage control for general, neurosurgical and orthopaedic interventions.

In preparation for the operating theatre, particularly in patients with haemodynamic instability, multiple interventions must be co-ordinated. These include large-bore intravenous access with the possible need for central venous catheterization at an appropriate location. Type and cross-match should be performed and MTPs activated appropriately. An arterial cannula should be placed to aid in monitoring resuscitation parameters such as blood pressure, pulse pressure variability, arterial pH and base deficit. Antibiotics should be administered preoperatively, and redosed if massive haemorrhage or long operative times are encountered. Additionally, the trauma surgeon must take aggressive measures to ensure prevention and/or prompt treatment of hypothermia.

Operative approach

The operative approach for abdominal trauma is straightforward. A midline incision is preferred, and there are few reasons to deviate from this. It allows excellent visualization of most intra-abdominal, pelvic and retroperitoneal organs. It also allows extension to a median sternotomy in the event that more proximal control of the vena cava or aorta is needed, or if results of a diaphragmatic window are positive. Because of this the chest should be prepared and included in the sterile field. When preparing the patient the pelvis, including both groins and anterior thighs, should also be included in the sterile field in the event that distal vascular control in the inguinal region is required for pelvic vascular injuries, or if a saphenous vein conduit needs to be harvested for complex vascular reconstructions.

Once the abdomen is opened obvious blood and clot is removed and all four quadrants are packed with sponges. These sponges are then sequentially removed to localize sources of bleeding and/or contamination. Once all areas of active haemorrhage are identified they can be repacked for temporary control. Additional inflow occlusion can be accomplished by clamping the aorta at the diaphragmatic hiatus (Figure 14.26). Obvious sources of intestinal contamination should rapidly be temporarily controlled with clamps, sutures or stapled resection without reconstruction. Retroperitoneal haematomas should be left intact if not ruptured and investigated only once all intra-abdominal catastrophes have been addressed. The major abdominal vessels are all centrally located and, because of this, all central retroperitoneal haematomas should be surgically explored. Lateral and pelvic haematomas are more likely to be caused

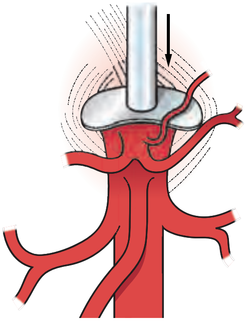

Figure 14.26 The exposed supracoeliac aorta with application of an aortic compression device for inflow occlusion during major abdominal vascular injury. (From Feliciano, http://www.acssurgery.com/acs/chapters/ch0710.htm#.)

by non-surgical bleeding or injury to the kidneys, small unnamed vessels or veins; because of this, lateral and pelvic retroperitoneal haematomas should only be explored if they are expanding, pulsatile or due to penetrating trauma.

Once haemorrhage has been controlled and ongoing contamination stopped, a decision has to be made whether to proceed with definitive repair of all injuries or whether the goals of care have changed to damage control, in which case temporary abdominal closure should be performed.

Damage control surgery was originally created for management of the exsanguinating, severely injured, penetrating trauma patient. Such patients present with extreme physiological derangements, including acidosis due to volume losses, hypoperfusion and anaerobic metabolism; hypothermia; and subsequent coagulopathy (the bloody viscous triad). Prolonged surgery and multicavitary exposure is likely to exacerbate these derangements, contributing to morbidity and mortality. Therefore, the initial surgery should be abbreviated so that treatment of these catastrophic injuries is staged into three distinct phases. First, control of acute haemorrhage and contamination; second, resuscitation; and, third, planned re-exploration for definitive surgical treatment. Indications for damage control surgery include haemodynamic instability, coagulopathy, acidosis (pH <7.2), hypothermia (<35°C), injuries to multiple body cavities, long estimated operative times, and massive transfusion requirements. Injury burden, comorbidities and physiological reserve should also be factored into the decision to pursue damage control surgery. The decision to perform damage control surgery should be made early in the procedure. If damage control surgery has been chosen, once haemorrhage and contamination have been controlled, a temporary abdominal closure should be applied. The temporary abdominal closure must maintain sterility, protect the bowel, prevent evisceration and adhesions, and ideally apply some traction to the abdominal wall to prevent retraction while allowing for expansion of abdominal contents to prevent development of abdominal compartment syndrome. Additionally, the closure should have a means of collecting, removing and quantifying abdominal fluid drainage. Any method that reapproximates fascia or skin should be avoided because of the high risk for abdominal compartment syndrome. The two most popular techniques are vacuum-assisted abdominal dressings and the Bogota bag. Once temporary closure has been achieved, the goal of resuscitation is to reverse acidosis with restoration of circulating blood volume with warm fluids and rewarming with blankets, forced air warmers or ventilation with warmed humidified air. Evidence of return of normal physiology such as normalization of blood pressure, heart rate and temperature; adequate urine output; clearance of elevated lactate levels; and normalization of haemoglobin and coagulation profiles should occur before the patient is returned to the operating theatre for definitive surgical repair and abdominal wall closure. Prior to any definitive abdominal closure care should be taken to carefully inspect the entire gastrointestinal tract from the diaphragmatic hiatus to the peritoneal reflection around the distal rectum, and ensure proper positioning of the nasogastric tube. Additionally, all solid organs should be inspected and palpated, retroperitoneal haematomas assessed for stability, the lesser sac visualized and the diaphragm inspected for any defects.

Specific injuries

Diaphragmatic injuries

Diaphragmatic injury occurs as a result of high-energy acceleration–deceleration trauma, or as a direct laceration from a weapon or broken rib. Blunt injuries tend to be large avulsions, while penetrating injuries tend to be smaller lacerations. Diaphragmatic injury following blunt trauma is rare, occurring in only 3% of cases, in which it is associated with other injuries in 52–100% of cases. Left-sided injuries are more common than right-sided injuries – accounting for 70% of cases. This is probably the result of several factors: first, the posterolateral aspect of the diaphragm is structurally weak on the left; second, the right diaphragm is protected by the liver; and, last, it is more difficult to diagnose injuries on the right. However, right-sided ruptures are associated with more severe injuries and a more significant mechanism. Unlike blunt trauma, diaphragmatic injury may complicate as many as 26% of stab and 13% of gunshot wounds. Injuries are often asymptomatic and imaging continues to have poor sensitivity and specificity. CXR may reveal air-filled organs or NGT above the diaphragm (Figure 14.27a,b), but can also be normal or non-specific in up to 50% of cases. Sensitivity for CT scan (Figure 14.28) and DPL are also poor ranging, from 14% to 61%.

Laparoscopy is the most effective means of both diagnosis and treatment of diaphragmatic injury after penetrating trauma. Sensitivity and negative predictive values are 87.5% and 96.8%, respectively. Any patient with penetrating trauma to the area bounded by the nipples superiorly and costal margin inferiorly should be suspected of having diaphragmatic injury and undergo diagnostic laparoscopy. If injury is found during laparoscopy, the defect can be repaired laparoscopically or the procedure converted to open laparotomy. Pneumothorax can occur with insufflation during laparoscopy and should be decompressed with chest tube placement. If there is another indication for exploratory laparotomy, care should be taken to inspect both diaphragmatic leaflets prior to closure. If the diagnosis is known prior to surgery acute diaphragmatic injury should be approached via the abdomen because of the potential for associated intra-abdominal injury. However, defects discovered remote from the time of injury can be approached through the abdomen, chest or laparoscopically at the discretion of the

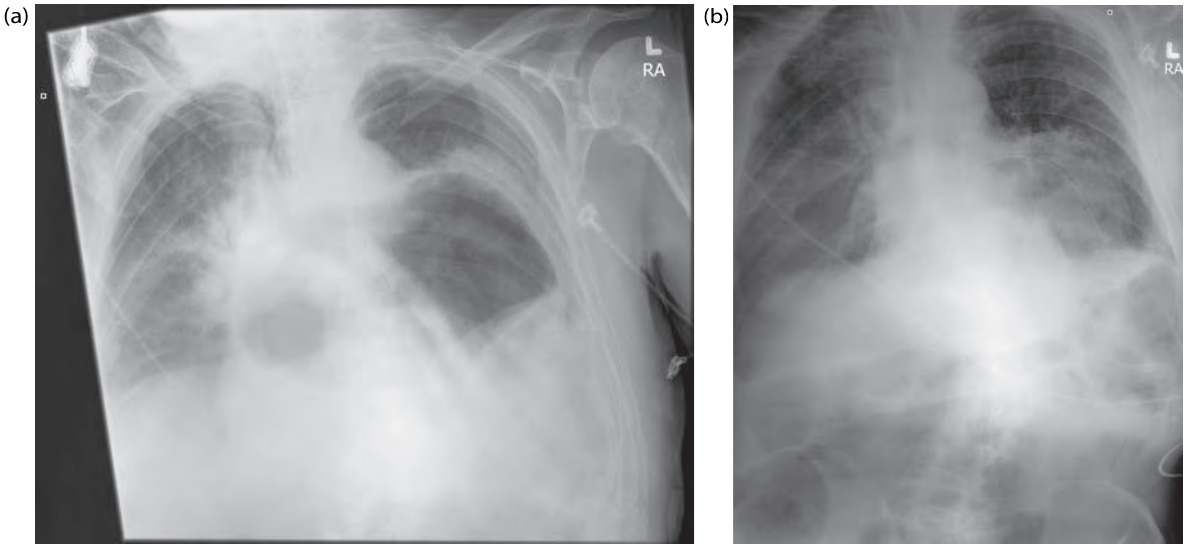

Figure 14.27 (a) Chest radiograph depicting large diaphragm rupture with herniation of the stomach into the left chest before stomach decompression. (b) Same patient as in (a), after placement of a nasogastric tube.

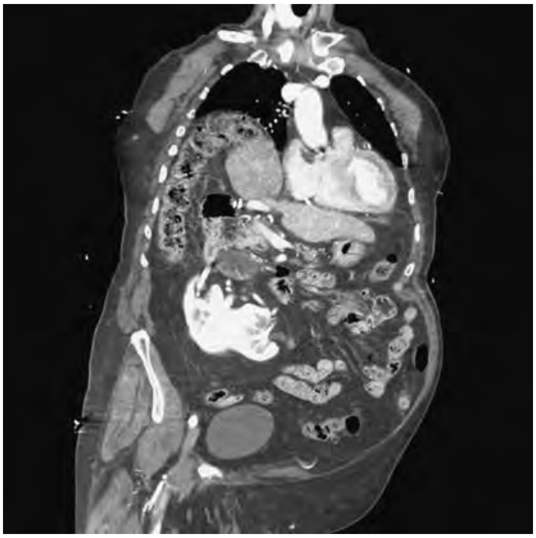

Figure 14.28 Coronal CT scan depicting a right diaphragmatic injury with herniation of the colon and right lobe of the liver into the right chest.

surgeon. All diaphragmatic injuries should be repaired surgically with non-absorbable interrupted sutures. Large injuries, such as those seen with blunt trauma, may require prosthetic material to bridge the defect; Goretex is most often chosen for such repairs. However, care should be taken to avoid placing artificial material into contaminated fields.

Despite careful work-up delay in diagnosis can occur in 30–50% of cases. This delay can range from 7 days to 40 years. During this time injuries can grow as viscera migrate into the thoracic cavity owing to the normal pressure gradient across the diaphragm. Herniation of abdominal contents may cause significant morbidity and mortality as a result of ischaemia of the herniated organs or respiratory distress (Figure 14.28). Mortality associated with diaphragmatic injury ranges from 1% to 28%, primarily related to associated injuries.

Splenic injuries

The spleen is one of the most frequently injured abdominal organs following trauma. The history may include a blow, fall or sports injury to the left flank, lower chest or upper abdomen. Injury to the spleen should also be suspected following penetrating trauma with wounds to the left upper quadrant, flank or back. Splenic injury may be completely asymptomatic, present with vague abdominal or left upper quadrant pain, or referred pain to the left shoulder (Kehr's sign). Stable patients are most likely to be diagnosed by CT scan, which is both highly sensitive and specific and can be used to grade the injury.

Splenic injuries are classified according to the American Association for the Surgery of Trauma Organ Injury Scale (AAST-OIS) (Figure 14.29a,b). Minor injuries include grade I and II, and are minor lacerations or subcapsular haematomas. Moderate injury, i.e. grade III, consists of larger and more severe subcapsular haematomas, lacerations or injuries involving trabecular vessels. Severe injuries include grades IV and V, which are severe lacerations of the segmental or hilar vessels resulting in devascularization or a completely shattered organ.

Management of splenic trauma has undergone a revolution since the 1990s as appreciation of the dangers of abdominal sepsis and overwhelming postsplenectomy sepsis has risen. Non-operative management of solid organ injury, angioembolization and splenic salvage during operative exploration are all acceptable and common alternatives to splenectomy. Rates of success with splenic non-operative management can be as high as 95% for paediatric and 80% for adult populations. Strict contraindications to non-operative management include peritonitis and haemodynamic instability. Studies have now shown acceptable rates of success with non-operative management in patients with neurological injury and in patients with high-grade injury, blush or haemoperitoneum, although these factors increase the risk for failure (Figure 14.30a,b). The addition of angiography with embolization has augmented success rates of non-operative management (Figure 14.31a–d), particularly among patients with

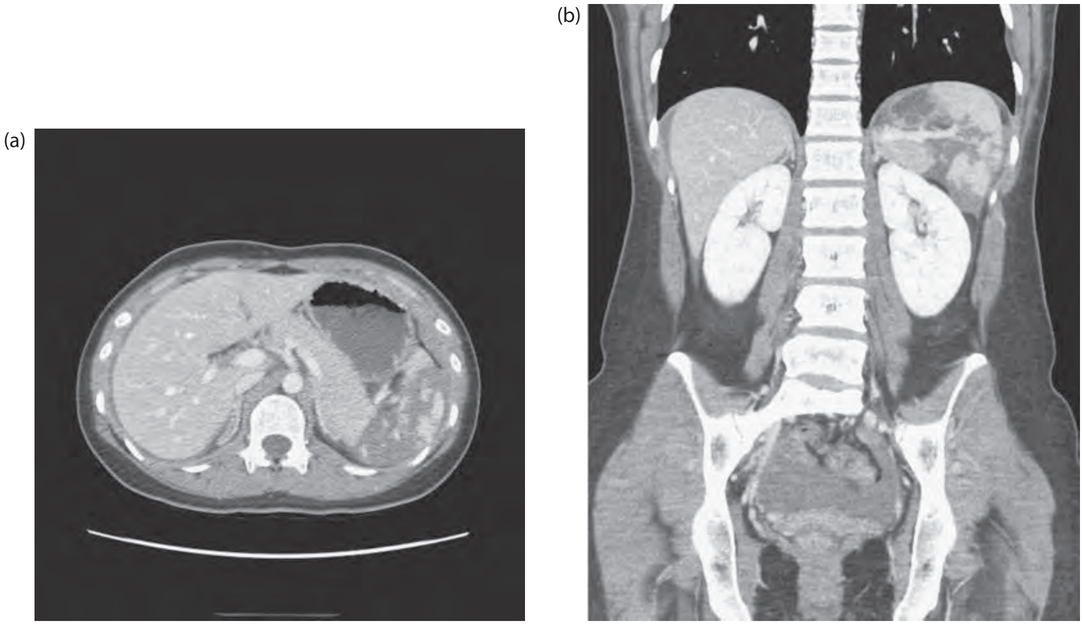

Figure 14.29 (a) Axial and (b) coronal CT scan of a grade IV splenic injury without evidence of active extravasation.

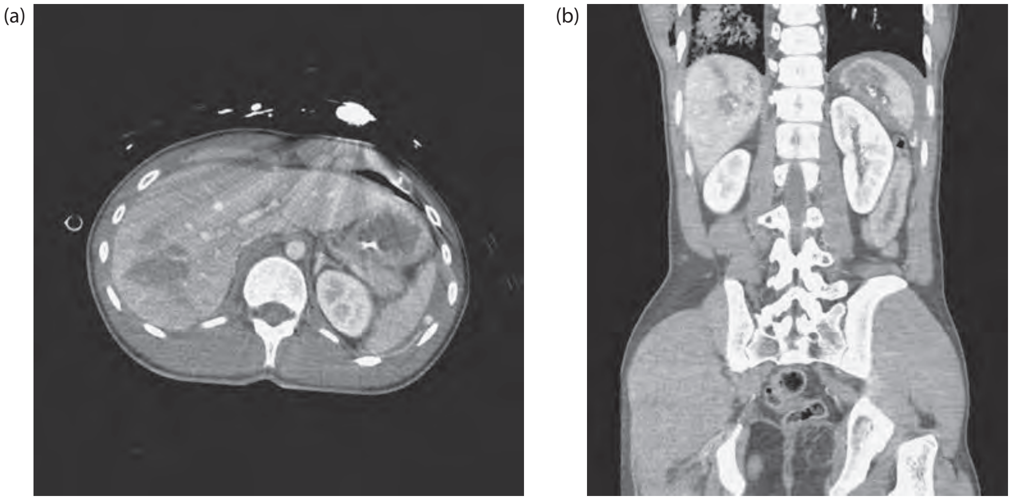

Figure 14.30 (a) Axial and (b) coronal CT scan of a splenic injury with an area of active extravasation in the lateral lower pole. Note that there is also a grade III liver injury to the right lobe.

evidence of arteriovenous fistula, active extravasation and transient responders. Angiography should also strongly be considered in patients with multiple solid organ injuries or concomitant pelvic fracture as it can be both diagnostic and therapeutic in patients with multiple potential sources of haemorrhage.

During operative exploration for another indication, splenic haemorrhage control or failure of non-operative management, the spleen should be carefully evaluated for injury and active bleeding. The process of medially mobilizing the spleen by incising its superior and lateral attachments to the abdominal wall and retroperitoneum is known as the Aird manoeuvre. Care must be taken during mobilization to prevent injury to the diaphragm, stomach and colon. After complete mobilization the spleen and distal pancreas should be delivered into the abdominal incision, allowing visual inspection of the entire organ anteriorly and posteriorly as well as full inspection of the hilum. Bleeding should first be controlled with direct application of digital pressure with a dry sponge. Shallow capsular tears or abraded areas can be controlled with application of topical haemostatic agents. Larger lacerations can be repaired with absorbable sutures. Major injury to the tissues, if localized and <50% of the mass, can be treated with partial splenectomy. However, major vascular injury, injury to >50% of the organ and ongoing bleeding despite splenorrhaphy should be treated with splenectomy (Figure 32). Additionally, splenic salvage techniques should not be pursued among patients with severe physiological derangements, prolonged hypotension or severe concomitant injury, particularly brain injury. With penetrating

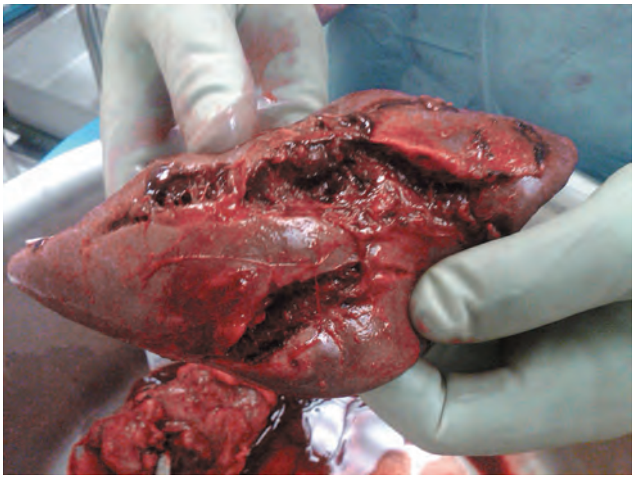

Figure 14.32 An injured spleen after splenectomy.

trauma damage to adjacent structures such as the stomach, colon, pancreas and diaphragm are common and must be investigated and treated.

Complications following splenectomy or splenorrhaphy include early transient thrombocytosis, which does not require treatment and generally resolves in 1–3 months, delayed haemorrhage, pancreatitis, pancreatic leak and abscess.

Postsplenectomy sepsis

The spleen is primarily an immune and haematopoietic organ, producing tuftsin and properdin; postsplenectomy patients are therefore immunosuppressed. Overwhelming postsplenectomy sepsis – the most dreaded and morbid infectious complication – is extremely rare, but may be increased among paediatric patients. However, infectious complications in general, including pneumonia as well as deep and superficial surgical site infections, are significantly increased following traumatic splenectomy even after correcting for injury severity. Postsplenectomy patients are at most risk for infection from encapsulated organisms, such as *Streptococcus pneumoniae, Haemophilus influenzae* and *Neisseria meningitidis*. Following splenectomy patients should receive *Haemophilus,* meningococcal and pneumococcal vaccinations. There is evidence to suggest that vaccinations are most effective if given 14 days following traumatic splenectomy. However, as many patients fail to follow up after trauma, vaccinations should, at a minimum, be given prior to discharge from the hospital. Patients should also receive booster immunizations every 3 years, and be advised of their increased infectious risk. Some clinicians recommend prophylactic antibiotics prior to any invasive dental, ophthalmological and medical procedures as well.

Liver injuries

The liver is the largest organ in the body and injury is a common occurrence following both blunt and penetrating trauma. The overwhelming majority of liver injuries are due to blunt trauma, most commonly motor vehicle accidents. Associated injuries are common following liver injury and occur in up to 80% of cases. Historically the majority of liver injuries were treated with operative exploration and repair. However, because of the low-pressure venous system within normal liver parenchyma, and the tamponade effect of the triangular, coronary and falciform ligaments, over 85% of injuries were found not to be bleeding at the time of surgery. Thus, over time, non-operative management has become the preferred treatment strategy, and the majority of patients tolerate this very well.

Diagnosis

Unfortunately, the history and physical examination are generally insensitive and non-specific for liver injury. The history may reveal blunt force or penetrating wounds to the abdomen, particularly the right upper quadrant or costal margin. Physical findings may be minimal: the abdomen may or may not be distended, tender or have visible findings such as bruising, lacerations, abrasions and abdominal seat belt signs. Diagnosis mainly relies upon imaging and operative findings.

In the hypotensive trauma patient, FAST can be extremely helpful as a positive study identifies the abdomen as the source of bleeding, requiring exploratory laparotomy. Unfortunately, a negative or indeterminate FAST cannot definitively rule out intraperitoneal bleeding. In these cases, DPA should be performed; if aspiration is positive, laparotomy is mandatory.

For stable patients without peritoneal signs CT is the standard method to identify and grade liver injuries according to the AAST-OIS scale for liver injury (Table 14.6). Most injuries are of minor to moderate severity (grades I–III). Some CT findings that have been found to increase the risk of failure of non-operative management include: left lobe injuries, injury into the hepatic veins (Figure 14.33a,b), large haemoperitoneum, laceration >6 cm and porta hepatis involvement. The presence of a 'blush' on CT scan suggests ongoing arterial bleeding or arteriovenous

Table 14.6 Liver injury scale

Grade*	Type of injury	Description of injury
I	Haematoma	Subcapsular, <10% surface area
II	Laceration	Capsular tear, <1 cm parenchymal depth
III	Haematoma	Subcapsular, 10–50% surface area: intraparenchymal <10 cm in diameter
IV	Laceration	Capsular tear 1–3 cm parenchymal depth, <10 cm in length
V	Haematoma	Subcapsular, >50% surface area of ruptured subcapsular or parenchymal haematoma; intraparenchymal haematoma >10 cm or expanding
VI	Laceration	
	Laceration	3 cm parenchymal depth
	Laceration	Parenchymal disruption involving 25–75% hepatic lobe

malformation, and is likely to benefit from angioembolization (Figure 14.34a,b).

Management

Overall success rates for non-operative management of liver injury ranges from 80% to 95%. Early on, non-operative management was used primarily with minor or moderate injuries (grades I–III). However, more recent experience has shown success in up to 40% of stable patients with grade IV and V injuries. The decision to pursue non-operative management should be based not on grade of injury but on clinical findings. Initially, the criteria for expectant management included intact mental status, absence of severe traumatic intracranial bleeding, age <65 years and transfusion of <2 units of PRBCs. Current data indicate that advanced age and comatose states are also no longer strict contraindications to non-operative management.

When performing non-operative management it is important to define a threshold for failure. Clinical predictors of failure include shock on admission, elevated Injury Severity Score, associated solid organ injury, positive FAST and the need for blood transfusion. Failure is generally defined as significant anaemia, transfusion of more than 3–4 units of PRBCs, or the onset of haemodynamic instability or peritonitis. Such failures occur mainly in the first 12–24 hours and rarely occur after 48 hours. When predetermined criteria for failure have been met or appear to be likely, patients should be treated with angiography or surgery as soon as possible.

Stable patients with a blush on CT scan and without peritonitis are candidates for angioembolization (Figure 14.35a,b). Angioembolization can be used before or after surgery and has a significant role in managing late complications such as arteriovenous malformations, pseudoaneurysm and arteriobilious fistula. It is required in 5–6% of patients with liver injury and leads to haemorrhage control in 80–100% of these cases. However, mortality and morbidity can be as high as 27% and 58%, respectively. Complications include hepatic necrosis, abscess and bile leak. A rare complication associated with angioembolization, particularly of the right hepatic artery and its branches, is gallbladder necrosis. Cholecystectomy will be required in these cases.

Angioembolization is an excellent adjunct to non-operative management; however, when there is a precipitous drop in haemoglobin, haemodynamic instability or peritonitis, patients should be taken to the operating theatre, where bleeding is found in 67% of cases. Satisfactory operative repair of significant liver injuries continues to be a challenge even for experienced trauma surgeons. However, the operative principles involved are simple and include: control of bleeding, removal of devitalized tissue and establishment of adequate drainage. In preparing for surgery, consideration should be given to including cell savers, massive transfusion protocols, rapid infusers and adjuncts such as the argon beam.

Once the liver injury has been identified, it should be packed. Extensive mobilization should be avoided in the presence of a haematoma in the ligaments or tissues around the hepatic veins, as this may unleash tamponade of injuries and cause significant bleeding. Packing can be temporary or used for up to 24–72 hours in damage control scenarios. Packing alone results in haemostasis in up to 80% of patients. If packs are to remain in place for a prolonged period of time, an absorbable material such as NuKnit, Surgicell or Vicryl mesh can be interposed between the sponges and the liver parenchyma to prevent bleeding when the packs are removed. Additionally, a dilute solution of saline and hydrogen peroxide can be used to help 'float' the packs off the liver without disturbing underlying clot. However, overpacking should be avoided as it may cause inferior vena cava compression, decreased venous return to the heart and hypotension.

If definitive repair is desired, multiple options are available. Simple lacerations can be controlled with the placement of topical haemostatic agents, argon coagulation or electrocautery. Larger lacerations can be sutured and parenchymal defects filled with viable omentum, creating a tamponade effect and providing macrophages and other cellular mediators of healing. If simple sutures or pressure do not control bleeding from lacerations, the wounds should be opened, providing a tractotomy. This will assist in identification of injured vessels and bile ducts, which can then be individually ligated. If haemorrhage persists, vascular isolation of the liver should be sequentially applied. This starts with clamping of the portal triad within the hepatoduodenal ligament (the Pringle manoeuvre). Although controversy exists, most surgeons agree that the Pringle manoeuvre can be applied safely for at least 30–60 minutes. If a Pringle manoeuvre stops or slows bleeding, the injury is likely to be in a portal venous or hepatic artery tributary. The Pringle manoeuvre can be removed to identify the exact location of injury so that it can be ligated. If selective ligation fails the hepatic artery can be ligated with few consequences as long as the portal flow is not compromised. However, consideration should be given to removal of the gallbladder as ischaemia and necrosis can occur after hepatic artery ligation.

If the Pringle manoeuvre fails to stop the bleeding, haemorrhage from a lacerated hepatic vein or the retrohepatic inferior vena cava is likely. Hepatic vein and juxtahepatic inferior vena cava injuries are rare and associated with very high mortality. Patients with these types of injuries often present in, or near, arrest; in these extreme cases, total vascular occlusion of the liver can be performed to staunch blood flow temporarily and allow the surgeon to identify and directly ligate or repair major vascular injuries. Total vascular isolation requires aortic clamping, a Pringle manoeuvre and occlusion of both the suprarenal and suprahepatic inferior vena cava. An alternative is the atriocaval or Shrock shunt (Figure 14.36). This is a shunt placed in the vena cava either from a venotomy in the infrarenal inferior vena cava or from an incision made in the right atrial appendage. The shunt allows blood flow to return from the renal veins and infrarenal inferior vena cava into the heart, bypassing the suprarenal inferior vena cava and liver. Venovenous bypass is another way to achieve vascular isolation of the liver. Again, a Pringle manoeuvre is performed. Unfortunately, all such advanced vascular techniques are associated with poor outcomes.

Non-anatomic liver resection may be required in up to 3% of cases if there is destructive parenchymal injury (Figure 14.37a,b). In this case, resectional debridement should be expeditiously performed using the finger fracture technique supplemented with the argon beam or electrocautery and selective ligation of encountered vessels. Anatomic liver resection for trauma is rarely required and often has a poor outcome, especially if done for haemorrhage control. This procedure is performed in fewer than 10% of patients, and is associated with 50–67% mortality.

In cases of liver resection, repair of deep or significant lacerations, and extensive or central parenchymal damage, the right upper quadrant should be widely and extensively drained

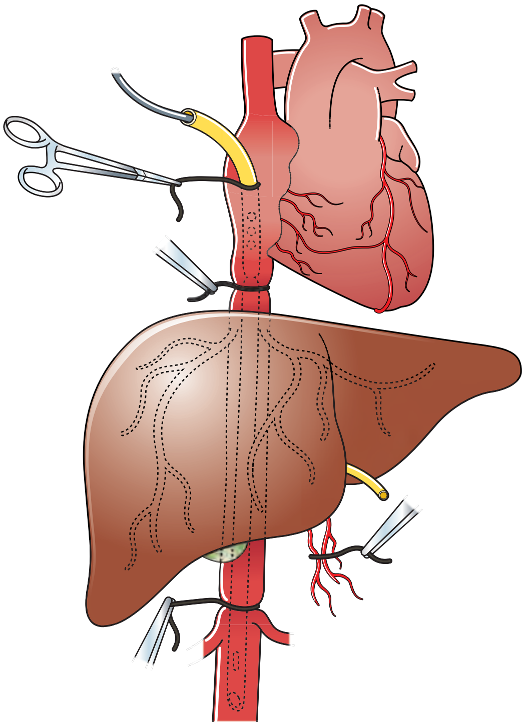

Figure 14.36 The placement of an atriocaval (Shrock) shunt achieved by introducing the catheter into the abdominal vena cava via the right atrial appendage. Sutures or vessel loops above and below the liver achieves proximal and distal control and allows venous return to the heart while completely excluding systemic venous back bleeding from within the liver injury. (From Hoyt *et al.*, *Surg Clin North Am* 2001;**81**:1299–330.)

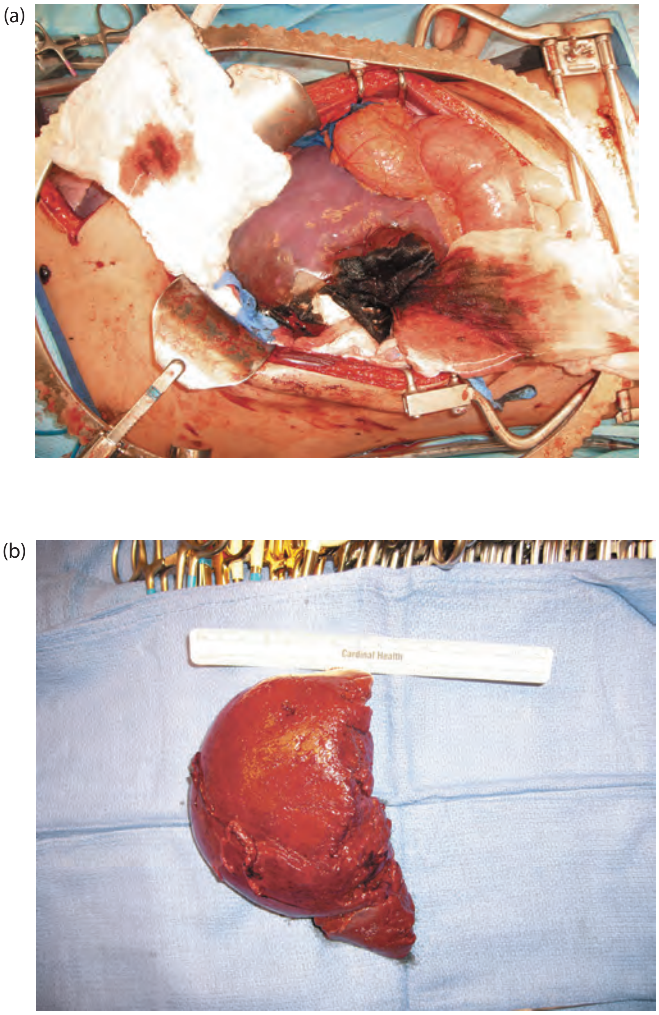

Figure 14.37 (a) A non-anatomical liver resection of the right lobe of the liver following blunt trauma. (b) The resected segment of the right lobe.

with close suction Silastic drains as these injuries are at high risk for developing temporary bile leaks.

Disseminated intravascular coagulation and impaired liver synthesis can occur following liver injury and resection and replacement of coagulation factors and intravascular blood volume are essential during resuscitation. Additionally, replacement and supplementation of magnesium and phosphorus are key during regeneration of liver parenchyma. Patients undergoing major hepatic resection may need continuous infusion of glucose until glycaemic balance can be restored, and aggressive nutritional support should be used.

Complications

The incidence and severity of complications from liver trauma increase with increasing injury grade and if operative management is required. Complications include rebleeding, abscess formation, biloma, biliary fistula and haemobilia. Symptoms of complications include fever, pain, jaundice, leucocytosis, feeding intolerance and tachycardia. Diagnosis of both abscess and biloma is established by ultrasound or CT scan, and both can be treated with percutaneous drainage and antibiotics, with a very high success rate. Persistent bile leaks after adequate drainage should be treated with endoscopic retrograde cholangiopancreatography and sphincterotomy or stent placement. Fistulous connections between the bile ducts and the hepatic vasculature are also possible. A duct-to-artery connection may result in haemobilia and may present with haemoptysis, coffee ground emesis, pain and jaundice. Presentation is often delayed and definitive diagnosis and treatment are established by hepatic angiography and embolization.

Gastric injuries

Stomach

Injuries of the stomach are very rare in blunt trauma but can be common following penetrating trauma. The stomach is partially protected by the rib cage, making gastric injuries relatively difficult to diagnose. Any penetrating wound in the left thoracoabdominal area should be suspected of causing injury to the stomach and requires investigation of the anterior and posterior surface at the time of laparotomy.

A nasogastric tube should be inserted during initial evaluation, and aspiration of blood may point to a gastric injury. The intraoperative evaluation of stomach injury includes good visualization of the oesophageal hiatus and anterior and posterior walls. Adequate evaluation of the posterior wall requires division of the gastrocolic ligament to enter the lesser sac. If there is any question regarding injury, the stomach can be distended with saline and methylene blue to evaluate for leaks. Concomitant injury to the left diaphragm, spleen, transverse colon and splenic flexure should be carefully ruled out during the exploration.

Penetrating wounds are debrided and closed primarily. Maceration of the stomach from significant penetrating or blunt injury may require gastric resection. Postoperative complications include intra-abdominal abscess, particularly in the lesser sac, but these are rare. The other complication of stomach injury is stomach fistula. The treatment is immediate reoperation and repair using healthy tissue. Because of its proximity to the diaphragm, stomach injuries are frequently found in conjunction with diaphragmatic injuries and contamination of the thoracic cavity with gastric contents can occur. In the presence of severe contamination empyema can be a worrisome complication. Drainage of the thoracic cavity with a large-bore chest tube and adequate lavage of the thorax prior to closure of the diaphragmatic injury are important if gastric contents have contaminated the chest.

Duodenum

Isolated injury to the duodenum rarely causes significant hypotension, and signs of peritonitis may be absent or delayed if the injury affects the retroperitoneal portion of the duodenum. Unfortunately, failure to recognize this injury in a timely fashion is associated with high morbidity and mortality caused by abscess formation and sepsis. Entry wounds in the right upper quadrant or between the xiphoid and umbilicus suggest possible injury to the duodenum. Non-penetrating duodenal injury may be caused by crushing as the duodenum is macerated or contused against the spine by a seat belt, steering wheel, handle bar or blunt weapon. Blow-out injuries can also occur as intraperitoneal and extraperitoneal portions of the duodenum create a closed air-filled loop that bursts when compressed (Figure 14.38).

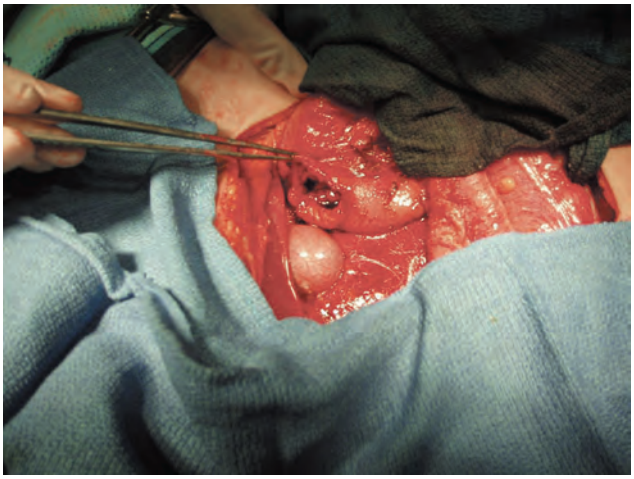

Figure 14.38 A typical antimesenteric blowout injury of the second portion of the duodenum.

Adjunctive diagnostic tests might include hyperamylasaemia. This occurs in about half of the patients with blunt injury to the duodenum as a result of extravasation of intra-abdominal pancreatic amylase. Elevated serum amylase following blunt trauma is not diagnostic of an injury but raises suspicion and necessitates further diagnostic study. Abdominal radiographs may suggest duodenal injury if they show obliteration of the psoas shadow, absence of air in the duodenal bulb or air in the retroperitoneum. Definitive diagnosis requires contrast duodenography or CT scan. Extravasation of contrast material is an absolute indication for laparotomy. Distortion of the duodenum, retroperitoneal air and periduodenal stranding indicate significant injury and are relative indications for surgery. An intramural duodenal haematoma alone without evidence of full thickness perforation is not a definite indication for operative intervention.

Intraoperative evaluation of the duodenum requires complete mobilization of the duodenum (Kocher manoeuvre). The hepatic flexure of the colon is taken down to expose the anterior aspect of the second portion of the duodenum, and inspection of the third and fourth portions of the duodenum at the base of the transverse colon should be done. Mural haematomas should be opened and evacuated to rule out full thickness lacerations that require repair. Retroperitoneal haematomas in the area of the duodenum must be explored and the lesser sac should be entered to exclude associated pancreatic injuries.

Duodenal haematomas in which lacerations have been excluded by contrast radiography or contrast-enhanced CT scans can be managed expectantly with nasogastric decompression until resolution of gastric outlet obstruction. Obstruction can last several weeks and supplemental nutrition via a nasojejunal feeding tube or with parenteral nutrition may be required. In rare cases prolonged obstruction may require surgical decompression; however, this is rare.

Limited perforations or simple lacerations of the duodenum treated within 6 hours of injury are treated with debridement and primary closure. Larger lacerations may require resection and reanastomosis. Suction decompression of the duodenum with a nasogastric or G-tube, as well as external closed suction drainage, is recommended. After 6 hours, the risk of leak increases, and wide drainage and diversion with pyloric exclusion may be required. Multiple or extensive lacerations and complex repairs may also require protection with pyloric exclusion. The pylorus may be sutured via a proximal gastrotomy or externally by application of TA stapler. Gastric drainage is maintained by a gastrojejunostomy. In the majority of cases, the pyloric exclusion, whether sutured or stapled, will open spontaneously a few weeks after surgery; in some instances, if this does not occur endoscopy to dilate a stapled pylorus or cut sutures is often successful in re-establishing an open channel. In extensive injuries and reconstructions thought should also be given to placement of a distal jejunal feeding tube for early enteral access. Historically, extensive duodenal injuries or injuries involving the sphincter of Oddi were decompressed by tube duodenostomy. However, there has been little evidence to suggest that this was effective at decreasing complications or time to healing, and such drains require the creation of additional duodenotomies, which were, themselves, potential sources of leaks and abscesses. As such, traditional tube duodenostomies are no longer advocated, and internal drainage via nasogastric tube and external drainage with Jackson–Pratt drains is now preferred. If additional internal drainage is desired, a jejunal tube can be guided in a retrograde fashion to drain the duodenum.

The distal duodenum (third and fourth portion) can be primarily closed as with the proximal duodenum if the injury is treated early; delays in surgical treatment generally result in poor tissue perfusion and maceration requiring resection and duodenojejunostomy. Pancreaticoduodenectomy (Whipple's procedure for trauma) is occasionally indicated for massive injury or devascularization of the pancreaticoduodenal complex.

Complications of surgical treatment of duodenal injuries include bleeding and leak resulting in duodenal fistulas. Fistulas occur in 5–10% of patients following anastomosis. Unlike a gastric fistula, duodenal fistulas are generally managed non-operatively with nasogastric decompression, nutritional supplementation and aggressive local wound care. Antibiotics are only indicated if there is evidence of infection such as fever, leucocytosis or systemic inflammatory response syndrome. Uncomplicated fistulas will generally resolve in 6 weeks, and operative repair should be considered if they persist beyond this point.

Pancreas

Pancreatic injury following blunt trauma is uncommon, occurring in less than 7% of abdominal trauma cases. Because they tend to have less intraperitoneal and extraperitoneal abdominal fat, children tend to be at increased risk of pancreatic injury. The force required to injure this organ is significant and associated injuries are common, occurring in 70–90% of cases. Anteroposterior compression of the pancreas against the lumbar spine can result in transection at this location adjacent and just to the left of the superior mesenteric vessels. Epigastric and posterior penetrating wounds likewise can penetrate the pancreas and are often associated with significant injuries to the kidney, vena cava and colon. While duct integrity is the main determinant of intervention and outcome, major duct injury is rare, occurring in <15% of pancreatic injuries, and is much more common following penetrating than blunt trauma. Associated injuries are of particular concern as enzymatically active pancreatic juices will increase the risk of anastomotic leaks. The shared blood supply between the pancreas and duodenum makes the likelihood of these two injuries occurring in combination very high. Diagnosis can be quite difficult as clinical findings are likely to be non-specific or non-existent. Suspicion must be raised and serial re-evaluation undertaken if there is any potential for injury. Elevation of serum amylase or lipase following blunt mechanisms is non-specific, but persistent elevation does suggest pancreatic injury and advanced imaging should be performed. CT scanning is most common but is not particularly sensitive, even with multislice scanners and three-dimensional and multiplanar reconstructions. MRI and magnetic resonance cholangiopancreatography may play a role in the diagnosis of pancreatic injury and elucidation of ductal involvement; however, because of the difficulty in obtaining MRI/magnetic resonance cholangiopancreatography particularly after hours, and the lengthy nature of image acquisition, its role may be quite limited.

Patients seldom undergo laparotomy because of pancreatic injury alone. Instead, they are generally operated on because of intraperitoneal blood loss or peritonitis. At the time of laparotomy the pancreas should be inspected and any evidence of adjacent injury excluded. Any retroperitoneal haematoma around the pancreas should be explored; any retroperitoneal bile staining indicates a concurrent duodenal or biliary tract injury which must be repaired. Low-grade injuries require wide surgical drainage and bowel rest only. Closed suction drains should be used as they decrease the rate of septic complications when compared with open or sump drains. Injuries to the distal body and tail that involve the main duct, or are refractory to simple debridement, should be treated with distal pancreatectomy with or without splenectomy. The decision to preserve the spleen should be based primarily on the patient's clinical status: those who are haemodynamically stable, with normal physiological parameters (normothermic, normal coagulation parameters) and few associated injuries may be considered for splenic preservation; however, patients who are unstable, have severe or multiple associated injuries requiring work-up and/or treatment should undergo splenectomy with distal pancreatectomy. If the main duct is injured in a more proximal segment (proximal body, neck), options for management include subtotal pancreatectomy, external drainage with postoperative endoscopic retrograde cholangiopancreatography, and distal drainage with Roux-en-Y pancreaticojejunostomy. If ductal injury is suspected but not definitive, invasive manoeuvres to interrogate the main pancreatic duct such as transection of the tail, duodenotomy and cannulation of the papilla, and cholecystopancreatography should be avoided.

Significant injury to the head of the pancreas or to the right of the superior mesenteric vessels will be associated with a 30–60% probability of temporary pancreatic fistula, and this should be accepted. Severe trauma to the head of the pancreas in association with duodenal injuries should be treated with debridement of the pancreas, closure of the duodenal wound and pyloric exclusion as previously described. Extensive damage to the head of the pancreas and duodenum may require a Whipple procedure. If this is the case the goals of surgery at the time of the initial procedure should be to control blood loss and contamination; reconstruction should be delayed until restoration of circulating blood volume and normal physiology.

The most common complication of pancreatic injury is a persistent pancreatic fistula; if well controlled it should close spontaneously unless there is obstruction to the pancreatic duct. Somatostatin has been used in the treatment of persistent pancreatic fistulas, with some evidence to suggest that its administration may decrease the volume of output; however, there is currently no evidence that somatostatin or octreotide will increase the rate or speed of fistula closure. Abscess, pancreatitis of the pancreatic remnant and pseudocyst may also occur and are generally treated with conservative management consisting of percutaneous drainage, bowel rest and parenteral or distal jejunal nutrition. Antibiotics should be reserved for cases with evidence of active infection. Although rare, if >80% of the pancreatic gland has been resected there is a risk for exocrine insufficiency; this generally can be treated with oral replacement of enzymes. Endocrine insufficiency is an even more rare complication following extensive resection, and is generally treated with alteration of diet and administration of insulin.

Small intestine

Injuries of the small intestine occur in approximately 15–20% of patients who require laparotomy after blunt trauma. The postulated mechanisms of injury include crushing between the spine and a blunt object such as the steering wheel or seat belt, deceleration shearing of the small bowel at fixed points such as the ileocaecal valve and around the superior mesenteric artery, and closed loop rupture caused by increased intra-abdominal pressure (Figure 14.39). Injuries to the small intestine are present in approximately 25–30% of patients who require laparotomy after penetrating trauma, and are due to direct laceration in low-velocity mechanisms, such as stab wounds, and direct laceration, crushing or blast in high-velocity mechanisms.

Diagnosis of hollow visceral injury is primarily clinical. Peritonitis or severe abdominal pain may occur as a result of peritoneal injury or indirectly as a result of irritation from succus or bleeding. Antibiotics should be started preoperatively and redosed if the procedure is prolonged or if there are massive fluid shifts anticipated owing to large blood loss, massive transfusion or a large volume of crystalloid resuscitation. However, prolonged antibiotic administration following completion of the procedure is not recommended, regardless of the amount of contamination encountered. There are no data to suggest an improvement in morbidity or mortality, particularly infectious complications, when antibiotics are continued after 24 hours.

At operation haemostasis is the first priority; when this is adequate and the patient has had a chance to be adequately resuscitated, attention can then be turned to control of contamination. This can be accomplished by application of non-crushing clamps or sutures. The small bowel should be examined from the ligament of Treitz to the ileocaecal valve.

The bowel wall and mesentery should both be examined for defects, lacerations or haematomas. All haematomas affecting the bowel wall should be explored to rule out full thickness injury (Figure 14.40). Large, expanding or pulsatile mesenteric haematomas should also be explored to rule out major vascular injury. Small stable haematomas of the mesentery away from the bowel wall can be observed as long as there is no evidence of ischaemia to the overlying bowel.

Small lacerations can be closed primarily, with care taken to close them transversely in order to prevent stricturing of the repaired bowel segment. Defects due to shotgun, gunshot or blast wounds should be debrided to healthy bleeding tissue prior to repair. It should be kept in mind that injuries due to penetrating mechanisms generally occur in pairs, and a single wound should always be viewed with scepticism and the adjacent bowel carefully examined for missed injury. If two adjacent holes are found, they can be connected across the bridge of bowel and again closed transversely. Large lacerations, macerated tissues or multiple injuries in close proximity benefit from resection and primary anastomosis. Mesenteric defects due to injury or following bowel resection and anastomosis should be closed to prevent internal herniation.

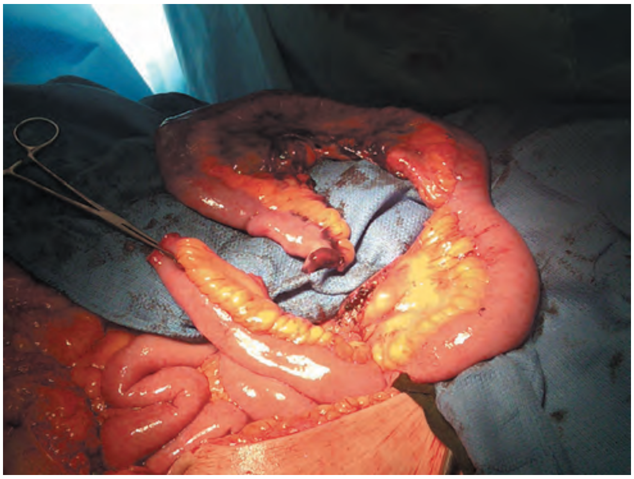

Figure 14.39 An extensive bucket-handle injury of the small bowel with associated complete transection of the bowel wall.

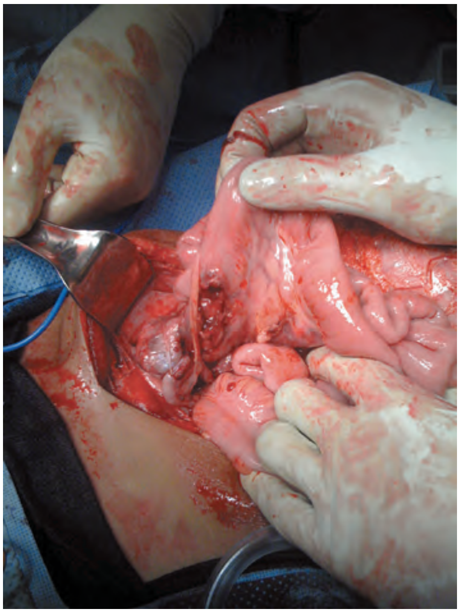

Figure 14.40 A terminal ileal mesenteric haematoma with adjacent full thickness laceration.

Major complications following small bowel injury include abscess, anastomotic leakage, enterocutaneous fistula, wound infection, ileus and anatomical obstruction. Most respond to conservative management with bowel rest and hydration, and antibiotics in cases of active infection and percutaneous drainage of mature fluid collections. Fistulas that are low output are likely to resolve with medical management; however, high-output fistulas, particularly those in the proximal small bowel, may require surgical treatment.

Colon/rectum

The majority of injuries to the colon and rectum are the result of penetrating trauma. The amount of force required to damage the colon is considerable; thus, the colon is relatively refractory to blunt injury, with only 5% of colonic injuries due to blunt mechanisms. Rectal injuries can occur in association with pelvic fracture and any patient with a significant pelvic fracture must have the possibility of rectal injury considered.

Signs and symptoms of colon and rectal injury are non-specific, including peritoneal irritation, leucocytosis and pneumoperitoneum on radiographs. However, patients are often asymptomatic with unremarkable laboratory and radiographic results. Peritoneal lavage is of value if the injury is intraperitoneal and may return fluid with blood or bacteria. If the injury is confined to the extraperitoneal colon or rectum, however, lavage is of no value. The extraperitoneal rectum is particularly vulnerable to injury following penetrating trauma to the buttocks or lower abdomen.

Digital rectal examination is essential. The presence of blood on examination is strong evidence for colon or rectal injury. Proctoscopic and sigmoidoscopic examinations should be performed following penetrating trauma to the buttocks or lower abdomen, or if there is gross blood found on rectal examination with abdominal or pelvic blunt or penetrating trauma. Peritonitis may occur as a result of inflammation of the peritoneum from blood or faeces. Patients with peritonitis, instability, frank blood on digital rectal examination or concerning findings on proctoscopy/sigmoidoscopy should undergo laparotomy. Once the decision to operate has been made, antibiotics should be given prophylactically. If colorectal injury is highly suspected based on physical examination findings, endoscopy or tract of injury, it is essential that broad-spectrum antibiotics with coverage of enteric Gram-negative and anaerobic organisms are chosen; this may include a third-generation cephalosporin with flagyl, or an advanced penicillin such as ampicillin–sulbactam or piperacillin–tazobactam. Use of inappropriate antimicrobial agents such as first-generation cephalosporins has been independently associated with increased risk of postoperative infectious complications. Again, studies have found no additional benefit to continuing antibiotic coverage beyond 24 hours postoperatively.

Simple lacerations of the colon and rectum can be safely repaired primarily after adequate debridement of devitalized tissues. These types of injuries generally heal very well with relatively few complications. In contrast, destructive colon injuries have a very high rate of postoperative complications, ranging from 20% to 40%. Complications include ileus, abscess, wound infection and anastomotic leak. Several factors can significantly increase the rate of complications following surgical repair or resection; these include severe faecal contamination, delay to treatment of >6 hours, transfusion of ≥4 units PRBCs or blood loss >1 litre, hypotension, inappropriate antibiotic choice and more than two associated organ injuries. Options for repair of destructive colon injuries include resection with end-colostomy, resection with primary anastomosis with diversion, and resection with anastomosis but without diversion. The method of repair appears to have no effect on the rate of complications; however, many still consider diversion with or without anastomosis if any of the previously mentioned risk factors for complications are present as the risk of anastomotic leak is high.

Rectal injuries cause morbidity and mortality primarily because of a delay in diagnosis and inadequate initial therapy. Rectal injury must be suspected when there is any penetrating perineal or gluteal injury or a sacral fracture that produces a pelvic ring disruption. Proctosigmoidoscopy is essential for diagnosis and is best done in the operating theatre with the patient in the lithotomy position with both the abdomen and perineum sterilely prepared and draped. Intraperitoneal rectal injuries require laparotomy and repair or resection. Low injuries may be difficult to access and repair and may benefit from resection with end-colostomy in a Hartmann-type procedure.

Treatment of extraperitoneal rectal injuries has evolved over the past decades. Traditionally, these injuries were treated with the triple approach of diversion, presacral drainage and rectal lavage. It now appears that this complex and invasive treatment is unnecessary. Comparisons of patients with and without presacral drainage show no benefit in speed of recovery or prevention of pelvic sepsis from drainage. Findings were similar for rectal lavage, with some studies suggesting worse outcomes with lavage. While transanal repair of the rectal defect may be useful in some patients in whom injuries are easily accessible, there is no role for transperitoneal repair of isolated extraperitoneal rectal injuries as this offers no benefit over diversion alone and often results in increased complication rates. Most studies continue to recommend faecal diversion with either open or laparoscopic loop sigmoid colostomy. Similar to other studies of prophylactic antibiotics, prolonged treatment courses do not decrease rates of infectious complications, and most authors recommend perioperative treatment for only 24 hours.

Complications following rectal injuries include pelvic abscess, rectovesical and rectovaginal fistulas, rectal incontinence and strictures, loss of sexual function and urinary incontinence.

Pelvic injuries

Pelvic fractures have been classified by a multitude of different schema; one of the most useful and widespread systems was created by Young and Burgess (Figure 14.41) and is based on the force vectors involved in creating injury. In this schema fractures are classified into three major groups: lateral compression (LC); anteroposterior compression (AC), traditionally known as open book; and vertical shear (VS), including the Malgaigne fracture. The LC and AC groups are further subdivided into three types (I, II, III) according to increasing injury severity and ligamentous disruption. In general, LC type I and AC type I and II are stable, whereas LC types II and III, AC type III and all VS fractures are unstable.

The diagnosis of pelvic fracture should be suspected in any patient with significant blunt abdominal trauma, pain with palpation of the pelvis, instability of the pelvis with anteroposterior or lateral compression or limited passive range of motion of the hips. Diagnosis is generally confirmed by plain radiography (Figure 14.42), although CT scanning with thin cuts through the bony pelvis allows for a very detailed delineation of fracture, displacement and associated soft-tissue injury (Figure 14.43). The addition of intravenous contrast

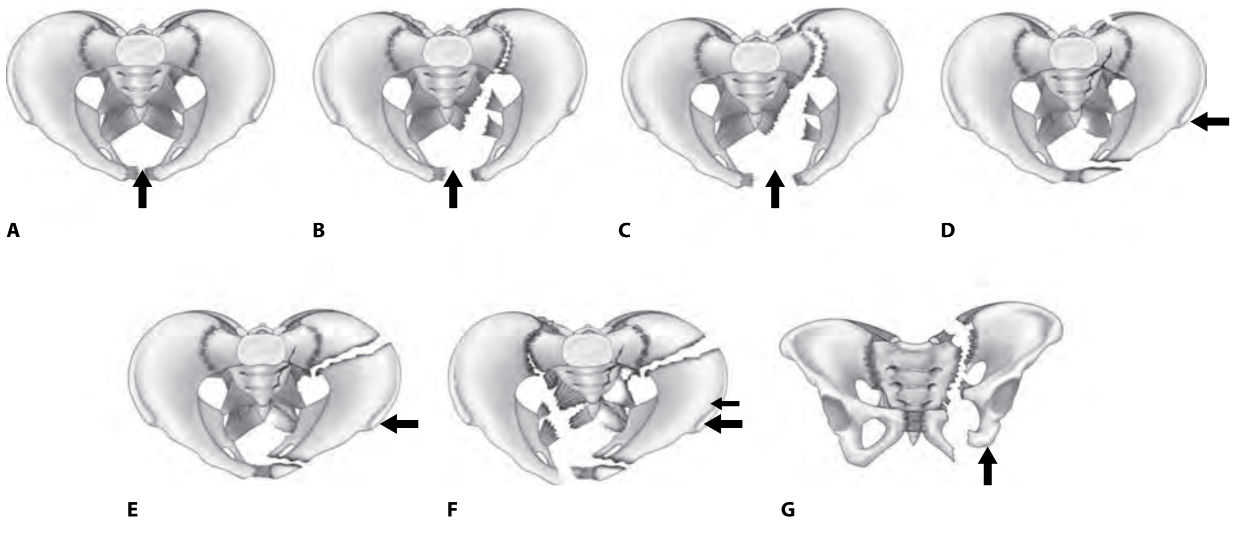

Figure 14.41 Young and Burgess classification of pelvic fractures based on vector of force. (From Hak *et al.*, *J Am Acad Orthop Surg* 2009;**17**:447–57.)

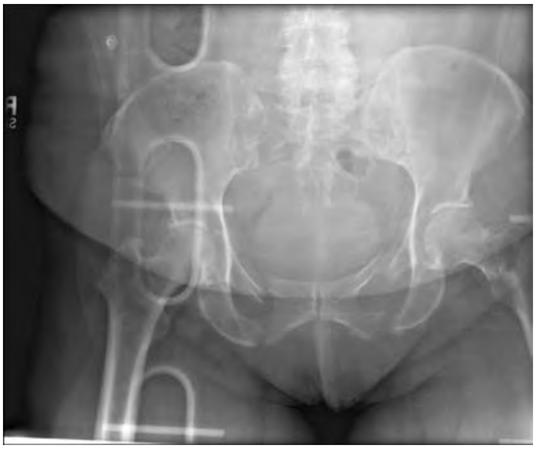

Figure 14.42 Pelvic radiograph; note the bilateral superior and inferior pubic rami fractures consistent with a butterfly fracture-type pattern.

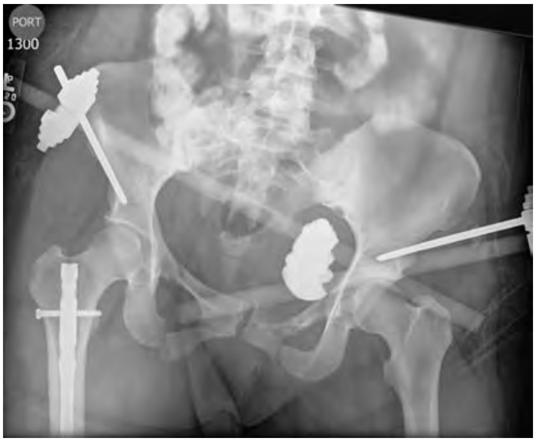

Figure 14.44 Pelvic radiograph demonstrating a butterfly-type fracture after the application of an external fixator.

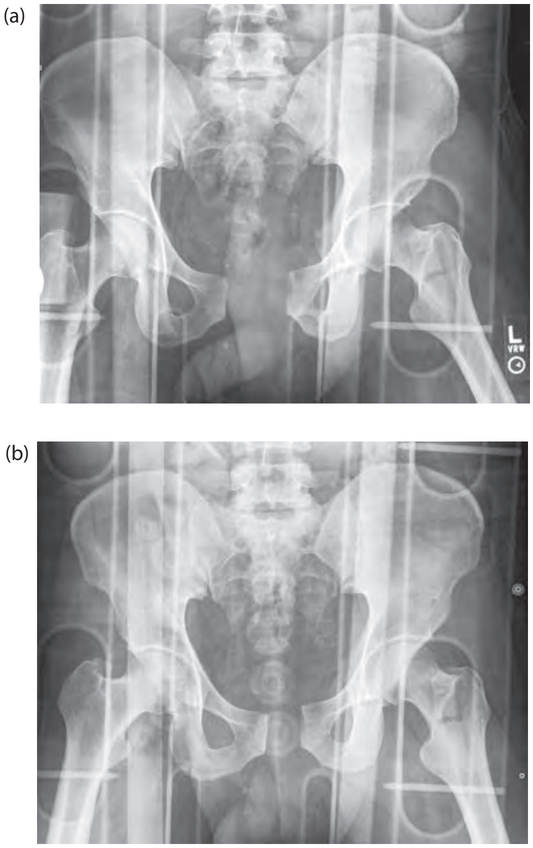

Figure 14.45 Pelvic radiographs depicting an open book fracture with wide pubic symphysis diastasis (a) before external compression and (b) after compression with a sheet.

also allows for detection of active haemorrhage and associated vascular injury; delayed images to assess the ureters and bladder can also be easily obtained with little additional time, and minimal additional contrast exposure. Pelvic fractures are also commonly associated with injuries to the distal genitourinary tract and care should be taken to rule out urethral injury prior to Foley placement and to image the bladder with cystography or CT cystogram in cases of gross haematuria.

Pelvic fractures are a major cause of morbidity and mortality. Blunt trauma is the cause of most injuries, with pedestrian and motor vehicle accidents accounting for the majority. Associated mortality ranges between 10% and 30%, although this can increase to as high as 60% with severe open fractures. Massive haemorrhage and coagulopathy continue to account for 40–60% of the mortality in this group of patients. Bleeding originates from lacerations of both small- and medium-sized arteries and veins of the rich sacral plexus, as well as from fractured bone. Success in managing these patients requires rapid assessment, vigorous resuscitation and reversal of coagulopathy and hypothermia. Haemorrhage can be controlled to some extent by external compression of the pelvis with pelvic binders, external fixators (Figure 14.44) or a bedsheet (Figure 14.45a,b). Binders or sheets are fitted over the anterosuperior iliac spines superiorly, and the femoral heads inferiorly. Stabilization devices close the pelvic ring, decreasing pelvic volume to tamponade bleeding. They also stabilize the broken ends of bone preventing further injury to nearby tissues and decrease pain with repositioning and transport.

In patients who are unstable with free intra-abdominal fluid or suspicion for intra-abdominal injury, laparotomy should be performed. If a stable pelvic haematoma is found it should be left intact, with consideration to postoperative angioembolization.

In expanding or ruptured haematomas with concern for major vascular injury, exploration should be performed. In the absence of identifiable iliac injury consideration can be given to operative bilateral internal iliac artery ligation and embolization with direct injection of a procoagulant such as Gelfoam, thrombin or glue. This performs the same function as angioembolization with a reduction in pelvic vascular inflow. Unstable patients with severe pelvic fracture but without free intraperitoneal fluid should be resuscitated with blood products and application of an external compression device, then taken for angiography. Even among patients who present with haemodynamic instability, angiography is increasingly viewed as an acceptable primary treatment option resulting in haemodynamic stabilization and a survival rate of 72–92%. An alternative or adjunct to angiography in non-responders with negative FAST and DPA is preperitoneal pelvic packing. This method involves making an infraumbilical incision, extending it through the anterior fascia, accessing the preperitoneal space and packing the pelvis. This helps tamponade the pelvic bleeding without decompressing the retroperitoneal haematoma into the peritoneal cavity and has been associated with an excellent ability to achieve haemostasis.

When patients are haemodynamically stable CT has become the diagnostic tool of choice and sensitivity is >90% for detecting pelvic bleeding requiring intervention. The majority of arterial bleeds are due to injuries to branches of the internal iliac artery; injuries to the common and external iliac arteries are rare. In patients with active extravasation on CT, angiography should be considered for diagnostic and therapeutic purposes. Angiography should also be considered for patients without active extravasation on imaging if there is clinical deterioration or transfusion requirements of >4–6 units of PRBCs in the first 24 hours. If significant arterial bleeding is found, selective embolization can be performed. Selective embolization is well tolerated and successful in arresting haemorrhage in 80–100% of cases. Embolization can be performed with Gelfoam, which is delivered easily and is absorbed within a few weeks. In larger vessels and pseudoaneurysms, coils may be required to achieve haemostasis. Gelfoam can be used to supplement coil embolization. In patients in whom selective embolization is not possible unilateral internal iliac artery embolization can be performed with a Gelfoam slurry. If no arterial bleeding is found, bilateral internal iliac artery embolization can also be performed prophylactically. The rich collateral circulation in the pelvis prevents ischaemia in most patients. Major complications following therapeutic or prophylactic angioembolization are rare but include necrosis of pelvic organs or gluteal compartment syndrome. Rebleeding, or continued haemorrhage following therapeutic angioembolization, is also rare; however, many trauma surgeons and interventional radiologists recommend leaving the arterial access sheath in place following the first angiogram for at least 24 hours.

Pelvic fractures can be associated with deep perineal lacerations and involve the rectum or vagina; these injuries are classified as compound pelvic fractures. Compound fractures are associated with a high incidence of septic complications and carry a high mortality – in many cases exceeding 50%. The primary source of contamination is the faecal stream, and diversion with a colostomy is necessary to reduce such complications in most cases.

Urinary tract injuries

General

Because of its location, injuries to the genitourinary tract often are clinically silent and frequently overlooked in the face of more obvious abdominal or thoracic injuries. An awareness of the subtle manifestations of genitourinary injuries is necessary to avoid missing injuries. The physical examination is unreliable in diagnosing urinary tract injuries but they are typically amenable to radiological diagnosis. Systematic, orderly evaluation of the urinary tract reduces the chance of missed injury and limits the number of unnecessary retroperitoneal explorations.

Different criteria should exist for initial evaluation of the urinary tract following blunt and penetrating mechanisms. In blunt trauma, fractures of the lower portion of the rib cage or spinous processes have been associated with an incidence of renal injuries as high as 20%. Findings of a frank haematoma or ecchymosis on physical examination or injury to adjacent solid organs are associated with an increased risk of renal trauma. Penetrating trunk trauma, particularly to the back or flank, has the potential for significant renal injury without any obvious clinical manifestations. A suspicion of renal injury should exist with any penetrating trauma in the vicinity of the renal tract, and in the absence of suspicion for urethral injury a Foley catheter should be inserted. The presence of macroscopic haematuria is indicative of urinary tract injury and should prompt further work-up. However, urinalysis is insensitive and absence of haematuria does not reliably exclude genitourinary injury. If further work-up is necessary the next step is generally CT scan with intravenous contrast and delayed images. Arterial and portal venous phases of the scan are excellent at detecting renal parenchymal injuries, and delayed phases can be obtained to assess the urinary collecting system. Axial CT has the advantage over plain films of providing a 360° view around the bladder, providing excellent sensitivity and specificity for both intra- and extraperitoneal bladder injuries. Additionally CT scan will allow excellent visualization of the surrounding soft tissue and bone, which is particularly helpful in cases of penetrating trauma for diagnosing associated injuries and delineating the tract of the knife or projectile.

If CT scan is not available intravenous pyelography and retrograde cystography can be performed to assess the ureters and bladder. Cystography should be performed with at least 200–300 mL of diluted contrast material. Images should be obtained in more than one plane to decrease the risk of missed injury; this is usually performed in the posteroanterior and oblique orientations. Postvoid images should be obtained in addition to images of the fully distended bladder to improve sensitivity for posterior and extraperitoneal ruptures.

Urethral injury is suspected if penetrating wounds are located in the scrotum, perineum or penile shaft; if, on examination, there is blood at the urethral meatus or a perineal or scrotal haematoma; or if the prostate is absent, free floating or high riding on digital rectal examination. Patients suspected of urethral rupture should not be catheterized until a retrograde urethrogram has been performed. A retrograde urethrogram is performed by inserting a paediatric Foley or red rubber catheter into the very tip of the penis so that it is located in the fossa navicularis; then, the balloon is inflated or a penile clamp is used to occlude the urethral meatus and prevent contrast extravasation. Approximately 30 mL of full-strength contrast is then injected and ideally fluoroscopy is used to assess for extravasation. If fluoroscopy is not available plain radiographs can be taken; again, multiple images in non-congruent planes, primarily lateral and oblique, must be taken. If no contrast extravasation is found a Foley catheter can be placed safely.

Kidney

The kidney is the most commonly injured part of the urinary tract, with injury occurring in 1–3% of all trauma patients and up to 10% of abdominal traumas. Renal injuries are graded according to the AAST-OIS; most injuries are minor, with contusions accounting for the vast majority. Major renal trauma includes deep cortical medullary lacerations involving the collecting system (Figure 14.46) and injuries to the renal vascular pedicle. Blunt mechanisms are far more common than penetrating, accounting for approximately 60% of injuries. Blunt trauma to the renal vessels is more likely to result in thrombosis, whereas penetrating trauma is more likely to bleed (Figure 14.47a,b). Non-operative management is successful in >90% of cases. Risk factors for failure include high-grade injuries, large perinephric haematomas and urinary extravasation. The only absolute contraindication to non-operative management is haemodynamic instability.

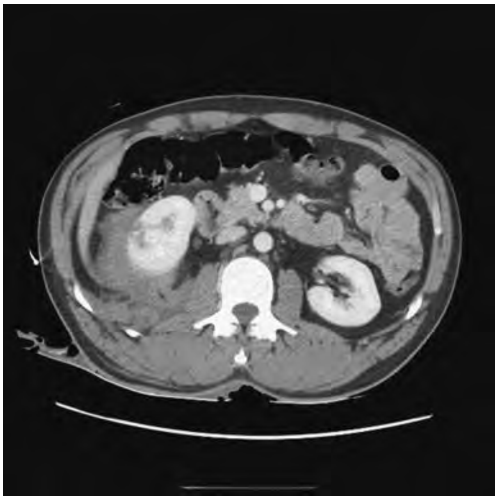

Figure 14.46 Axial CT demonstrating cortical laceration of the right kidney with extension into the urinary pelvis and adjacent perinephric haematoma.

If laparotomy is performed for another injury, and a perinephric or zone 2 haematoma is found, the decision to explore may be difficult. If there is frank haematuria, exploration should be performed to rule out an injury to the collecting system; however, if there is no gross haematuria, and the haematoma is stable, it is reasonable to leave the haematoma as even advanced grade injuries are unlikely to require operative repair, and complications of conservative management generally respond well to percutaneous and endoscopic interventions. If the decision to open the haematoma is made, care should be taken to palpate the contralateral renal fossa to ensure that the opposite kidney is present should rapid nephrectomy be required upon entering the haematoma. The kidney is exposed by medial visceral rotation and can be bluntly delivered from Gerota's fascia. Minor parenchymal injuries can be treated with topical haemostatics. Lacerations should be explored for involvement of the collecting system. If there is no collecting system injury patients can be observed if they are haemostatic or if bleeding can be controlled with simple sutures either with or without pledgets. Absorbable suture should be used to avoid stone formation. Larger parenchymal injuries can be treated with partial nephrectomy. Nephrectomy should be considered based on the degree of injury and the physiological status of the patient.

Complications are more common following nephrorrhaphy than following nephrectomy. Early complications include rebleeding, urine leak and abscess. Late complications include

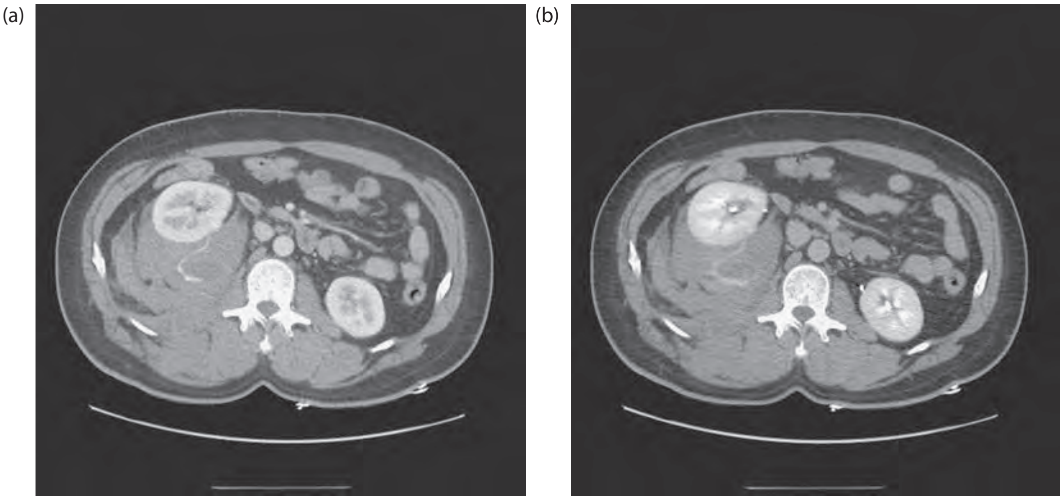

Figure 14.47 Axial CT depicting a right renal cortical laceration with a large adjacent perinephric haematoma and (a) an area of active extravasation during the arterial phase that persists on (b) delayed images consistent with arterial bleeding; note that there is no apparent urinary extravasation from the renal pelvis or proximal ureter.

Page kidney, renovascular hypertension and hydronephrosis. Acute renal dysfunction can occur after traumatic nephrectomy, but tends to be transient and self-limited.

Ureteral injury

Ureteral injury is uncommon and occurs primarily following penetrating trauma. The presence of haematuria is not consistent, as the affected ureter may spasm, particularly following complete transection, and not contribute any blood-tinged urine to the bladder following injury. Ureteral injury should be suspected based on the location of penetrating wounds and the tract of injury seen on CT scan or at the time of laparotomy. Many ureteral injuries are missed at the initial evaluation and present as late urinomas with associated fever, flank mass and pain, or as a urinary fistula with urinary extravasation from the site of the original injury.

In those patients whose clinical condition does not allow for preoperative imaging, the diagnosis of ureteral injury may be made at the time of surgery by the administration of intravenous methylene blue. Extravasation of blue-tinged urine into the operative field serves to localize and confirm the presence of injury.

Surgical options include simple repair, resection with primary anastomosis or reimplantation. All repairs should be made with small absorbable sutures to prevent future complications of stone formation and should be performed over a stent to reduce the risk of stricture.

Bladder

Most bladder injuries occur as a result of blunt external trauma, and should be strongly suspected in patients with haematuria in the presence of pelvic fractures. Bladder rupture may be extraperitoneal or intraperitoneal. The former are usually the result of perforations by adjacent bony fragments from the site of the pelvic fracture. The latter are the result of rupture of the dome that occurs when a full bladder sustains a direct blow. Diagnosis is made by CT or traditional cystography.

Extraperitoneal ruptures are primarily treated conservatively with the placement of a Foley catheter for decompression. The patient is then re-evaluated at regular intervals for resolution of extravasation prior to a voiding trial. Complications can occur in up to 20–25% of patients and include infection, prolonged leak and the need for delayed operative repair. Intraperitoneal injuries require surgical repair through a midline laparotomy. Although previously advocated, placement of a suprapubic catheter is no longer recommended; simple decompression with a Foley catheter in the immediate postoperative period is sufficient.

Urethral

Urethral injuries occur primarily in men following blunt pelvic fracture or straddle injuries, and are uncommon, seen in only 4–10% of patients with pelvic fractures. Blood at the urethral meatus, perineal haematoma, a high-riding prostate on rectal examination, inability to void or gross haematuria are all indicators of urethral injury. When present, suspicion for urethral injury should be high and a retrograde urethrogram should be performed. If there is extravasation of contrast this is diagnostic of urethral disruption. The majority of patients with posterior injuries will have a complete tear, whereas those with anterior injuries will have a complete disruption only half of the time. If the patient is stable an attempt at immediate endoscopic realignment can be made. If a urologist is successful in passing a wire beyond the injury, the Seldinger technique is then used to pass a large Foley catheter over the wire; in essence, this stents the injury open and maintains proper alignment of the proximal and distal urethra, allowing healing to occur while the bladder is adequately drained by the catheter. In unstable patients, or those in whom endoscopic alignment is unsuccessful, a suprapubic catheter should be placed and no further attempts at Foley placement should be made to avoid worsening the severity of the disruption or converting a partial disruption to a complete disruption. Surgical repair of urethral injuries, if necessary, is performed in a delayed fashion. Delayed repair has markedly diminished the incidence of stricture, impotence and incontinence. Concomitant bladder injury is seen in up to 15% of patients with urethral injury, and strong consideration should be given to imaging to rule out this possibility.

Compartment syndrome

Trauma patients with severe intra-abdominal injuries presenting in profound shock and requiring large-volume resuscitation are susceptible to the development of significant bowel wall oedema and sudden increases in intra-abdominal pressure, causing intra-abdominal hypertension. The most accurate way to diagnose intra-abdominal hypertension is with intravesicular measurement. Physical examination has a very poor sensitivity, even in experienced individuals, with sensitivity ranging from 40% to 60%. Intra-abdominal hypertension is defined by the World Society of the Abdominal Compartment Syndrome as intravesicle pressure >12 mmHg. Intra-abdominal hypertension can progress to the point of abdominal compartment syndrome. Abdominal compartment syndrome is defined as sustained intra-abdominal hypertension >20 mmHg associated with new organ dysfunction or failure. Abdominal compartment syndrome can affect many body systems, including neurological, cardiac, pulmonary, gastrointestinal, hepatic and genitourinary (Table 14.7). As with other types of compartment syndrome, the absolute value of intra-abdominal pressure is not as important as the perfusion pressure and the clinical picture. A patient may have abdominal compartment syndrome with organ failure at intra-abdominal pressures <20 mmHg. Increasing use of damage control surgery/temporary abdominal closure may decrease

Table 14.7 Consequences of increased intra-abdominal pressure

Increased	Cardiac rate Pulmonary capillary wedge pressure Peak inspiratory pressure Central venous pressure Intrapleural pressure Systemic vascular resistance
Decreased	Cardiac output Central venous return Visceral blood flow Renal blood flow Glomerular filtration

risks of intra-abdominal hypertension/abdominal compartment syndrome; however, while abdominal compartment syndrome is less likely in the patient with an open abdomen, it is not impossible.

Treatment includes adequate sedation, pain control, pharmacological paralysis, nasogastric decompression, percutaneous catheter decompression and surgical decompression. Non-invasive methods of treatment, especially pharmacological paralysis and catheter decompression, have been shown to be very effective in treating intra-abdominal hypertension, and even abdominal compartment syndrome in certain patient populations.

Vascular trauma

Major vascular injury following trauma is uncommon; however, it can result in extremely high mortality and morbidity. Rapid diagnosis and repair, limiting ischaemic time as much as possible, is crucial to the successful management of these injuries. Modern technological advancements in imaging, prosthetic grafts and endovascular therapies have significantly altered management of vascular injuries. While patients with classic 'hard signs' of vascular injury should still be taken immediately to the operating theatre for open exploration, patients with soft signs of injury now have myriad screening and treatment options. Vascular injuries that were classically difficult to diagnose, expose and definitively treat, such as thoracic aortic and subclavian artery injuries, now have minimally invasive diagnostic and treatment options available as well. One of the most important advancements in the diagnosis of vascular trauma has been the development of CT-A. This has now become the screening tool of choice for traumatic aortic injury, and is becoming more commonly utilized in the diagnosis of upper and lower extremity vascular injury. In the therapeutic realm, minimally invasive endovascular techniques such as stent graft deployment and embolization with coils, glue or Gelfoam are increasingly utilized in the treatment of vascular injury.

Pathophysiology

The spectrum of blood vessel injury consists of transection, laceration, contusion and spasm. Any arterial injury can result in thrombosis, haematoma, pseudoaneurysm or arteriovenous fistula. Complete transection of an artery often induces retraction of the intima and media, which prevents exsanguinating haemorrhage. Partial transection precludes this mechanism and often results in more significant blood loss. Disruption of the intima can lead to thrombosis in the absence of external signs of blood loss or significant haematoma. Traumatic arterial spasm is a rare entity that is difficult to diagnose with certainty, but represents a myogenic reaction independent of the autonomic nervous system in medium-sized muscular arteries. If not recognized early, these injuries can lead to significant morbidity from ischaemia. However, arterial spasm is an angiographic rather than a clinical diagnosis, and it must be emphasized that other types of arterial injury must be ruled out before one can assume that spasm is responsible for poor limb perfusion.

Diagnosis and initial management

Rapid evaluation and restoration of blood flow are essential in order to avoid ischaemic complications of injury. While muscle and peripheral nerve tissue may tolerate anoxia for 4–6 hours, delays in revascularization will lead to intravascular stasis, activation of coagulation and thrombosis. The eventual outcome is irreversible damage to skeletal muscle, peripheral nerves and visceral organ function. Initial management includes airway control, vigorous resuscitation and appropriate prioritization of other accompanying life-threatening injuries. Any external sources of haemorrhage should be controlled with direct application of pressure or tourniquets. Blind probing of a stable wound and attempts at clamping injuries in the emergency department should not be tried as disrupted clot may result in uncontrollable haemorrhage.

Patients with haemodynamic instability, or hard signs of injury, should be transferred immediately to the operating theatre. Patients presenting with soft signs of arterial injury or victims of multilevel penetrating or blunt trauma should undergo angiography for diagnosis and to help determine the optimal surgical approach. Hard signs of vascular injury include arterial bleeding; large, expanding or pulsatile haematoma; hypotension; absence of distal pulses; injury to anatomically related nerves; and thrill or bruit. Soft signs include neurological defect, non-expanding non-pulsatile haematomas and a history of profuse or pulsatile bleeding.

Although vascular injuries resulting in haemorrhage are generally diagnosed promptly, others causing ischaemia or with contained haemorrhage may be more insidious and require a high index of suspicion.

These patients are likely to be haemodynamically stable but may present with signs of ischaemia, including pain, pallor, pulselessness, paralysis and paraesthesiae; however, these generally occur very late in the course of injury. It is paramount to recognize that a palpable pulse or one that can be identified by Doppler imaging does not exclude vascular injury. Pulses may be intact in the presence of injury owing to pulse wave propagation through soft clot, flow past an intimal flap or by way of collateral blood flow around a thrombosed vessel. Any pulse asymmetry, stable haematoma, concerning injury pattern or significant extremity fracture/dislocation should prompt further work-up.

In the extremities, the primary screening examinations are the ABI or BBI. The blood pressure, taken below the level of injury in the affected extremity, is compared with the blood pressure in a non-affected upper extremity. The ABI/BBI has a very good sensitivity, ranging from 95% to 100%, a negative predictive value of 98% and can be easily and rapidly performed at the bedside. If the ABI/BBI is <0.9 further imaging is mandatory as up to 35% of these patients will have a surgically significant injury.

If the ABI or BBI is abnormal, or there are soft signs of injury, further imaging should be performed to definitively diagnose or rule out vascular injury. Options include ultrasonography, CT-A and traditional angiography. Each test has its own set of advantages and disadvantages. The choice of imaging study should primarily depend on institutional availability, reliability and patient presentation. Ultrasonography has the benefits of portability and can be performed in the operating theatre in cases of instability, it is non-invasive and does not require contrast administration. However, it is operator dependent, and has poor sensitivity for thoracoabdominal injuries and in the presence of severe soft-tissue injury. CT-A is an excellent choice for the stable patient, and has very high sensitivity and specificity for cervical, thoracoabdominal and proximal extremity vascular injury. However, it is not appropriate for haemodynamically unstable patients, and requires contrast administration. Angiography has been the traditional gold standard for diagnosis of both truncal and extremity vascular injury, is excellent for preoperative planning and can be both diagnostic and therapeutic. However, it may not be immediately available, requires specialized equipment and personnel, exposes the patient to intravenous contrast and ionizing radiation, and requires arterial puncture.

General operative principles

When preparing for surgery endotracheal intubation must be carefully performed and can be hazardous, particularly when a patient has vascular injuries of the neck and great vessels. The patient should undergo skin preparation and be draped widely with consideration given to potential sources of autogenous vein for subsequent repair prior to induction of anaesthesia. Broad-spectrum antibiotics are routinely administered prior to surgery and in the immediate postoperative period. MTPs should be instituted and adjuncts such as cell saver or other blood reclamation techniques mobilized. Every effort should be made to maintain normothermia as a core temperature of <34°C has been found to be a significant predictor of mortality among these patients.

Incisions should generally be made parallel to the injured vessel with transverse extensions at joint creases. Attempts should be made to preserve arterial and venous collaterals. The time-honoured principle of gaining proximal and distal control prior to evacuation of haematomas remains critical. In situations in which proximal or distal access is difficult, the use of balloon catheters for occlusion has been found to be invaluable. Systemic heparin at a dose of 50–75 units/kg can be administered prior to clamping in isolated vascular injuries; however, multisystem trauma often contraindicates its use. In contrast, regional heparinization is appropriate for most cases that prohibit systemic anticoagulation. Careful use of balloon catheter thrombectomy is essential prior to vascular repair to remove proximal and distal thrombi, minimizing postoperative thromboembolic complications.

Arterial repair can often be performed by simple lateral arteriorrhaphy or resection with primary anastomosis or interposition graft with either autogenous saphenous vein or prosthetic grafts. It is important to adequately debride damaged arterial tissue. Experimental and clinical data indicate that polytetrafluoroethylene (PTFE) is the most infection resistant of available prosthetic materials. Vascular injuries in the presence of massive contamination may be treated by placing an extra-anatomic bypass to provide flow continuity; however, some studies have reported no significant increase in the incidence of graft infection even when placed in a grossly contaminated site.

Accompanying venous injuries, particularly to the deep femoral and popliteal veins, should be repaired to maximize the chances of success when the artery is repaired. Adjunctive intermittent venous compression stockings and elevation of the injured limb should be utilized to prevent oedema formation and development of postphlebitic syndrome. It should also be kept in mind that the risk of compartment syndrome increases significantly in the presence of concomitant arterial and venous injury.

Management of specific injuries

Intrathoracic aorta and great vessels

Thoracoabdominal vascular trauma is a rare entity, accounting for 0.01–2.00% of all trauma admissions. Penetrating mechanisms are responsible for the vast majority of injuries; of blunt causes, motor vehicle crashes are the most common, followed by falls from height and pedestrians struck by vehicles. The morbidity and mortality rates of these injuries are among the highest in vascular trauma. Most of these patients expire prior to arrival at the hospital from profound shock secondary to massive haemorrhage. Successful management of these injuries depends upon aggressive resuscitation, early intubation, prompt diagnosis and rapid surgical control of haemorrhage.

Unlike extremity vascular injury in which external evidence of injury is common, besides hypotension, there are few clinical signs of truncal vascular injury. Some diagnostic signs suggestive of great vessel trauma are described in Box 14.1. Radiographic adjuncts can be very useful in diagnosis of truncal vascular injury but should not delay surgery in unstable patients. Once in the operating theatre, MTPs should be activated and rapid infusers and blood reclamation tools should be utilized. Wide preparation of the neck and chest is essential as the aorta and its branches can be difficult to access and expose, and a variety of incisions or combinations may be required (Figure 14.48).

BOX 14.1 Signs suggestive of major thoracic vascular injuries

- Cardiac arrest
- Persistent shock
- Cardiac tamponade
- A mediastinum widened to >8 cm
- Recurring haemothorax
- Blunting of the aortic knob
- Pleural capping
- Deviation of the left mainstem bronchus
- Displacement of the nasogastric tube
- Neurological deficits
- Pulse deficits
- Bruits

However, about one-third of these injuries will have no obvious clinical signs of vascular trauma, except for a penetrating cutaneous wound. High-grade arteriography is useful, but should not delay surgery in the haemodynamically unstable patient.

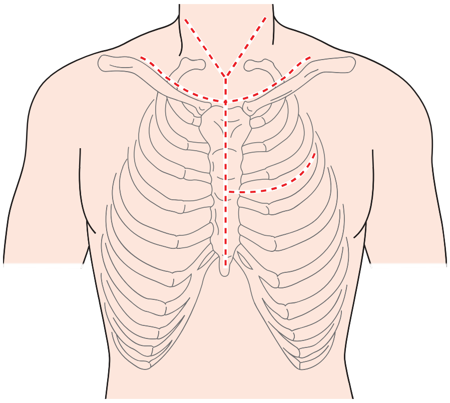

Figure 14.48 Surgical approaches for thoracic aorta and proximal great vessel injuries. (From Hoyt *et al*., *Surg Clin North Am* 2001;**81**:1299–330.)

Innominate vascular injury

Access to the innominate vessels is best accomplished through a median sternotomy. Although minor injuries can be repaired primarily or with a patch graft, major injuries require bypass grafting, usually originating from the proximal aorta. Prosthetic grafts are usually used, although the saphenous vein is an acceptable alternative. If there is significant contamination, ligation and extrathoracic bypass (carotid–carotid, subclavian-subclavian, axillary–axillary, subclavian-carotid) through uncontaminated tissue planes has been used successfully. During repair of the innominate artery, one must consider the need for adequate cerebral blood flow and utilization of an intraluminal shunt. Poor distal back bleeding, stump pressures in the carotid artery <60 mmHg or electroencephalographic changes during intraoperative monitoring suggest the need for shunt placement to maintain cerebral perfusion while repairing the innominate artery.

Accompanying injuries to the superior vena cava and innominate vein are common. The superior vena cava should always be repaired and may require temporary shunting to allow venous return. Although repair of innominate venous injuries is desirable, unilateral ligation is tolerated in most cases. Bilateral ligation results in a superior vena cava-like syndrome. Both superior vena cava and innominate vein injuries may be a source for air embolization. In the event of this complication, immediate direct aspiration of air from the pulmonary artery, right ventricle, atrium and superior vena cava is required.

Subclavian vascular injuries

Subclavian vessel injuries are primarily due to penetrating mechanisms, but are rare, affecting <3% of all penetrating traumas. Injuries associated with blunt trauma are even more uncommon. Injuries often also have accompanying spinal cord or brachial plexus injuries, which are responsible for significant and sometimes devastating disability. These injuries are highly lethal, and patients often present with hypotension, hard signs of vascular injury or compartment syndrome, and are taken for emergency surgery. In rare instances, patients present in stable condition with soft signs of injury, or are asymptomatic; in these cases, CT-A can be very helpful in detecting injuries, for preoperative and endovascular planning. Several large series have found excellent sensitivity and specificity – near 95–100%. Traditional angiography may also be utilized and may be both diagnostic and therapeutic.

Immediate operative repair has been the mainstay of treatment for subclavian arterial and venous injuries. Exposure of the vessels can be performed through a periclavicular or trap-door incision. More proximal injuries can be accessed by median sternotomy for the right, and a high lateral thoracotomy on the left. Because of the posterior location and intimate relationship of the subclavian artery to the brachial plexus, operative exposure and repair can be incredibly difficult. Once localized primary repair is preferred, however, tissue loss often makes this unfeasible as this vessel has very little mobility; in these cases, the artery may be ligated or shunted, venous injuries may be ligated with relative impunity. With any operative repair there is significant risk of bleeding, nerve injury and, in the case of ligation, compartment syndrome and ischaemia. Because of this, alternatives to open surgical repair are very attractive, and there is growing experience with covered stents for treatment of subclavian artery injuries. Several case series have reported mortality rates ranging from 0% to 33%, with technical success rates ranging from 67% to 100% and primary patency rates of 83–100%. These series are, however, limited by relatively short-term follow-up and small study populations.

Patients who are unstable should not considered be for endovascular therapy; other contraindications to endovascular repair include vessel transection and a lack of a proximal vascular fixation site. In some cases stent–graft deployment may occlude the origins of one of the subclavian artery branches, the most important of which are the vertebral and internal mammary arteries. If the vertebral artery may be occluded it is imperative to assess whether the contralateral vertebral circulation is intact, and whether cerebral perfusion will be maintained after occlusion. The internal mammary may be sacrificed, however, at the cost of future use for cardiac revascularization.

Carotid artery injuries

Penetrating trauma accounts for the majority of carotid injuries, and the common carotid is the most frequently injured segment. Carotid injury is often accompanied by injury to vascular, nervous or aerodigestive injury. Injuries due to penetrating trauma most often present with haemorrhage, haematoma, a threatened airway or shock. Associated mortality remains high, and persistent neurological deficit is common.

Carotid injuries are most often approached through a vertical incision along the anterior border of the sternocleidomastoid muscle. Adequate debridement or resection followed by primary anastomosis or interposition grafting is utilized to repair the defect. Shunts should be liberally used when there is concern regarding the adequacy of collateral perfusion. A quick measure of collateral perfusion is the stump pressure: stump pressures <40–55 mmHg are considered by most to be an indication for shunt use. However, few studies have found any significant benefit among patients in whom shunts were used. Reconstruction is associated with better functional outcomes than ligation; therefore, ligation should be reserved for cases of severe physiological derangement, severe concomitant brain injury, a documented ischaemic lesion in the distribution of the injured vessel, in the presence of severe distal thrombosis and with very high skull base injuries.

There has been concern that restoration of cerebral blood flow in the presence of a severe neurological deficit may convert ischaemic infarction to haemorrhagic infarction, and a high mortality rate has been associated with operative repair among these patients. However, neurological impairment may be due to hypoxia and shock associated with carotid injury, rather than directly resulting from cerebral ischaemia, and may reverse with resuscitation and intubation. There are also data to suggest that an aggressive approach to revascularization even in the setting of a significant deficit may result in neurological improvement. Most authors now favour carotid reconstruction in patients with mild to moderate deficits when antegrade flow has been preserved.

Occasionally patients with penetrating carotid injuries may present with haemodynamic stability. In these cases, if there are no hard signs of vascular injury CT-A has become very useful. In these stable patients consideration can also be given to endovascular therapies. These may be particularly attractive in zone 1 and zone 3 injuries, which are technically difficult to access and repair. Small series have found good technical success and low associated mortality with both covered and bare stents as well as coils in the treatment of pseudoaneurysm, arteriovenous fistula and dissection. However, there are some data to suggest increased morbidity due to stent placement, particularly following blunt carotid injuries.

Vertebral artery injuries

The vertebral arteries originate from the subclavian arteries bilaterally and enter the neck in zone 3 laterally. They enter the transverse foramen at the level of C6, and superior to this point they are contained within the bony vertebral canal before entering the base of the skull through the foramen magnum. Traumatic injury of the vertebral artery is rare because of this bony protection. Penetrating trauma accounts for the majority of injuries. CT-A is an excellent screening test in patients with suspect wounds, or concerning blunt mechanisms (hyperextension/rotation). Definite injuries should undergo angiography as they can result in significant haemorrhage, thrombosis or development of a pseudoaneurysm or arteriovenous fistula. Because of the confluence of the vertebral arteries to form the basilar artery, ligation alone is inadequate treatment for most injuries. Percutaneous occlusion with detachable balloons is a useful adjunct in treating these injuries.

Intra-abdominal vascular injuries

Injuries to major intra-abdominal vascular structures are rare and associated with both significant haemorrhage and risk of visceral ischaemia. Penetrating mechanisms are responsible for the vast majority of vascular injuries in the abdomen. Of blunt causes motor vehicle crashes are the most common. Although optimal treatment is repair and reconstruction of normal vascular pathways, knowledge of the anatomy and collateral circulation allows ligation of many injuries when necessary.

Presentation is variable. If the injury has been contained in the retroperitoneum the patient may be relatively stable; however, with free rupture into the peritoneum, the patient will probably present *in extremis*.

Most patients will be in an advanced stage of haemorrhagic shock and immediate large-bore intravenous access, resuscitation and rapid surgical control of bleeding are essential. MTPs should be instituted as soon as abdominal vascular injury is suspected. Despite modern advancements in surgery, mortality from abdominal vascular injuries remains high and increases with increasing number of vessels injured and in the presence of associated non-vascular injuries. In general, venous injuries are the more poorly tolerated and result in a mortality of 50% in many series. Additionally, these injuries pose a technical challenge in exposure and repair or reconstruction of the thin venous walls, which are easily torn. Because flow rates are low, venous repairs are more prone to thrombosis, particularly when prosthetic material is used. When venous ligation is required, fluid sequestration occurs in the affected vascular bed and patients require additional fluid administration to maintain intravascular volume until collateral flow improves. This third spacing significantly increases risks of abdominal compartment syndrome and organ dysfunction. When collateral flow is inadequate, infarction secondary to venous obstruction can occur (Figure 14.49).

The majority of vascular structures are located in the retroperitoneum, which is divided into three zones (Figure 14.50). Zone 1 spans the midline of the abdomen and can be divided into the supramesocolic and inframesocolic regions; it contains the aorta, inferior vena cava, and the coeliac, superior and inferior mesenteric arteries. Zone 2 is located in the paracolic gutters bilaterally and contains the renal vessels and kidneys. Zone 3 begins at the sacral promontory and contains the iliac vessels. The remaining major abdominal vessels, the portal and superior mesenteric veins, are intraperitoneal. All zone 1 haematomas should be explored owing to the high risk of major vascular, pancreatic and duodenal injury. Zone 2

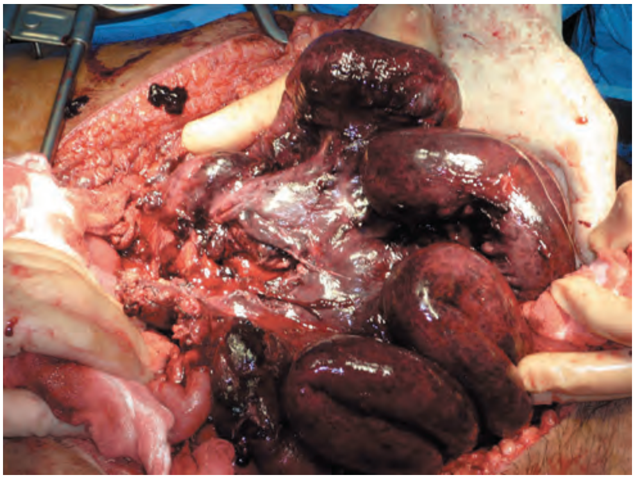

Figure 14.49 Infarction of the small bowel due to venous outflow obstruction after superior mesenteric vein ligation. Note the congested dark appearance of the mesentery, which upon pathological analysis demonstrated sequestered clotted blood within the mesenteric veins.

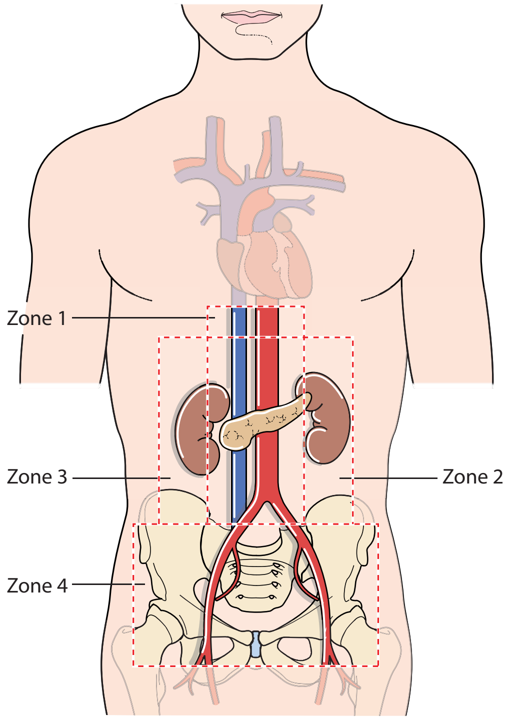

Figure 14.50 Zones of the retroperitoneum. (From Hoyt *et al.*, *Surg Clin North Am* 2001;**81**:1299–330.)

haematomas, both penetrating and blunt, should be explored only if they are expanding or pulsatile, or if they are adjacent to the colon and potentially concealing colonic injury. Zone 3 injuries due to penetrating trauma should be explored to exclude ureteral and iliac artery/vein injury. Those due to blunt trauma usually have associated pelvic fractures and exploration of the haematoma can be hazardous. There is often extensive injury to the rich presacral venous and arterial circulation. Opening the haematoma destroys the tamponade effect, and dissection may result in catastrophic bleeding, and is associated with increased transfusion requirements and high mortality as discrete bleeding points can rarely be identified. If ongoing bleeding is suspected in these cases, pelvic angioembolization should be considered.

Abdominal aorta

Injuries to the abdominal aorta are classified as either suprarenal or infrarenal. Injury to the abdominal aorta is associated with high morbidity and mortality. Shock, acidosis, suprarenal injury and lack of retroperitoneal tamponade are independently associated with mortality. Initial efforts in the management of aortic injuries should be directed at gaining proximal control to limit ongoing haemorrhage. This can be done manually by applying pressure at the diaphragmatic hiatus with either a hand or an aortic compression device. Another option is to clamp the aorta via a left anterolateral thoracotomy; this option should be reserved for patients who are *in extremis* and require open cardiac massage. Once proximal control has been achieved, the suprarenal aorta can be exposed by left-sided medial visceral rotation (Figure 14.51). This should allow visualization of the aorta from its entry at the diaphragmatic hiatus to the bifurcation. Once the injury is identified and isolated, care should be taken to examine both the anterior and posterior walls to evaluate for through-and-through injuries. Small injuries should be repaired primarily. If the defect is large, patch angioplasty can be performed using PTFE or autologous vein. In some instances, significant loss or destruction of the aorta may require replacement of the resected segment with PTFE conduit. If the patient is unstable, temporary intravascular shunts can be used to span the injury and maintain blood flow to the lower limbs. Most evidence suggests systemic heparinization is unnecessary. While temporary intravascular shunts remain a viable and attractive damage control option, indications, type of shunt, dwell time and long-term outcomes have yet to be clarified in the literature.

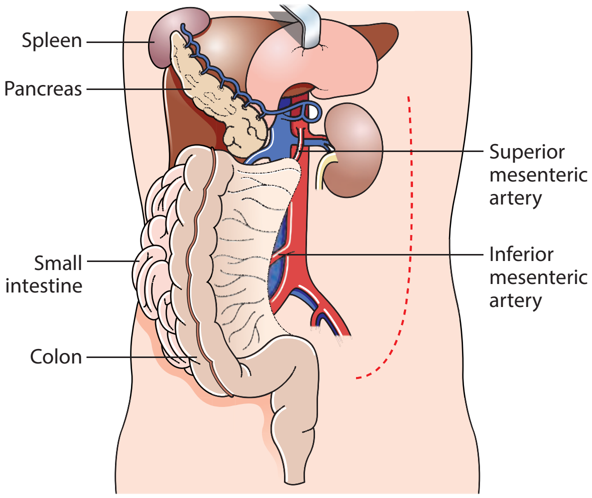

Figure 14.51 A left medial visceral rotation (Mattox manoeuvre) exposing the abdominal aorta from its entry at the diaphragmatic hiatus to the bifurcation including the left iliac vessels. This rotation also provides exposure of the left kidney and renal hilum, as well as the origins of the mesenteric arteries. (From Hoyt *et al.*, *Surg Clin North Am* 2001;**81**:1299–330.)

Inferior vena cava

Inferior vena cava injuries occur after both blunt and penetrating trauma, and are among the most common of intra-abdominal vascular injuries. Inferior vena cava injuries are classified by location as infrarenal, suprarenal or retrohepatic/suprahepatic. Mortality can be high, ranging from 36% to 70%, and increases with increasing number of associated injuries. Mortality is also increased following blunt trauma, if there is release of the retroperitoneal tamponade and in the presence of shock or acidosis.

The most common approach to the infrahepatic inferior vena cava is a right-sided medial visceral rotation (Cattell–Braasch manoeuvre). This manoeuvre exposes the inferior vena cava from the inferior border of the liver to its bifurcation (Figure 14.52). Infrarenal inferior vena cava injuries are considered the easiest to repair, carry the lowest mortality rate and can usually be controlled with compression directly above and below the injury digitally or with sponge sticks. The majority of injuries to the inferior vena cava are repaired primarily. The back wall should be inspected for through-and-through injuries. Posterior defects can be repaired by rotating the vessel, or through the anterior defect. In circumstances in

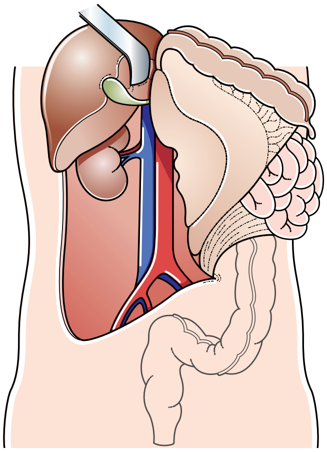

Figure 14.52 Depiction of a right medial visceral rotation (Cattell–Braasch manoeuvre) exposing the right kidney and renal hilum, inferior vena cava, right iliac vessels and the posterior aspect of the duodenum and pancreas. (From Hoyt *et al.*, *Surg Clin North Am* 2001;**81**:1299–330.)

which the defect is large, either saphenous vein or prosthetic patches can be utilized to repair the defect. In damage control situations ligation of the infrarenal inferior vena cava can be considered. In these cases four-compartment lower extremity fasciotomies should be considered as compartment syndrome is common. The bilateral lower extremities should be elevated in all cases in order to decrease accumulation of oedema. In contrast to infrarenal inferior vena cava injuries, the suprarenal inferior vena cava should not be ligated in cases of severe injury as this would preclude renal outflow.

Injuries to the suprarenal or retrohepatic inferior vena cava are particularly difficult to treat, and carry the highest mortality rates. Bleeding is massive and the diagnosis should be suspected when major hepatic parenchymal bleeding persists despite the Pringle manoeuvre. Mobilization and division of the hepatic ligaments are required and vascular control by isolation and clamping of the hepatic inflow and outflow may be necessary. Occlusion of the hepatic veins and inferior vena cava are poorly tolerated owing to the abrupt decrease in venous return to the heart. The use of atriocaval shunts has been described as a temporizing measure to bypass the area of injury while maintaining venous return to the heart until adequate mobilization and repair of the injury is completed. Atriocaval shunts are rarely used, and are associated with mortality exceeding 50%. Another damage control option is total hepatic isolation; requiring clamping of the supra- and infrahepatic inferior vena cava and a Pringle manoeuvre, this also requires application of an aortic cross-clamp to prevent arrest due to severely diminished preload. Total hepatic isolation still often results in arrest or severe shock and outcomes are generally poor. Hepatic venous injury can usually be treated with lateral repair after mobilization and division of the hepatic ligaments but ligation of a single hepatic vein is well tolerated.

Mesenteric vessels

Coeliac artery injuries are rare and primarily due to penetrating trauma (Figure 14.53). Most patients present with hypotension, haemoperitoneum or peritonitis. Mortality associated with coeliac arterial injury is high, and correlates with advancing AAST-OIS grading, hypotension and presence of associated injuries. Exposure of the coeliac artery is best approached via left medial visceral rotation. Once the injury is exposed and proximal and distal control obtained, the surgical options include ligation or repair. Complex reconstructions are not well tolerated and are not recommended. The coeliac artery can be ligated safely if the superior mesenteric artery is patent due to extensive collateral circulation. There are no reports of significant bowel ischaemia following coeliac ligation; however, ischaemia and necrosis of the gallbladder has been described, and cholecystectomy is advocated for patients undergoing ligation. Branches of the coeliac artery may be ligated with relative impunity; however, common hepatic artery ligation distal to the origin of the gastroduodenal artery can result in hepatic ischaemia, particularly if the portal vein is also compromised.

Superior mesenteric artery injuries can be classified according to the schema created by Fullen *et al.* (1972) or by that created by the AAST-OIS. Small defects should be repaired primarily; however, large defects are unlikely to come together primarily as extensive branching of the superior mesenteric artery makes significant mobilization impossible. In these cases, techniques such as vein patch, interposition graft and reimplantation may be utilized. In unstable patients, if primary repair is not possible the injury should be ligated or shunted. Ligation of the superior mesenteric artery is tolerated because of collateral flow through the coeliac axis; however, mortality is higher when ligating proximal than when ligating distal injuries. It should also be kept in mind that bowel ischaemia may result if multiple distal injuries are ligated. In damage control situations temporary intravascular shunts are an alternative to ligation. Compared with extremity injury, truncal temporary intravascular shunts are associated with significantly higher transfusion requirements and higher rates of thrombosis. Strong consideration should be given to temporary abdominal closure for severe superior mesenteric artery injuries because of the high risk of ischaemic complications and abdominal compartment syndrome, particularly after ligation or when concomitant arterial and venous injuries are present. Venous injuries are difficult to control and repair without tension or tearing and are more prone to thrombosis, particularly when prosthetic materials are used.

In very rare cases, patients with superior mesenteric artery injuries may be haemodynamically stable; in these cases, there may be a role for endovascular intervention. A few small case reports of angioembolization for superior mesenteric artery injuries found embolization was successful in controlling haemorrhage in all cases, with no documented bleeding, ischaemia or perforation requiring subsequent laparotomy. However, angiography cannot diagnose or address associated injuries, and it may be best suited to a role as a surgical adjunct.

Injuries to the inferior mesenteric artery/inferior mesenteric vein are rare. Generally, isolated injuries are well tolerated if they are surgically addressed quickly. Mortality is highly dependent on physiological derangements at the time of admission and associated injuries. Inferior mesenteric artery/inferior mesenteric vein injuries are approached directly and, if amenable, primarily repaired or ligated. Ligation is generally well tolerated because of the extensive collateral circulation. However, the surgeon should keep in mind that, although extremely rare, there can be complications of rectal or colonic ischaemia, particularly in patients with advanced atherosclerotic disease.

Renal artery/vein

Renal vascular injuries consist of avulsion, laceration or thrombosis. Penetrating injuries are more common than blunt and most often result in laceration or transection and haemorrhage. Blunt injury can result in the formation of an intimal flap, causing thrombosis and occlusion of the renal artery. Prompt identification of renal artery occlusion is required if an attempt to revascularize the kidney is pursued, as delays to treatment increase the likelihood of nephrectomy. Stable patients should undergo CT scanning to assess for renal or renovascular injury; if unavailable, intravenous pyelography can be performed. Intraoperatively, renovascular injuries may be evidenced by either central or lateral retroperitoneal haematomas. Renal and renal vascular injuries are graded based on the renal AAST-OIS, which has been validated to predict outcome in patients with renal trauma. Advanced grade and blunt mechanisms are both associated with higher nephrectomy rates.

Renal injuries are approached by either right or left medial visceral rotation, the kidney is then delivered from Gerota's fascia. After adequate exposure and proximal control, small renal artery injuries can be repaired primarily. More frequently, renal artery injuries require mobilization and end-to-end repair. Interposition grafts using saphenous vein or PTFE can also be considered for larger arterial defects. Although renal artery repair should be attempted if diagnosed early, renal salvage beyond 6 hours after injury is rare. Nephrectomy should be performed in unstable patients as long as there is confirmation of a contralateral kidney. Autotransplantation or *ex vivo* renal repair may be contemplated in haemodynamically stable patients with bilateral renal injuries to avoid chronic renal failure. Despite an aggressive approach to renal artery repair, it is successful in <30% of cases.

The majority of renal vein injuries can be repaired primarily. Injury to the left renal vein can be treated safely with ligation near the inferior vena cava provided that adrenal and gonadal collaterals have been preserved. The right renal vein lacks collateral outflow, and nephrectomy is indicated if repair of the vein is not possible.

Iliac artery and vein

Injury to these vessels is most commonly due to penetrating trauma, and can be quite morbid. Injuries due to blunt trauma, although rarer, are associated with increased morbidity and mortality, usually because of the high number of associated injuries seen in this population. Patients with shock and evidence of significant haemoperitoneum should be taken for operative exploration. Injury to the iliac artery should be suspected with rapidly expanding or pulsatile haematomas in zone 3, or in any patient with penetrating pelvic trauma and a zone 3 haematoma. Exposure of the iliac artery is achieved by incising the retroperitoneum over the aortic bifurcation, alternatively left or right medial visceral rotation may be performed to expose the left or right iliacs. Initial proximal control is achieved with manual compression; care should be taken to identify and preserve the ureter during dissection. Vessel loops or vascular clamps can then be used to gain definitive proximal control. Distal control of the external iliac can be obtained near the inguinal ligament. Control of the internal iliac artery is also necessary to avoid back bleeding from the extensive collateral circulation during isolation and repair. Small injuries should be repaired primarily; larger or destructive injuries should be resected. The resected gap can be spanned with primary anastomosis after adequate mobilization of the proximal and distal ends or with PTFE or saphenous vein interposition grafts. Injuries to the iliac arteries may be associated with injury to the bowel resulting in the spillage of enteric contents into the pelvis; in these cases, ligation of the injury with subsequent extra-anatomic bypass in a non-contaminated field may be required. In patients with significant physiological derangement and complex injuries, shunting is an alternative to ligation. In common and external iliac arterial injury there are some data to suggest that temporary intravascular shunts can significantly reduce the need for later fasciotomies and amputation. Injuries to the internal iliac artery can be ligated with little consequence owing to the rich pelvic collateral blood flow.

Among haemodynamically stable patients, diagnosis of iliac arterial injury primarily occurs following CT scan, which has a sensitivity of >90% for detecting pelvic bleeding requiring intervention. If associated hollow viscous injury cannot be ruled out, or if the patient's clinical course deteriorates, immediate laparotomy and surgical repair is the treatment of choice. However, in stable patients with isolated iliac artery injuries, good outcomes have been noted with the deployment of covered stent grafts. Successful occlusion of the injury and haemostasis are achieved in 75–100% of cases, with few complications. The most common complications are stent–graft occlusion followed by stenosis.

Iliac vein injuries are frequently associated with arterial injuries. Iliac vein injury can occur after blunt or penetrating trauma and as a result of iatrogenic injury following pelvic procedures. Mortality for venous injuries is similar to that for arterial injuries and can be as high as 70%. Access to common iliac vein injuries, especially on the right side, may be limited by the overlying common iliac artery. Transection of the artery for visualization and repair of the venous injury has been described historically, but is not advocated in modern times. Minor lacerations can be repaired primarily; however, more destructive injuries associated with gunshot wounds and blunt trauma most often require ligation. Complex venous reconstructions after traumatic injury are rarely indicated and should only be performed in stable patients. Postoperative anticoagulation should be considered if the venous repair results in significant narrowing of the vein to prevent thrombosis. Previous studies have shown that ligation of the common or external iliac vein is well tolerated with few adverse sequelae. Complications may include extremity oedema, compartment syndrome, thromboembolic complications and outflow ischaemia. While leg oedema is common after ligation, compartment syndrome is rare unless there is also arterial injury or prolonged hypotension.

Superior mesenteric vein/portal vein

Injuries to the portal and superior mesenteric veins are rare, highly lethal injuries occurring in <1% of all traumas. Most injuries occur as a result of penetrating trauma, lead to exsanguination in a short period of time, and present with hypotension or peritonitis requiring emergency laparotomy. An additional minority may require resuscitative thoracotomy. The need to undergo either resuscitative or operating theatre thoracotomy is associated with an increased risk of death.

Because the portal vein and superior mesenteric vein are centrally located, nearly all patients have associated injuries, averaging three or more per patient, and the surgical approach can be difficult owing to the proximity of other vital structures. Initial haemorrhage control of injuries in the hepatoduodenal ligament can be obtained by application of the Pringle manoeuvre. Once the haematoma and areolar tissue in the hepatoduodenal ligament have been dissected, vascular clamps or vessel loops should be placed above and below the injury. The distal portal vein is exposed by medial retraction of the common bile duct; however, approach to the more proximal portal vein requires reflection of the pancreas and duodenum via a wide Kocher or Cattell–Braasch manoeuvre. Extra length and access to more proximal portal and distal superior mesenteric vein injuries can be gained by dividing the neck of the pancreas. Portal vein injuries can be addressed by repair, reanastomosis, interposition graft, portosystemic shunt or ligation. Ligation is well tolerated as long as the hepatic artery is patent, with mortality ranging from 20% to 90%; however, concomitant hepatic artery injury mandates portal vein repair. Ligation of the portal vein may result in splanchnic hypervolaemia, and systemic hypovolaemia causing haemodynamic compromise. Careful monitoring of preload and aggressive intravascular volume replacement are essential in these circumstances.

Superior mesenteric vein injuries can be treated with ligation or repair with similar outcomes. If ligation is performed, it should be kept in mind that, similar to portal vein ligation, the syndrome of splanchnic hypervolaemia/systemic hypovolaemia is a significant risk. Because of the risk of bowel ischaemia due to acute outflow occlusion and portal hypertension, damage control laparotomy is particularly well suited to portal vein and superior mesenteric vein ligation. A second look to assess bowel viability is useful and the risks of abdominal compartment syndrome may be decreased with temporary abdominal closure techniques.

Injuries to the extremities

Extremity vascular injuries are common sequelae of both blunt and penetrating trauma. Lower extremity injuries are more common than upper, and the majority of injuries are due to penetrating trauma. Although tolerance to ischaemia is greater than that of the viscera or brain, rapid diagnosis and treatment are still essential. Because of the superficial location of extremity vessels clinical examination is very sensitive for detection of arterial injury. Patients with any hard signs of injury should be taken to surgery immediately. The one exception would be in blunt trauma patients or victims of multilevel penetrating trauma, such as shotgun wounds, where angiography or CT-A can be used for surgical planning to optimize exposure and exploration.

In stable patients without hard signs of injury a complete assessment of all peripheral pulses should be performed. If any pulse asymmetry or obvious orthopaedic injury (Box 14.2) is noted, an ABI or BBI should be performed. Patients with no hard or soft signs of injury, and normal ABI/BBI results may be discharged. Patients with ABI/BBI <0.9 should undergo imaging. Options include ultrasound, angiography and CTA.

Ultrasound is an excellent option below the inguinal ligament and below the shoulder. It has the benefit of being portable, non-invasive and does not require ionizing radiation. However, fractures, subcutaneous emphysema and soft-tissue injury significantly decrease sensitivity. Traditional angiography, including surgeon-performed on-table angiography, is both sensitive and specific with a low complication rate. Because both ultrasound and angiography require mobilization of advanced imaging teams with specialized training and are unlikely to be immediately available in most centres after hours or on holidays/weekends, CT-A has become popular as a screening method. It is rapid, easily performed, does not require an interventional radiology team or arterial puncture and has few complications. CT-A also has the benefit of giving additional information on

BOX 14.2 Orthopaedic injuries associated with vascular trauma

(a) Axial views demonstrate significant soft-tissue injury and loss of the left knee, and occlusion of the right popliteal artery. (b) Three-dimensional reconstruction of the same patient demonstrating a long segment occlusion of the right popliteal artery with distal reconstitution of flow.

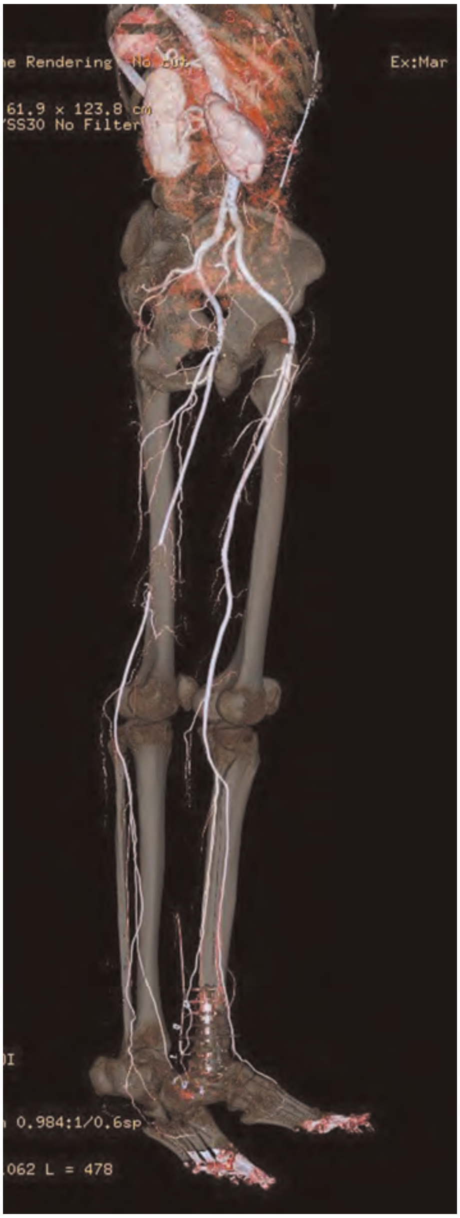

Figure 14.55 Three-dimensional CT angiography reconstruction of a patient with injury and occlusion to the left distal superficial femoral artery just above Hunter's canal.

non-vascular structures such as the bone, joint and soft tissue (Figure 14.54a,b). Overall CT-A has excellent sensitivity and specificity for detecting both upper and lower extremity vascular injuries. Accuracy appears to be particularly good when using multidetector 16- and 64-slice scanners, and reformatting such as maximum intensity projections and two- and three-dimensional reconstruction (Figure 14.55). CT-A is also reported as being the least uncomfortable vascular examination in many series comparing it with MRA, ultrasound and traditional angiography, and may have a cost benefit over traditional angiography.

Limitations of CT-A include the need to transport the patient to the radiology suite and exposure to contrast and ionizing radiation. Additionally, in victims of gunshot and shotgun wounds images may be compromised by metallic fragments.

The femoral artery is the most commonly injured vessel in the lower extremity. Although most often due to penetrating trauma, fractures, dislocations and iatrogenic injuries are also important causes. Femoral artery injuries are often associated with injury to accompanying veins and nerves. In addition to arterial repair, extensive attempts at deep vein reconstruction are warranted to minimize early and late morbidity. In general, injuries to the profunda femoris artery should also be repaired because of the significant incidence of subsequent atherosclerotic vascular disease involving the superficial femoral artery. Injuries are repaired by resection and primary anastomosis or interposition graft. The contralateral saphenous vein is preferentially used when a venous conduit is required for major lower extremity arterial and venous injuries.

The popliteal vessels are particularly susceptible to blunt traumatic injury from fractures and dislocations. The amputation rate for unreconstructed injuries in this area is as high as 61%. Concomitant popliteal vein injury decreases the likelihood of success following arterial reconstruction. Therefore, expeditious repair of both the vein and artery is essential.

Although the ideal sequence of repair in patients with combined orthopaedic and popliteal vascular injuries has been debated for many years, most surgeons now use shunts to temporarily perfuse the extremity while orthopaedic stabilization is performed (Figure 14.56). Proximal and distal thromboembolectomy should be performed prior to shunt placement and local heparinization should be used if possible. Temporary intravascular shunts appear to be well tolerated, particularly in the extremities, and do not require systemic heparinization. Maximum dwell times are unknown, but some series have shown excellent patency as long as 72 hours. Once the fractures have been stabilized the temporary intravascular shunts can be removed and definitive vascular repair performed in the stabilized limb.

Injury to the small vessels below the popliteal trifurcation can pose difficult management problems. When both tibial arteries are injured, the amputation rate may reach 65%, whereas with injury to only one vessel the rate is much lower. Arteriography in this area is important in defining the site and extent of all the injuries. This is particularly true with multiple pellet wounds from a shotgun blast. If arteriography demonstrates only a single isolated arterial injury below the knee without active bleeding, pseudoaneurysm or arteriovenous fistula, and the patient does not have an ischaemic limb, then observation without surgical intervention is justified. On the other hand, any patient who demonstrates ischaemia, bleeding or a vascular complication of the injury should undergo immediate exploration and repair of the artery. If a vein graft is required for repair, it should be harvested from the contralateral extremity. Fasciotomy is often required when prolonged ischaemia or soft-tissue injury is present. Salvage of a useful limb is often more dependent on the extent of neuromuscular injury than vascular injury.

Vascular injuries of the upper extremity are extremely common. These injuries are not only seen with penetrating trauma but are also encountered after use of the brachial artery for arteriographic and cardiac catheterization, and following cannulation for arterial blood gas monitoring. Long-bone fractures with or without joint dislocation are another potential source of vascular trauma. In children the brachial artery is particularly vulnerable to injury from supracondylar fractures of the humerus. Most upper extremity vascular injuries do not result in limb-threatening ischaemia and physical examination or angiography can establish the diagnosis. Injuries to the axillary and brachial arteries require urgent exploration and can usually be managed by thrombectomy and primary repair with or without a vein patch. Injuries to the radial and ulnar arteries are often easily repaired but either can be ligated if the other vessel is patent and there is an intact palmar arch. Fasciotomy of the forearm may be needed if ischaemia or soft-tissue injury causes a compartment syndrome.

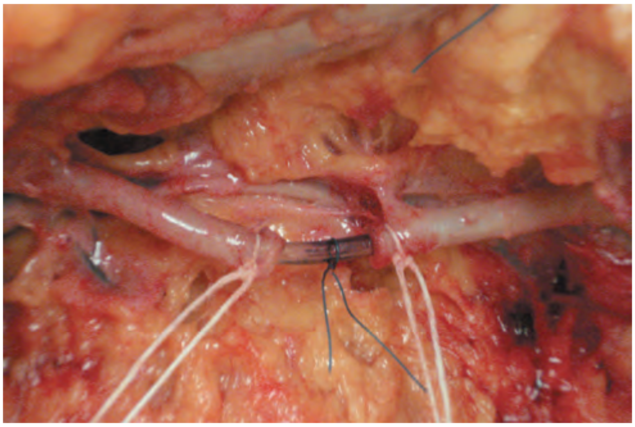

Figure 14.56 A temporary intravascular shunt spanning a defect in the popliteal artery; note that a silk suture has been used to mark the midline of the shunt to prevent dislodgement during orthopaedic manipulation of the knee joint.

Acute and chronic sequelae of vascular injury

Haemorrhage

Bleeding subsequent to arterial repair is uncommon, occurring in <5% of cases. It may present as frank haemorrhage from the operative incision or as a rapidly expanding haematoma. In virtually all cases, the cause is a technical error, resulting from inadequate haemostasis in the wound or from the suture line of the vascular repair. Rarely, bleeding may be due to a missed arterial or venous injury. Patients who develop this complication should be returned to the operating theatre immediately for evacuation of any surrounding haematoma and identification and correction of the problem.

Thrombosis

Occlusion of a vascular repair is the most frequently encountered acute complication of vascular surgery. Depending on the vessel involved and the type of repair (i.e. lateral arteriorrhaphy, interposition grafting, etc.) thrombosis can occur in approximately 10% of cases. If late thromboses are included, the incidence rises to about 20%. Early thrombosis is due to a technical problem, most commonly stenosis of the repair or inadequate thrombectomy. Other causes include intimal dissection with prolapse and missed injury. Because these technical problems are easily corrected if discovered early, it is prudent to perform completion arteriography or intraoperative ultrasound if available.

Thrombosis presents with a loss or diminution of distal pulses; these may or may not be associated with signs of ischaemia (i.e. pallor, poikilothermia, pain, paralysis and paraesthesia). If loss of pulse occurs the diagnosis is thrombosis and there is no need for confirmatory arteriography. These patients should be returned as soon as possible to the operating theatre for thrombectomy, possible revision of the repair and completion arteriography. On the other hand, if pulses were never palpable after the repair and the patient is hypothermic, vasospasm may be present. In such cases, every effort should be made to rewarm the patient and improve perfusion to the extremity. If pulses do not return, either arteriography or exploration should be considered.

Arteriovenous fistula

Arteriovenous fistula after trauma occurs in 2–7% of cases. The most common causes are fragment, shrapnel or shotgun wounds. Numerous physiological changes occur as flow increases through the fistula – going from the high-pressure arterial system to the low-resistance venous system. Among these changes are increases in cardiac output, heart rate, central venous pressure and blood volume. Local changes in the region of the fistula include dilatation of the proximal artery and the distal vein, distal varicosities and extremity oedema. Most of these changes are reversible with correction of the fistula. Patients may present with signs of venous stasis disease, arterial insufficiency or heart failure. The physical findings are often suggestive of the diagnosis and include a palpable thrill and audible bruit or a continuous machinery-type murmur. Occlusion of the fistula may cause a decrease in the elevated pulse rate (Nicoladoni–Branham sign). Arteriography should always be performed to confirm the diagnosis, localize the lesion anatomically and determine the presence of any associated pathology. Less than 2% of fistulas will close spontaneously, so treatment is required. Treatment options include endovascular placement of covered stent grafts and open repair.

Pseudoaneurysm

The incidence of pseudoaneurysm following trauma is difficult to ascertain since it is often reported in association with arteriovenous fistulas. A pseudoaneurysm may cause symptoms by encroachment on local structures as it expands or it may present acutely with rupture, distal embolization or thrombosis. Small pseudoaneurysms (<3 cm) will often thrombose spontaneously, particularly when due to iatrogenic injury. In stable patients without local complications, a period of observation is reasonable. This may be augmented with percutaneous treatments such as ultrasound-guided compression, image-guided thrombin injection, or endovascular techniques such as coil or gel embolization in aneurysms with long narrow necks or occlusion of the mouth of the pseudoaneurysm with a covered stent graft.

If the pseudoaneurysm is large or persistent, arteriography should be obtained to define the anatomy and associated pathology, and followed by surgical repair. Although primary repair may be possible, most cases require resection with end-to-end anastomosis or interposition graft.

Infection

Infection of an arterial suture line is a disastrous complication, often leading to haemorrhage, thrombosis, distal ischaemia and eventual amputation. Factors predisposing to infection include closure of a contaminated wound, inadequate soft-tissue coverage of an arterial repair and inadequate debridement of a traumatized, contaminated vessel. This complication is best avoided by vigorous cleansing of contaminated wounds, use of appropriate antibiotics, aggressive debridement of devitalized tissues and coverage of arterial repairs with well-vascularized soft tissue.

Compartment syndrome

Extremity compartment syndrome is the result of soft-tissue trauma or ischaemia–reperfusion injury, which leads to swelling within a closed fascial space. This contained swelling results in a rise in tissue hydrostatic pressure to the point that blood flow is compromised. If untreated, compartment syndrome will result in myonecrosis and limb dysfunction. The most commonly involved areas are the anterior compartment in the lower leg and the volar compartment in the forearm. Since nerve tissue is more susceptible to ischaemia than is muscle, initial symptoms include paraesthesia and pain in the involved extremity. The muscle is usually tense and pain may be severe, especially with passive movement of the involved compartment. Pulses are usually palpable, even in advanced stages, and are not a reliable indicator of the severity of the syndrome. If one suspects development of a compartment syndrome, compartment pressure should be measured. This can be done by insertion of a plastic cannula or a wick catheter directly into the involved muscle or muscle group. Fasciotomy is indicated in those patients with a compartmental pressure >40 mmHg initially or a pressure of 30 mmHg that is sustained for longer than 4 hours. If compartmental pressures cannot be obtained, one must proceed based upon the clinical impression. Risk factors associated with compartment syndrome include crush injuries, concomitant arterial and venous injury, vascular injury requiring ligation, and ischaemic time ≥6 hours.

Treatment of compartment syndrome should not be delayed, as irreversible myonecrosis with resultant contracture will occur within 12 hours. Treatment of compartment syndrome of the calf consists of four-compartment fasciotomy; this can be performed through a standard two-incision approach or through a single lateral incision (Figure 14.57). Compartment syndrome of the thigh requires a single lateral incision to decompress the three compartments of the thigh. The upper and lower arm contain two and three compartments, respectively, and can be decompressed via a single anterolateral oblique incision running the length of the upper extremity, supplemented with an additional posterior incision in the forearm to access the posterior compartment and mobile wad. Care should be taken to open the carpal tunnel during forearm fasciotomy.

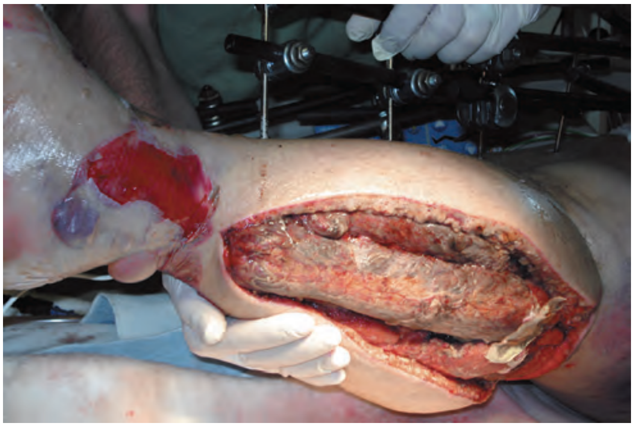

Figure 14.57 A four-compartment calf fasciotomy. The image depicts the lateral incision; note the bulging muscle beds. An external fixator spanning an associated severe tibia/fibula fracture can be seen in the background.

CHAPTER 15

Head injuries: Pathophysiology and management

SAM ELJAMEL

Introduction

The goals of head injury management are prevention of secondary brain damage and giving the best environment for brain recovery from primary brain injury. Secondary brain damage occurs from hypoxia, hypotension, intracranial haematomas or brain oedema. Prevention, early detection and treatment of the causes of secondary brain damage are the cornerstones of successful head injury management, rehabilitation and good outcome.

Epidemiology of head injuries

Head trauma is a major public health problem worldwide that causes death and disability in young people and makes considerable demands on health resources. Epidemiological studies are essential to initiate appropriate preventive measures and plan necessary services. However, routinely collected data are often unreliable sources of statistics for planning these services. International statistics for accidental deaths and road traffic accident (RTA) deaths do not categorize head injuries as a cause of death independent of other injuries. RTAs are the tenth cause of death throughout the world (2.1% of worldwide mortality) and the incidence of head injuries varies from country to country depending on road and health safeties, e.g. RTAs in the UK are the fourth cause of death (7.7%). International statistics list differences in accident rates between countries and over time. For example, RTA deaths are more frequent in France, Australia and the USA. Head injuries in the UK affect 6–10 per 100 000 of the population and 20% of patients with head injuries attending emergency departments in the UK are admitted to hospital, with 0.2% mortality. Head injuries are steadily decreasing each year in developed countries owing to increased road safety and safety at the work place, e.g. seat belts, better car designs, better roads, speed cameras, and implementation of health and safety regulations by employers. However, head injuries are still responsible for 25–33% of accidental deaths in hospitals and more than 60% of traumatic deaths. To reduce morbidity and mortality of head injuries, several guidelines and protocols have been developed and implemented worldwide. The National Institute for Clinical Excellence (NICE) and the Scottish Intercollegiate Guidelines Network are just a few to list in this chapter.

Head injuries vary from mild concussion to severe brain injury leading to severe disability or death. The successful management of a patient following head trauma requires understanding of the pathophysiological processes that occurred and processes that might occur after a head injury.

Pathophysiology of head injuries

Most head injuries are caused by blunt trauma. In adults such injuries are caused by RTAs, assaults and falls, whereas in children the commonest causes are falls and injuries from recreational activities such as biking, skating and skateboarding. A small but important cause of head trauma in children is non-accidental head injuries. The mechanisms of head trauma include those listed below.

Direct trauma

In blunt trauma, the energy of impact is spread over a large area of the skull, whereas penetrating injuries cause most of their damage by direct trauma.

Cerebral contusion

Contusion of the brain may occur at the site of the impact – 'coup injury' – but it is most common and most severe at the opposite site of the primary impact – 'contrecoup injury' (Figure 15.1). As the brain is stationary within the skull, if the back of the head is struck by an object causing local scalp laceration, bruising, skull fracture or focal brain contusion, the sudden acceleration and deceleration of the brain within the skull causes the opposite poles of the brain to collide against the inside ridges of the skull bone, leading to severe brain contusions, e.g. a sudden blow to the occiput may cause scalp laceration, cephalohaematoma, skull fracture or occipital contusion. In addition, owing to the brain acceleration and deceleration the temporal and frontal lobes slide against the sphenoid ridge and the floor of the anterior and middle cranial fossae, leading to severe contusion of the undersurface of the frontal and temporal lobes (Figure 15.1).

Diffuse axonal injury

Diffuse axonal injury is caused by sheering forces from acceleration and deceleration of the brain following blunt trauma. These rotation forces cause petechial haemorrhages, particularly in the upper brainstem, cerebellum and corpus callosum, that are seen as retraction balls and microglial scars early on, and widespread myelin degeneration a few weeks after the injury. CT scan demonstrates multiple petechial haemorrhages (Figure 15.2).

Cerebral oedema

Cerebral oedema occurs as a result of vasomotor failure leading to brain swelling around the cerebral contusions or as a result of cytotoxic effects throughout the brain. Brain oedema can cause raised intracranial pressure (ICP). Raised ICP can lead to brain herniation from one side of the supratentorial compartment to another (subfalcine), or the medial temporal lobe down the tentorial hiatus compressing the ipsilateral third nerve (true localizing sign) and pushing the brainstem against the contralateral edge of the tentorium, leading to ipsilateral hemiparesis (false localizing sign). This type of transtentorial descent of the temporal lobe is called transtentorial herniation. The final stage of raised ICP causes descent of the cerebellar tonsils in the foramen magnum, leading to brainstem compression and respiratory arrest. At postmortem the impression on the cerebellar tonsils caused by transforaminal magnum herniation is described as coning, and the impression of transtentorial brain herniation on the contralateral brainstem is called a Kernohan notch (Figure 15.3).

Traumatic intracranial haematomas

Traumatic intracranial haematomas include extradural, subdural, subarachnoid and intracerebral haemorrhages. Traumatic intracranial haematomas can cause similar brain shifts to those described under cerebral oedema.

Extradural haematoma

Extradural haematoma is blood clot between the skull bone and the dura. The classic history of an extradural haematoma is that a patient was concussed with brief loss of consciousness followed by a lucid interval that can last minutes to hours during which the patient appears normal, followed by sudden deterioration in the level of consciousness. The classic history occurs in <27% of extradural haematomas. In 85% of patients, the source of bleeding is the middle meningeal artery; in young patients (<30

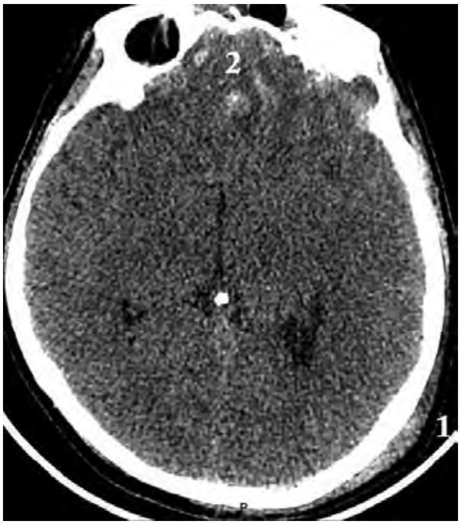

Figure 15.1 Axial CT of the head demonstrating small cephalohaematoma (1) at the impact site and contrecoup contusions (2) at the under-surface of both frontal and left temporal lobes.

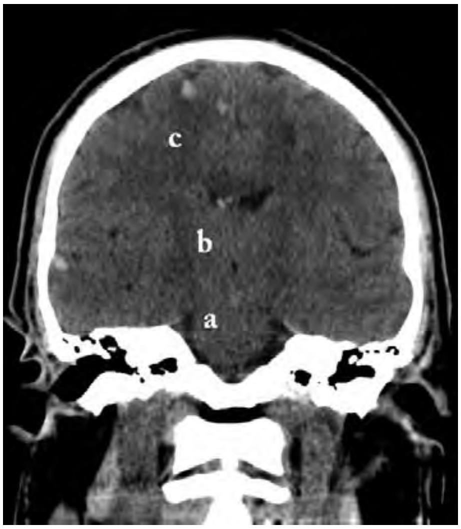

Figure 15.2 Coronal CT of the head demonstrating petechial haemorrhages in the midbrain (a), corpus callosum (b) and right hemisphere (c).

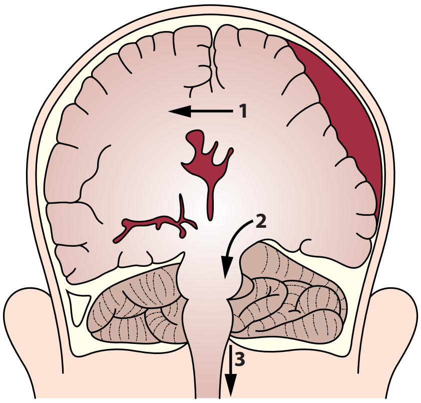

Figure 15.3 The coronal section of the head demonstrating an extradural haematoma (4) compressing the left hemisphere, causing subfalcine brain hernia (1), transtentorial brain hernia (2) and transforaminal magnum tonsillar hernia (3).

years old) 40% of extradural haematomas were associated with fracture of the cranial vault, whereas in those >30 years old skull fracture was found in almost all patients. It is associated with acute subdural haematoma in 20% of patients and the mortality rate from extradural haematoma was 20–55%; however, with new head injury guidelines and early treatment the mortality from extradural haematoma has been reduced to 5–10%.

On CT scan extradural haematoma appears as a high-density collection beneath the skull bone, taking the shape of a bilenticular (biconvex) lens (Figure 15.4). Symptomatic extradural haematoma requires removal via craniotomy.

Subdural haematoma

Subdural haematoma is a collection of blood in the subdural space and used to be classified according to the age of the haematoma into acute if discovered within 72 hours; subacute if discovered within 3 days to 3 weeks; and chronic if the haematoma was >3 weeks old. However, most patients do not remember the onset of head injury and therefore this classification became obsolete after CT and MRI scans were introduced. The most relevant classification clinically is to classify these lesions as follows.

Hyperdense subdural haematoma

This occurs when the clot is higher density than the brain on CT and takes the shape of the brain, as demonstrated in Figure 15.5. If the lesion is symptomatic, its removal requires craniotomy. If it is >1 cm thick it generally needs to be removed. Its volume can be measured by the formula: (thickness × height × length)/2. If the volume is >80 mL, removal is also recommended. Other factors that influence the decision-making process include mass effect in the form of midline shift and the Glasgow Coma Scale (GCS) score. If a hyperdense subdural haematoma is removed within 4 hours of injury, survival can be expected in up to 70% of patients compared with only 10% if the surgical evacuation is delayed >4 hours or if the patient's pupils are unreactive. More than 79% of patients who had a hyperdense subdural haematoma that was evacuated surgically develop raised ICP; therefore, monitoring of ICP is desirable in these patients after surgery.

Mixed density subdural haematoma

This occurs when the density of the clot is a mixture of high density and isodensity in appearance. This is usually treated in the same fashion as hyperdense subdural haematoma.

Isodense subdural haematoma

This is when the density of subdural haematoma is the same as that of the brain. This can be a challenging diagnosis and keeping a high index of suspicion is essential to detect these lesions on CT. They can be detected by observing indirect signs such as midline shift, effacement of the lateral ventricle or effacement of the ipsilateral sulci. Intravenous contrast injection will often show enhancement of the subdural membrane and makes visibility easier. These lesions can be evacuated through two burr holes.

Hypodense subdural haematoma

This is when the collection has a lower density than the brain. This can be drained via one or two burr holes. If the brain surface did not come to the skull surface during drainage, it is advisable to leave a subdural drain *in situ* to drain any residual clot and avoid tension pneumocephalus. The latter can arise if a hypodense subdural haematoma is drained while the patient's head is elevated and the cavity is filled with air at room temperature that will heat up during the next few hours. The air then will expand according to Boyle's law, leading to tension pneumocephalus. Routine scans are not required after drainage of a hypodense subdural haematoma, as removal of 20% of the fluid normalizes the ICP and 78% of patients would have residual collection by day 10 and 15% by day 40 after drainage. The important step to prevent recurrence of symptoms of hypodense subdural haematoma is to leave the dura within the burr hole open and make a small pocket in the subgaleal space for any residual collection to be absorbed.

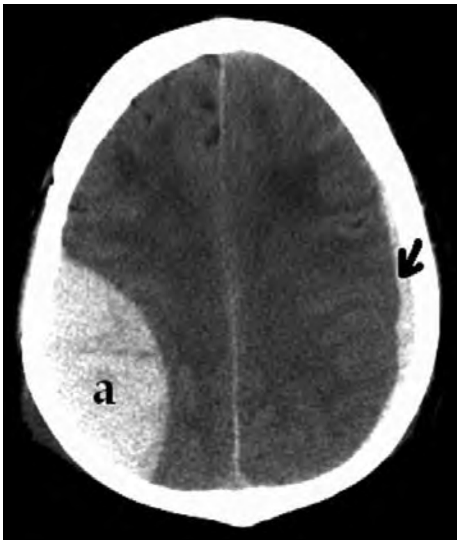

Figure 15.4 Axial CT scan demonstrating a right extradural haematoma (a) and a contralateral acute subdural haematoma (arrow).

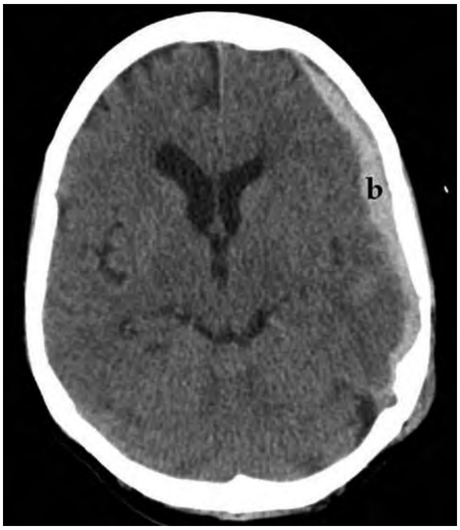

Figure 15.5 Axial CT scan demonstrating hyperdense subdural haematoma (b). The shape of the collection is convex to the outside towards the skull surface and concave towards the brain surface. The hyperdense subdural haematoma caused subfalcine brain herniation.

More than three-quarters of hypodense subdural haematomas are treated by a single burr hole (Figure 15.6).

Traumatic intracerebral haematoma

Traumatic intracerebral haematoma often occurs in addition to acute subdural haematoma or contusion. The difference between cerebral contusion and traumatic intracerebral haematoma is arbitrary. Both are characterized by hyperdense parenchymal lesions on CT scan. Contusions often reach the cerebral cortex and they appear bigger than their actual mass effect, whereas traumatic intracerebral haematomas appear more distinct and their size and mass effect appear proportionate to a midline shift (Figure 15.7).

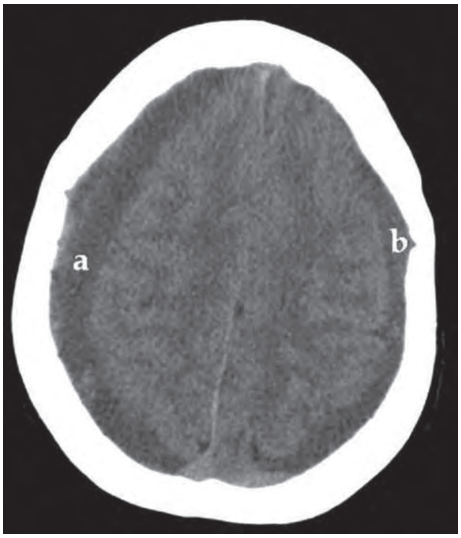

Figure 15.6 Axial CT of the head demonstrating bilateral hypodense subdural collections (a,b). The right is bigger than the left and both are lower density than the brain. These are the CT characteristics of chronic subdural haematoma (hypodense subdural haematoma).

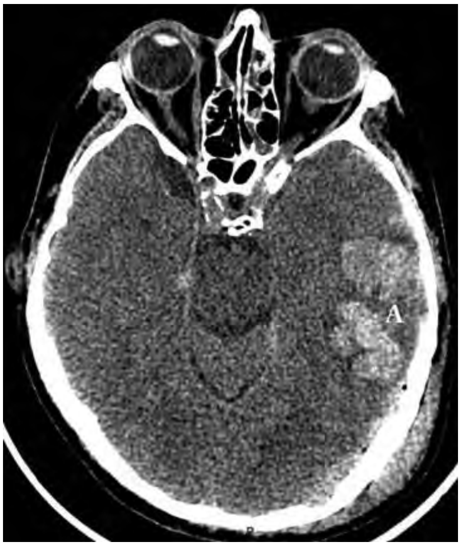

Figure 15.7 Axial CT scan of the head demonstrating a large hyperdense parenchymal lesion in the left temporal lobe (A), a traumatic intracerebral haematoma.

Traumatic subarachnoid haemorrhage

Traumatic subarachnoid haemorrhage is blood in the subarachnoid space following trauma, and frequently occurs in moderate or severe traumatic brain injury and is related to worse outcome at time of discharge. The presence of traumatic subarachnoid haemorrhage appears to be associated with worse vocational outcome in survivors of moderate or severe traumatic brain injury. As such, the presence of traumatic subarachnoid haemorrhage appears to have predictive value with respect to outcome.

Hydrocephalus

Hydrocephalus is an uncommon cause of raised ICP in head injuries in the acute stage. It can happen when a blood clot obstructs the fourth ventricle or the cerebral aqueduct. Hydrocephalus may also follow traumatic subarachnoid haemorrhage because traumatic subarachnoid haemorrhage blocks the cerebrospinal fluid (CSF) absorption sites. More often unilateral hydrocephalus follows subfalcine brain hernia owing to obstruction of the third ventricle. When contralateral hydrocephalus occurs as a result of raised ICP, the raised ICP becomes worse and brain hernia ensues (Figure 15.8).

Concussion

Concussion is transient loss of consciousness following non-penetrating closed head injury without gross or microscopic brain damage. Concussion is divided into three grades as follows:

Grade 1 No loss of consciousness; confusion without amnesia.
Grade 2 No loss of consciousness; confusion with amnesia.
Grade 3 Loss of consciousness.

Other injuries associated with brain injuries

In addition to concussion, cerebral contusion, intracranial haematomas and cerebral oedema, the following injuries may

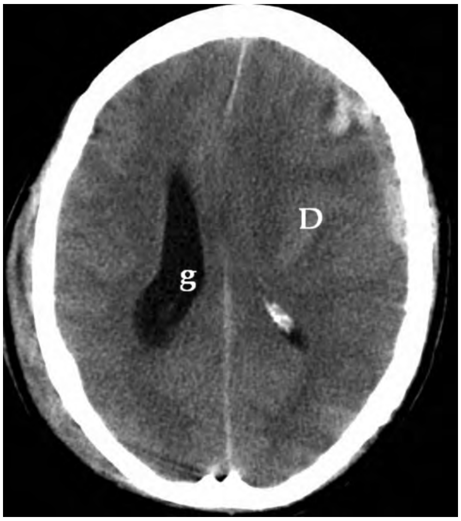

Figure 15.8 Axial CT scan of the head demonstrating very extensive brain swelling (D), causing severe subfalcine brain hernia and contralateral hydrocephalus (g).

occur: scalp lacerations, scalp haematomas, skull fractures, cranial nerve injuries, vascular injuries and spinal injuries. These injuries need to be considered in patients with head trauma.

Scalp lacerations

The extent of scalp lacerations does not indicate the severity of brain injury. However, they need to be treated promptly to stop blood loss and to make sure that there is no associated depressed skull fracture. The scalp has five layers: **S** for skin; **C** for connective tissue where the blood vessels and nerves are located, hence the blood vessels are kept open and lead to excessive blood loss unless the bleeding is stopped by compression; **A** for aponeurosis that keeps the scalp stretched; the aponeurosis must be closed when suturing scalp wounds to prevent stretching of the scar; **L** for loose areolar tissue; and **P** is for pericranium. Scalp lacerations must be cleansed and closed, making sure the aponeurosis is approximated to prevent the edges from retraction and widening the scar. Local anaesthesia, to be effective, must be injected in the connective tissue layer above the aponeurosis.

Cephalohaematomas

Haematomas of the scalp are not uncommon and do not need specific treatment. However, a large cephalohaematoma in an infant may represent significant blood loss. Cephalohaematomas around the eyes are often associated with basilar skull fracture of the anterior cranial fossa and CSF leaks (panda eyes or racoon eyes). Cephalohaematoma around the mastoid is often referred to as Battle's sign and is associated with basilar skull fracture of the petrous bone and otorrhoea.

Skull fracture

Injuries to the head may cause skull fractures. These are classified into simple linear fracture of the skull vault (Figure 15.9); depressed skull fracture if bone fragments were depressed deeper than the inner table of the skull; or compound skull fracture when the skin or the mucosa overlying the skull fracture is deficient, e.g. via scalp laceration or basal skull fracture crossing the paranasal sinuses, the middle ear or the mastoid. Basilar and simple linear skull fractures do not require specific treatment but they could indicate serious underlying brain injury, e.g. basilar skull fractures could be associated with CSF leaks and cranial nerve injuries, i.e. olfactory, optic, vestibulocochlear and facial nerves. Compound skull fractures by definition are contaminated and require wound lavage, primary closure and antibiotic treatment for 7 days according to local antibiotic policy. Depressed skull fractures on the other hand may need treatment if they are compound, depressed more than the thickness of the skull or cosmetically unacceptable except when they overly venous sinuses.

Dural fistulas and cerebrospinal fluid leaks

CSF rhinorrhoea or otorrhoea indicates that there has been a breach of the dura mater. This often occurs in association with skull base fractures involving the anterior cranial fossa, sphenoid or temporal bones. It is often difficult to be sure that blood-stained nasal or ear discharge contains CSF. Glucose and protein estimations in the discharge are often positive, even in the absence of CSF. The best test to confirm the presence of CSF is to measure β_2-transferrin (β_2T). β_2T is present only in the CSF and aqueous humour of the eye. So, if there is any doubt, fluid should be collected and sent for β_2T measurement. The reason why CSF leaks are treated seriously is the high risk of recurrent meningitis in these patients, often due to *Streptococcus pneumoniae*, which still carries high mortality. Prophylactic antibiotics are not indicated here because they merely change the type of organism rather than prevent meningitis. CSF leaks can be diagnosed and localized using fine-slice CT to demonstrate the bony defect and MRI scan to demonstrate CSF fistula (Figure 15.10) or brain hernia through the fistula. Persistent CSF leaks and those complicated by meningitis require dural repair.

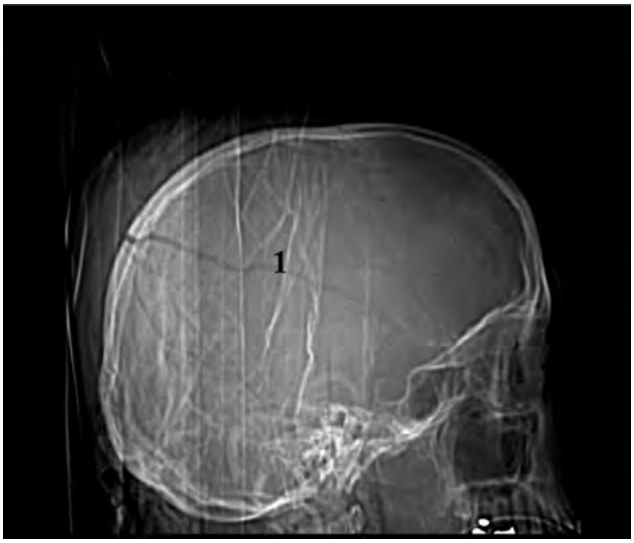

Figure 15.9 Sagittal scanogram demonstrating linear skull fracture (1) in the parietotemporal bone.

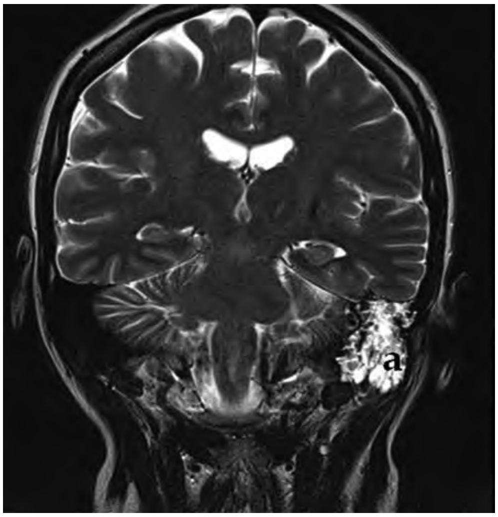

Figure 15.10 Coronal T_2 weighted magnetic resonance image demonstrating a cerebrospinal fluid (CSF) fistula in the left petrous temporal bone with CSF filling the left mastoid air cells (a).

Cranial nerve injuries

Anterior skull basal fractures can be associated with injuries of the first (olfactory) and second (optic) cranial nerves. While the first cranial nerve can be injured and lead to anosmia after minor head injuries, the second cranial nerve is more resistant to injury. Optic nerve injury occurs in about 5% of moderate to severe head injuries. The fourth cranial nerve is susceptible to injury leading to diplopia because of its slender long intracranial course. The sixth nerve is also susceptible to injury because of its long intracranial course. Sixth nerve palsy in head injuries is a false localizing sign. The seventh nerve is susceptible to injury because of its long bony course in the facial canal leading to facial weakness. Facial palsy can occur early owing to direct nerve injury, or late owing to oedema and swelling of the nerve in the facial canal. Injury to the cochlear nerve leads to deafness.

Other injuries

Head injuries do not occur in isolation and it is paramount to look for and treat associated spinal and systemic injuries such as chest, vascular, skeletal and abdominal injuries. A high index of suspicion is essential to discover and treat these injuries. Doctors involved in early management of victims of trauma need to avoid the temptation of labelling a patient as having an isolated head injury unless other injuries are ruled out beyond doubt.

Initial management of head injuries

Initial management of head injuries involves adequate clinical assessment of the head injuries and any associated injuries to make the diagnosis of underlying pathological processes, provide timely appropriate treatment and detect any neurological deterioration. The initial assessment should include the assessment of airways, breathing and circulation, followed by a primary survey looking for life-threatening conditions that require treatment on the spot; these include haemothorax, haemoperitoneum, cardiac tamponade, tension pneumothorax and intracranial haematomas. This must be followed by a complete history and physical examination, paying special attention to consciousness, pupils, limbs and cranial nerves, detecting in the process any lacerations, cephalohaematomas, panda eyes, Battle's sign, CSF leakage, haemotympanum, Le Fort or orbital rim fractures, proptosis or carotid bruit. Once the patient becomes stable he or she should be transferred immediately to an appropriate emergency department. It is essential to obtain the initial neurological state of the patient after the injury from witnesses and rescue service personnel to detect neurological deterioration.

Neurological assessment

Neurological assessment must include assessing the level of consciousness, speech and language, memory, cranial nerve examination, motor and sensory examination, and co-ordination. The time of each neurological assessment must be recorded to monitor neurological progress. Neurological observation must be recorded on the observation chart (Figure 15.11) every 15 minutes four times; if the patient is stable or improving, the observation is continued half hourly four times; if the patient is stable or improving, the observation is continued hourly four times; if the patient is stable or improving, the observation is continued 2 hourly four times; if the patient is stable or improving, the observation is continued 4 hourly for the rest of inhospital stay. Any neurological deterioration should be investigated to detect and treat the underlying pathological processes.

Assessment of level of consciousness

Level of consciousness is assessed at the bedside by the GCS. The GCS consists of observing the patient's responses to verbal or painful stimulation. Three responses are observed: best eye-opening response, best verbal response and best motor response.

Best eye-opening response

There are four possible best eye-opening responses in any patient: 1, no eye opening to any stimulus; 2, eye opening to painful stimuli; 3, eye opening to verbal stimuli; and 4, eye opening spontaneously (Table 15.1). One drawback of the best eye-opening response assessment is that it cannot be assessed in patients who have bilateral complete third nerve palsies or bilateral orbital haematomas. In these patients, the best eye-opening response should be recorded as 'C' for closed eyes rather than '1' for no eye-opening response. In patients who have either of these abnormalities in one eye only, the response of the better eye should be recorded for the purpose of level of consciousness assessment.

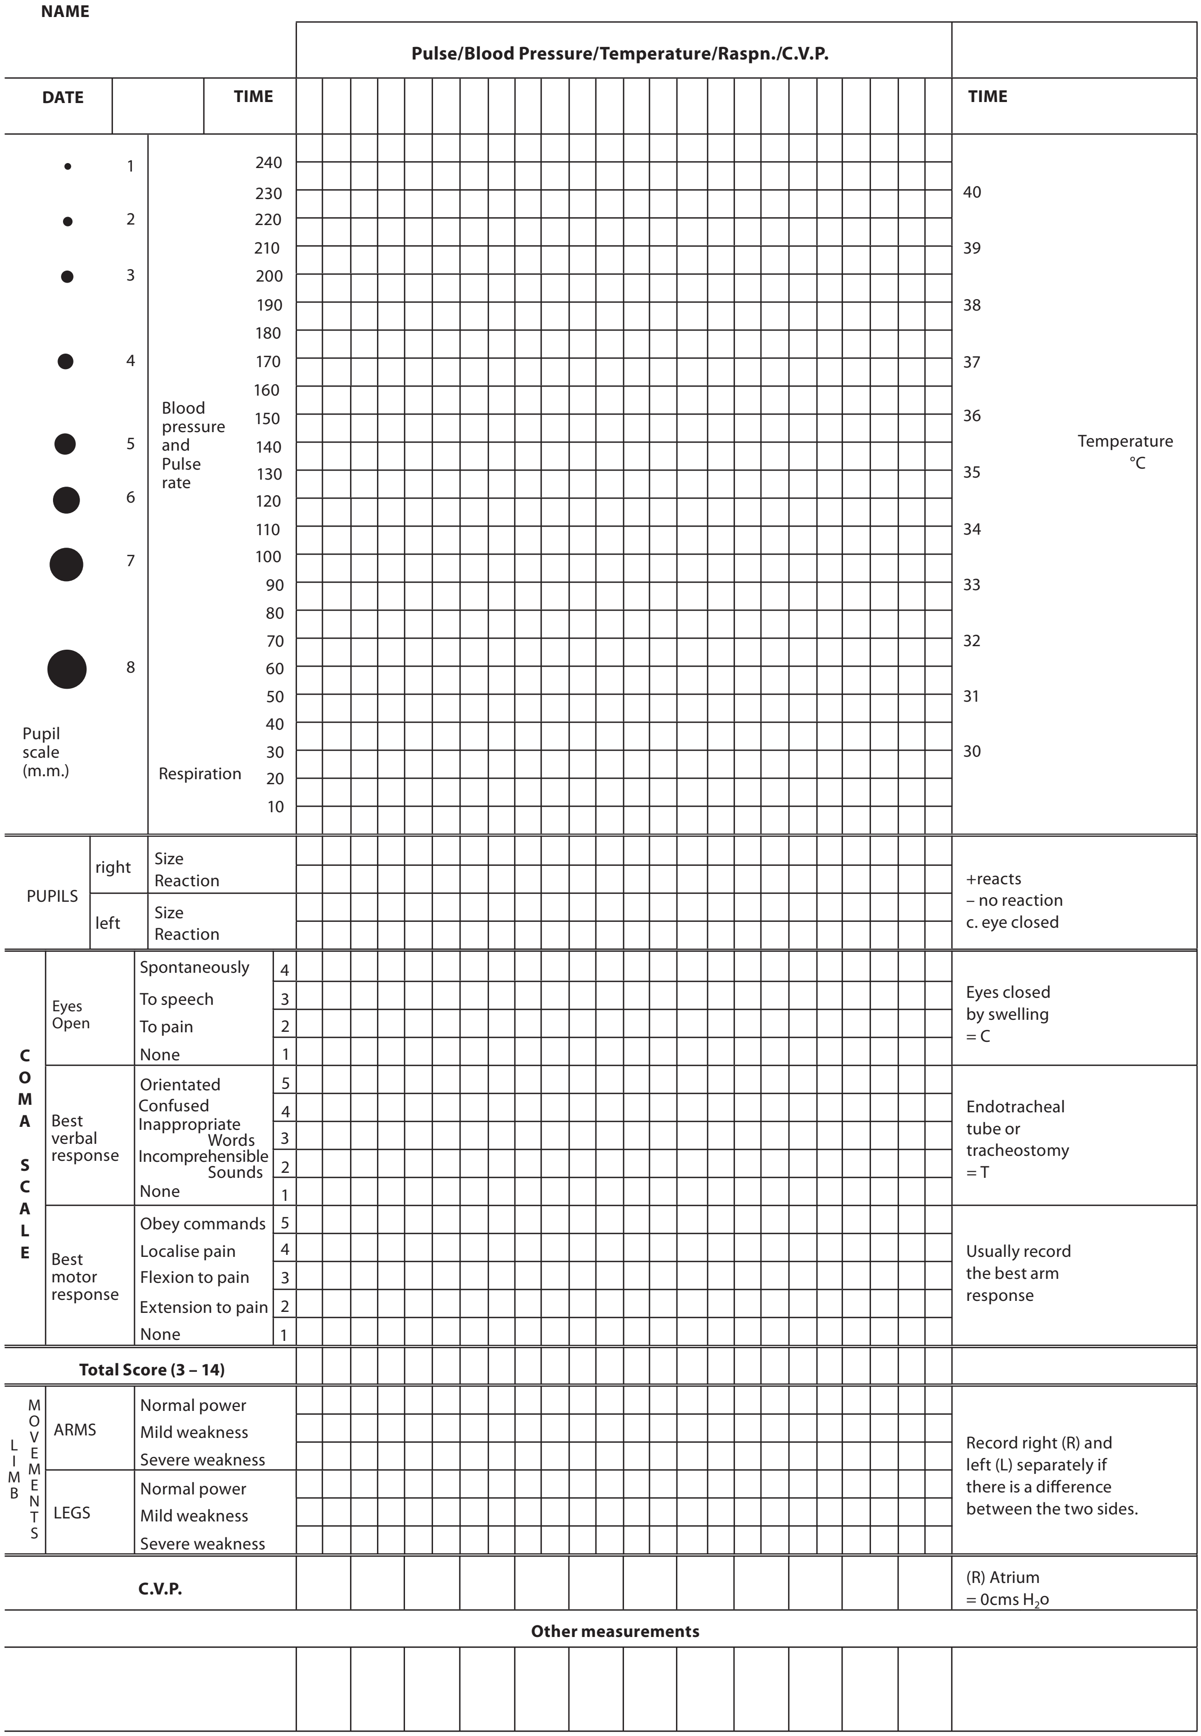
Best verbal response

There are five possible responses under best verbal response: 1, no verbal response to any stimulus; 2, incomprehensible sounds; 3, uttering words; 4, confused; and 5, oriented in time, place and person. It would not be possible to assess best verbal response in patients who are dysphasic and it should be recorded as 'D' for dysphasia rather than '1' for no verbal response. Similarly, patients who are artificially ventilated via endotracheal tube or tracheotomy cannot be assessed for best verbal response and it should be recorded as 'T' for tube rather than '1' for no verbal response (Table 15.1).

Best motor response

There are six possible responses within this category: 1, no motor response to any stimulus; 2, extension to pain; 3, abnormal flexion to pain; 4, flexion to pain; 5, localizing pain; and 6, obeying simple commands (Table 15.1). It would not be easy to assess best motor response in patients with spinal cord injury leading to tetraplegia, although, if they can obey simple commands, best motor response can be assessed by observing motor responses in the face area, e.g. closing the eyes or showing the tongue. If the best motor response cannot be assessed because of paralysis of the limbs due to injury or because of sedative or muscle relaxant drugs, the best motor response should be recorded as 'P' for paralysis rather than '1' for no motor response.

Coma is defined on the GCS as any patient who fulfils all of the following three criteria: 1, no eye-opening response to



NAME

Table 15.1 The Glasgow Coma Scale (GCS)

Score	Best eye-opening response	Best verbal response	Best motor response	Definition
1	None	None	None	Any patient within these shaded areas is in coma
2	To speech	Sounds	Extension to pain	
3	To pain	Words	Abnormal flexion to pain	
4	Spontaneous	Confused	Flexion to pain	
5		Orientated	Localizing pain	
6			Obeys simple commands	Not in coma

any stimulus (score of 1); 2, no comprehensible sound (score of 1 or 2); and 3, not obeying simple commands (score of 1–5). Therefore, coma is a GCS score of ≤8 provided that the patient does not obey commands, does not utter any words and does not open his or her eyes to any stimulus.

Although each response of the GCS carries a number against it, the aggregated numbers should not be used to describe patients as that leads to avoidable misunderstandings and misinterpretations of the numbers. For example, a GCS of 8 could mean a patient with a best eye-opening response of 1, a best verbal response of 2 and a best motor response of 5 (patient is comatose) or it could mean a best eye-opening response of 2, a best verbal response of 3 and a best motor response of 3 (the patient is not comatose). It would be far better to use the actual description of the patient's response in each category rather than the numbers. Aggregate numbers are useful in determining trends of progress and to perform statistical analysis in research and audit studies.

Categorization of head injuries

Once the initial assessment of a head-injured patient is performed, the risk of raised ICP and brain injury can be categorized as follows:

- *Low-risk head injury*: asymptomatic – there was no loss of consciousness, the patient is fully conscious and oriented and there is no clinical or radiological evidence of skull fracture. The risk of significant intracranial pathology in this group is <9/10 000. The skull radiograph is normal in 99.6% and patients can be discharged home provided there is a responsible adult who can observe the patient and has been given written head injury advice.
- *Moderate-risk head injury*: if there is a history of loss of consciousness, progressive headache or vomiting, post-traumatic seizures, post-traumatic amnesia, an unreliable history or there are signs of basilar fracture or penetrating facial injury. These patients can only be discharged home if they fulfil all the following criteria: normal CT of the brain, initial GCS score >13, discharge GCS score of 15, there is a responsible adult who can look after them and bring them back to hospital if necessary, there are no complicating factors such as non-accidental injury or domestic violence and the patient is given written head injury advice.
- *High-risk head injury*: any patients with a reduced level of consciousness, neurological deterioration, focal neurological deficit, penetrating head injury or depressed skull fracture are a high risk for brain injury.

Management of head injuries

Patients with a GCS score >13 should be admitted to hospital with the following instructions:

1. Activity level: bed rest with head elevated by 30–45°.
2. Neurological observation every 2 hours; if concerned, hourly.
3. Feeding: nil by mouth until fully alert; advance as tolerated.
4. Analgesia: simple analgesics such as tramadol or codeine.
5. Antiemetics: as required.

Patients with a GCS score of 9–13 should also be admitted to hospital with the following instructions:

1. Activity level: bed rest with head elevated by 30–45°.
2. Neurological observations every hour; consider high-dependency unit.
3. Feeding: nil by mouth until fully alert; advance as tolerated.
4. Analgesia: simple analgesics such as tramadol or codeine.
5. Antiemetics: as required.
6. Fluids i.v.: 100 mL/h normal saline with 20 mmol/L KCl.
7. If not awake by 12 hours, repeat the CT brain scan.

Patients with a GCS score <9 should be transferred to a dedicated neurosurgical facility. Prior to transfer, consider the following problems:

- If there is any concern about hypoxia or airway protection during interhospital transfer, intubate and artificially ventilate the patient.
- If the patient has had any seizures administer anticonvulsants.
- If there are any concerns about neck injuries, immobilize the spine.
- If there are any concerns about raised ICP, administer mannitol 2 g/kg of 20% and keep the $P\mathrm{aCO}_2$ between 3.5 and 4 kPa during transfer.

When should a head-injured patient be intubated and artificially ventilated?

This should always be performed for the following reasons:

- to protect the airway if the GCS score is <8 or there is a maxillofacial injury
- if there is evidence of raised ICP, e.g. pupillary dilatation, asymmetric pupillary reaction, decerebrate/decorticate posture or progressive neurological deterioration
- to carry out safe interhospital transfer
- to properly assess a combative or agitated patient by CT.

When should a patient be referred to hospital after a head injury?

When referring a patient to a hospital emergency department, a full history and full neurological examination are required. The history should include the circumstances and timing of the injury, whether the patient lost consciousness, what was the last thing the patient remembers before the injury and what is the first thing he or she remembers after the injury. Amnesia prior to the injury is called pretraumatic or retrograde amnesia. Amnesia after head injury is called post-traumatic or antegrade amnesia. A history of persistent headaches; nausea and vomiting; weakness; sensory disturbance; loss of vision, hearing, sense of smell or balance; diplopia; seizures; or speech impairment is important to note. Clinical examination should include assessment of the level of consciousness, short-term memory, speech and language, vision, hearing, motor power, sensory function and co-ordination. It is also important to note any external bruises on the face and the scalp. Bruising around the mastoid is called Battle's sign and indicates a temporal skull base fracture and may be associated with blood in the middle ear, conductive hearing loss, facial palsy or otorrhoea (CSF leak through the ear) or even paradoxical rhinorrhoea (CSF leak through the nose; this occurs when the tympanic membrane is intact and CSF flows through the fracture into the middle ear, via the Eustachian tube into the nostril). Bilateral black eyes or panda eyes indicate anterior cranial fossa basal skull fracture and may be associated with CSF rhinorrhoea. Scalp lacerations may overlie a depressed skull fracture that needs wound cleaning and fracture elevation. The level of consciousness is assessed by the GCS score (Table 15.1).

A patient who has a head injury should be referred to an emergency department using an emergency ambulance service if:

1. The person presents with an altered level of consciousness. Any person who is not fully conscious at the time of examination after head injury must be referred to the emergency department as an emergency.
2. The patient has had a seizure since the head injury.
3. There is evidence of a basal skull fracture, such as CSF leak from the nose or ear; a black eye with no damage around the eyes (panda eyes); bleeding from one or both ears; haemotympanum (blood behind the ear drum); or bruising around both or one mastoid (Battle's sign).
4. There is evidence of focal neurological deficit, such as double vision, speech impairment, problems with balance, loss of muscle power; or sensory disturbance of the extremities.
5. The patient has a deteriorating level of consciousness.
6. There are associated other injuries such as chest or abdominal trauma; limb or pelvis trauma; or there is significant vascular injury.
7. If the patient does not have access to adequate transportation to hospital.
8. The patient has amnesia for the incident or subsequent events.
9. The patient has any neurological symptoms, e.g. severe and persistent headache, nausea and vomiting, irritability or altered behaviour, seizure, speech impairment, limb weakness or double vision.
10. The mechanism of injury suggests: high-energy injury (e.g. road traffic accident, fall from height), possible penetrating brain injury, possible non-accidental injury (in a child) or continuing uncertainty about the diagnosis after first assessment.
11. The patient has a medical comorbidity, e.g. anticoagulant treatment (warfarin), antiplatelet therapy (aspirin, clopidogrel, dipyridamole), drug abuse or alcohol abuse.
12. There are adverse social factors, e.g. no one able to supervise the patient at home.

When can a person be sent home after minor head injury?

Patients can be sent home if the clinical history and examination indicate a low risk of brain injury and the hospital referral criteria were not met, providing the patient has appropriate support structures and competent supervision at home. Patients must be given verbal and written head injury advice.

When are skull radiographs indicated after head injury?

Skull radiographs should be performed if any of the following apply and if CT is not being performed:

- if the patient is fully conscious and the mechanism of injury has not been trivial, or
- consciousness has been lost, or
- the patient has amnesia or has vomited, or
- the scalp has a full thickness laceration or a boggy haematoma, or
- the history is inadequate, or
- if the level of consciousness is impaired.

When does a CT scan of the head become indicated?

CT scanning should be done in a patient who has any of the following features:

- impaired consciousness
- a deteriorating level of consciousness or progressive focal neurological signs
- confusion or drowsiness followed by failure to improve within at most 4 hours of clinical observation
- radiological or clinical evidence of a fracture, whatever the level of consciousness
- new focal neurological signs that are not getting worse
- full consciousness with no fracture but had other features, e.g.
  - severe and persistent headache
  - nausea and vomiting
  - irritability or altered behaviour
  - development of a seizure.

When do radiographs of the cervical spine become essential?

CT scanning of the cervical spine down to C2 should be undertaken routinely, at the time of head scanning. Imaging of the rest of the cervical spine, including the cervicothoracic junction, should be carried out in the following circumstances:

- fully conscious patient if clinical symptoms or signs or the mechanism of injury indicate the possibility of injury to the spine
- persisting impaired consciousness
- unconscious patient, not localizing pain.

Which patients should be discussed with a neurosurgeon after head injury?

A head-injured patient should be discussed with a neurosurgeon if one or more of the following features existed:

- a CT scan in a general hospital showed a recent intracranial lesion
- the criteria for CT scanning are fulfilled but CT cannot be done within an appropriate time frame locally
- irrespective of the result of any CT scan, if the patient fulfils any of the following criteria:
  - persisting coma after initial resuscitation
  - persisting confusion for more than 4 hours
  - deterioration in the level of consciousness after admission (a sustained drop of one point on the motor or verbal subscales, or two points on the eye-opening subscale of the GCS)
  - progressive focal neurological signs
  - seizure without full recovery
  - compound depressed skull fracture
  - definite or suspected penetrating injury
  - CSF leak or other sign of a basal skull fracture.

Raised intracranial pressure and intracranial pressure monitoring

Raised ICP in head injuries is caused by cerebral oedema or mass lesions such cerebral contusion, intracerebral haematoma, subdural haematoma or extradural haematoma. Treatment of raised ICP requires the treatment of the underlying cause. Significant intracranial haematomas are evacuated and residual raised ICP should be monitored closely to see the response to therapy. The following are some of the indications for ICP monitoring:

- severe head injury: GCS score <8.
- following evacuation of a mass lesion
- ventilated patients with an abnormal CT
- multiple injuries.

ICP monitoring should be avoided in awake patients and in the presence of coagulopathy. ICP monitoring is not without risks: the risk of infection is approximately 1–2%, the risk of bleeding is 2.8% and the risk of malfunction is 6–40%. ICP monitoring can be performed by inserting a transducer in the subdural space, ventricle or brain parenchyma, e.g. a Camino bolt, Codman transducer or Spielberg transducer. Most neurosurgical units treat any ICP ≥25 mmHg to maintain cerebral perfusion pressure of >70 mmHg. Cerebral perfusion pressure is measured by subtracting the mean ICP from the mean arterial blood pressure. Causes of raised ICP include reduced venous return, e.g. severe neck flexion or head-down position, venous thrombosis, sustained seizures or intracranial pathology, such as extradural haematoma, subdural haematoma, cerebral oedema, diffuse axonal injury or ischaemia.

What is the relationship between intracranial pressure and cerebral perfusion pressure?

The cerebral perfusion pressure remains constant when the mean arterial blood pressure is 60–160 mmHg in normal individuals; however, in head-injured patients and those with subarachnoid haemorrhage autoregulation is lost and the cerebral perfusion pressure is directly related to mean arterial blood pressure (Figure 15.12).

How to treat raised intracranial pressure

Raised intracranial pressure should be treated initially with simple measures such as adjusting the head and neck posture, checking the ventilator settings and controlling any seizures or pyrexia.

If simple head and neck position changes do not normalize ICP, the second-tier manoeuvres are instituted: increasing mean arterial blood pressure, for example, leads to increased cerebral perfusion pressure, and reducing body temperature to 32–35°C reduces cerebral metabolism and reduces ICP in the process; however, the patient should be monitored for reduced cardiac output, pancreatitis and renal impairment.

Hyperventilation and reducing $P\text{aCO}_2$ to 3 kPa in the short term will lead to vasoconstriction that reduces intracranial blood volume and reduced ICP. However, if hyperventilation is maintained for more than a few days, cerebral ischaemia will occur. Surgical decompression of the skull vault reduces ICP; however, the key is to include subtemporal decompression for it to work.

Finally, induced barbiturate coma reduces cerebral metabolism and the ICP; however, this can lead to hypotension.

Mannitol is used to reduce ICP and impart cerebral protection; the dose is 2 g/kg of 20% i.v. over 20 minutes; thereafter, the smallest effective dose can be used. Mannitol is used before CT if there is clinical evidence of raised ICP or mass lesion, or in sudden neurological deterioration. Mannitol is also used to assess salvageability in patients with severe head injuries with unreactive pupils. After CT, mannitol is used in patients with mass lesions with raised ICP just before and during surgery. Mannitol would not work during hypotension and raised plasma osmolality (>300 mosmol/L).

The role of exploratory burr holes is now questionable because of the wider availability of CT scan and safe, speedy interhospital transfer of patients. However, rarely this may have to be used when a patient suddenly deteriorates with pupillary dilatation after a lucid interval when it is not practical or possible for the patient to undergo CT. A burr hole can then be made in

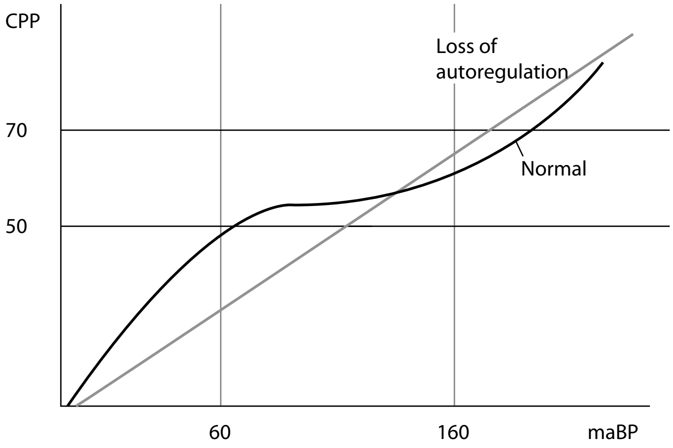

Figure 15.12 The relationship between cerebral perfusion pressure (CPP) and mean arterial blood pressure (maBP) in normal and abnormal autoregulation.

the temporal area 2 cm in front and above the tragus on the side of the first pupillary dilatation; then a frontal burr hole should be made just behind the hairline at least two finger breadths from the midline; finally, a parietal burr hole should be formed over the parietal eminence.

Advice for patients after head injury on discharge home

Patients should be instructed that if they are affected by any of the following after leaving the hospital, they should return to their nearest hospital emergency department as soon as possible:

- unconsciousness, or lack of full consciousness (e.g. problems keeping their eyes open)
- any confusion (not knowing where they are, getting things muddled up)
- any drowsiness (feeling sleepy) that goes on for longer than 1 hour when they would normally be wide awake
- any problems understanding or speaking
- any loss of balance or problems walking
- any weakness in one or both arms or legs
- any problems with their eyesight
- a very painful headache that will not go away
- any vomiting
- any fits (collapsing or passing out suddenly)
- clear fluid coming out of their ear or nose
- bleeding from one or both ears
- new deafness in one or both ears.

Things patients should not worry about

It is important that patients understand that, over the next few days, they may experience one or more symptoms, which usually disappear in the following 2 weeks. These symptoms include a mild headache, feeling sick (without vomiting), dizziness, irritability or bad temper, problems concentrating or problems with their short-term memory, tiredness, lack of appetite or problems sleeping. If patients are very concerned about any of these symptoms in the first few days after discharge, they should go and see their own doctor.

Finally, patients should be told that, if these problems do not go away after 2 weeks, they should go and see their doctor anyway. Ideally, patients should also seek a doctor's opinion about their ability to drive a car or a motorbike.

Specialist general surgery

CHAPTER 16

Disorders of the skin and soft tissues

SIR ALFRED CUSCHIERI

Anatomy and function of the skin

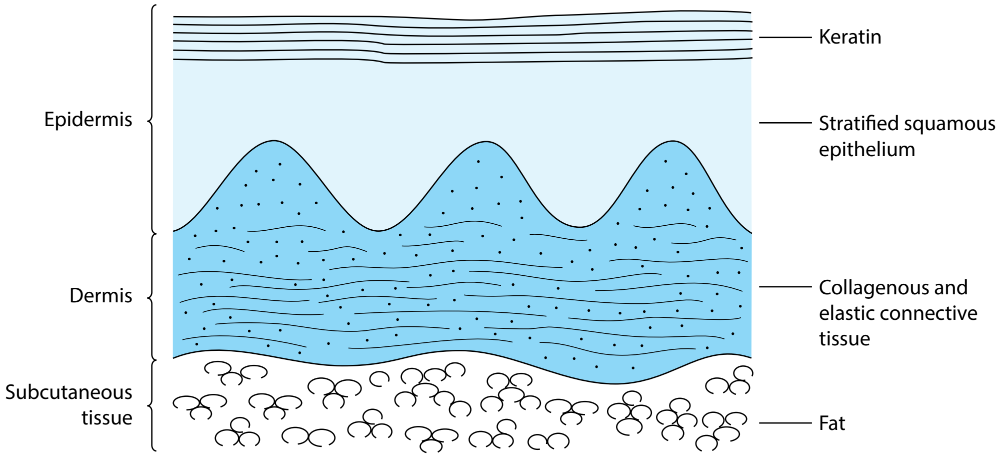
The skin is the largest organ in the body and carries a range of important physiological functions/adaptations, including (1) waterproofing, (2) forming a barrier against infection, (3) vasoconstriction during erect posture and (4) acting as an efficient heat exchanger with the environment in the maintenance of body temperature.

The skin is divided into two main layers: the surface epithelium or epidermis and the underlying dermis (Figure 16.1). The epidermis is a keratinized stratified squamous epithelium and, for descriptive purposes, it is divided into five layers (Figure 16.2) from below upwards:

1. stratum basale
2. stratum spinosum
3. stratum granulosum
4. stratum lucidum
5. stratum corneum.

The stratum basale is the deepest layer and consists of a single layer of cylindrical cells with deeply basophilic cytoplasm and centrally placed nuclei. Interspersed between the basal cells are *melanocytes*, a specialized group of dendritic cells which synthesize the pigment melanin. Above the stratum basale is the stratum spinosum, which consists of two to six rows of cuboidal cells that become flattened towards the surface. Mitotic activity in the resting epidermis occurs mainly in the stratum basale, although, in regeneration following injury, this extends to the stratum spinosum.

The next layer is the stratum granulosum, which is made up of one to three layers of diamond-shaped cells with darkly staining



Epidermis
Dermis
Subcutaneous tissue
Keratin
Stratified squamous epithelium
Collagenous and elastic connective tissue
Fat

Figure 16.1 The anatomy of human skin.

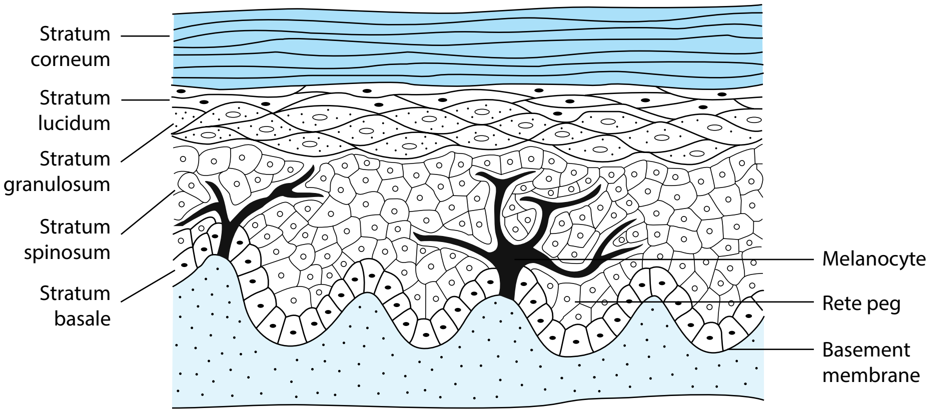


Figure 16.2 The different layers of the epidermis.

pyknotic nuclei. This layer is most obvious in the thick skin of the palms and soles of the feet. This is the layer that produces the fibrous protein *keratin*. In thick skin immediately above the stratum granulosum is a single layer of hyaline anucleate cells termed the stratum lucidum, which is only present in the skin of the palm of the hands and soles of the feet. The outermost layer of the skin is the stratum corneum, consisting of a variable number of flattened anucleate dead cells containing keratin. Over pressure areas such as the hands and the feet, the keratin layer is dense and compact, whereas, over the rest of the body surface, it forms a looser covering.

The under surface of the epidermis consists of downward epithelial projections into the dermis called *rete* or *interpapillary pegs*. The dermis itself is composed of fibroelastic tissue, which supports the epidermis and its appendages. It has two layers: the superficial zone containing the papillary pegs and the deeper reticular layer. The dermis becomes continuous with the denser subcutaneous fascia.

The epidermal appendages

Sweat glands

Sweat glands are found all over the skin and consist of simple tubular glands extending from the epidermis to the mid-dermis, where they become coiled. This is the part of the gland that produces sweat, which is a clear hypotonic electrolyte fluid (with respect to plasma). The main solute of sweat is sodium chloride, but it also contains potassium, lactic acid and urea. Sweating is a mechanism involved in the regulation of body temperature and is controlled by the hypothalamus via cholinergic fibres of the sympathetic nervous system; sweating is stimulated by a rise in body temperature brought about by an increase in environmental temperature or exercise. It is also induced by hypotension, anxiety and fear.

Apocrine glands

These glands are found in the axilla, anogenital region, the mammary areola and the canal of the external ear. Similar to the sweat glands, apocrine glands form coiled tubules which are, however, much larger and situated lower in the dermis, extending into the subjacent subcutaneous fat. Unlike the sweat glands, which penetrate the epidermis, the apocrine glands open into hair follicles above the ducts of the sebaceous glands. The secretion from the apocrine glands has a milky appearance and its production is stimulated by adrenergic stimuli including fear or pain. Apocrine glands become active only after puberty, although their physiological role is not clear. Blockage of the apocrine glands leads to the recurrent inflammatory condition of *hidradenitis suppurativa*.

Hair

Hair grows from hair follicles, which are tubular invaginations of the epidermis into which open sebaceous and apocrine glands. The fact that the epidermis is continuous with the hair follicles is of surgical importance as the follicular epithelium and, to a lesser extent, the epithelium of the sweat glands can grow and migrate to the surface to regenerate the skin after the epithelium has been destroyed by trauma or burns or following procurement of split skin grafts. Each single hair is basically a long, dead keratinized shaft which starts as a small growth area in the depths of the follicle known as the hair bulb. This area is situated in the upper layer of the subcutaneous fat and is invaginated on the underside by vascular connective tissue known as the hair papilla. Above the hair bulb, the cells become elongated and undergo keratinization and, from this point onwards, the hair shaft is a dead structure made up of an outer cortex and a looser inner medulla. Inserted into the walls of the hair follicles are small strips of smooth muscle, the *erectors pilorum*. These are supplied by adrenergic nerve fibres and cause erection of hairs induced by cold and emotional stress.

Sebaceous glands

These glands are absent from the palms of the hands and soles of the feet, but are otherwise found all over the skin surface. They are holocrine glands that produce their secretion by disintegration of the contents of the cells, which are then discharged directly into the sebaceous duct, which enters the hair follicle (Figure 16.3). The function of the secretion (sebum) is to lubricate the skin and act as a physical protective barrier. Sebum consists of a mixture of fatty acids, glycerides, cholesterol and other substances. Sebaceous gland activity rapidly increases after puberty.

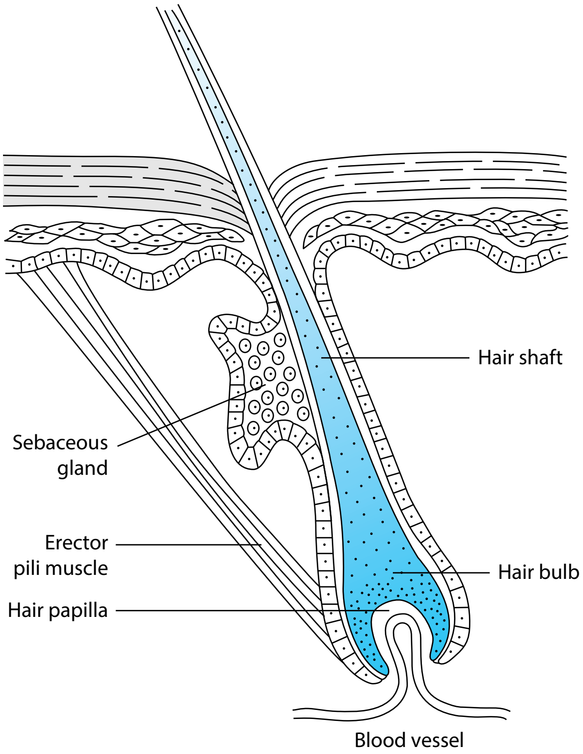

Figure 16.3 Anatomy of the hair follicle.

Nails

Nails are made of semitransparent keratin and are surrounded proximally and laterally by folds of skin. They arise from the nail bed, which consists of a modified epidermis lacking a stratum granulosum. It has a highly vascular dermis, which is continuous on the deep aspect with the periosteum of the distal phalanx.

Pigmentation

In man the main function of pigmentation of the skin appears to be the provision of protection against the harmful effects of sunlight, and dark skin appears to be the result of selective adaptation to intense prolonged exposure to sunlight. The cells responsible for pigmentation are the *melanocytes* found between cells of the stratum basale at the junction of the epidermis and the dermis. These cells synthesize the black pigment *melanin* from the amino acid tyrosine by means of the copper-dependent enzyme oxidase tyrosinase. Melanin is transferred to the surrounding basal cells by the dendritic processes of the melanocytes. Pigmentation by melanin is controlled by the melanocyte-stimulating hormone (MSH) produced by the anterior lobe of the pituitary gland. Excess MSH secretion results in increased melanin pigmentation. Interestingly, the number of melanocytes per unit area of the skin is the same in all races and increased pigmentation therefore reflects an increased melanin synthesis.

Blood supply of skin

The blood supply to the skin not only supplies oxygen and nutrients but also plays an important role in temperature regulation and maintenance of the peripheral vascular resistance during prolonged standing. Skin requires a minimum flow of 0.8 mL of blood per minute per 100 mL of tissue to supply its oxygen requirements, but there is an abundant blood supply which allows considerable variation in blood flow. Indeed, it has been estimated that, during whole body heating, maximal skin blood flow may reach 7–8 L/min. Only skeletal muscle has the potential to receive a greater blood flow.

Small arterial branches penetrate the subcutaneous fat and form a plexus from which loops of vessels go up to supply the individual papillae. Branches from these plexuses supply the glands and the hair roots. The blood is returned via venous plexuses which are situated below the arterial one, and many arteriovenous shunts, known as glomus bodies, are found in certain regions, particularly the palms, the soles, the ears and the central part of the face. These allow the capillary circulation to be short circuited and are concerned with temperature regulation. The very smallest cutaneous arterioles contain muscle fibres, which are again important for thermoregulation. The epidermis itself is avascular and receives nourishment from the vessels at the tip of the papillae via the intercellular spaces. The dermis also has a rich network of lymphatics which start in the papillae and eventually join the larger subcutaneous lymph channels.

In the skin of the trunk and limbs, cutaneous blood flow is controlled by the noradrenergic vasoconstrictor system and an active vasodilator system, in addition to local factors. The skin blood flow response to rapid local heating is biphasic with an initial rapid increase in skin blood flow, followed by a more prolonged plateau phase. The initial phase appears to be largely mediated by an axon reflex, whereas the secondary prolonged hyperaemic phase is caused predominantly by the endothelial release of nitric oxide. The skin hyperaemic response to local heating has caused considerable interest in recent years following the documentation that it is impaired in both type 1 and type 2 diabetic patients and that this reduced capacity for maximal flow can be detected before the onset of diabetes. It is a reflection of impaired endothelial function known to be a feature of this disease.

Nerve supply of the skin

The skin is supplied by cutaneous nerves (eight cervical, 12 thoracic, five lumbar and five sacral) and each area of skin supplied by a single spinal nerve (which form the various named cutaneous nerves) is known as a dermatome (Figure 16.4). The sensory nerve endings are of three forms: (1) endings with expanded tips or discs (Merkel's discs); (2) encapsulated nerve endings (Meissner's corpuscles in the dermal papillae), Ruffini, Pacinian and Golgi–Mazzini corpuscles in the dermis and subcutaneous tissue; and (3) bare nerve endings, which are found in all layers of the skin including base of hair follicles. In addition, recently, it has been demonstrated that some nerve fibres on the cutaneous arterioles may also provide sensory information.

The five primary forms of cutaneous sensation are touch–pressure (mechanoreceptors), cold and warmth (thermoreceptors), pain and itch. Each quality is served by a specific set of cutaneous

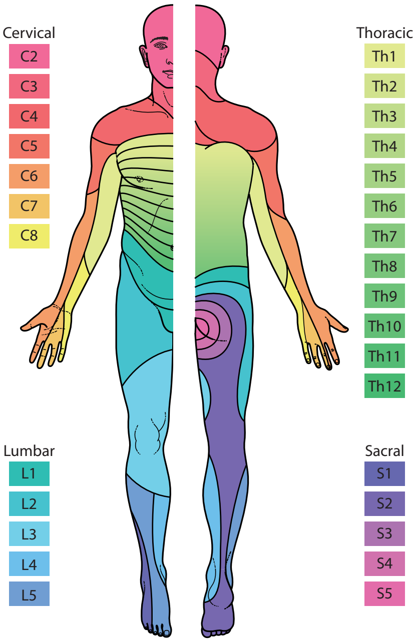

Figure 16.4 Dermatomes of the human skin.

peripheral myelinated and non-myelinated nerve fibres. More complex sensations result from an integration within the central nervous system. The two receptors which are responsible for light touch are Merkel's discs and Meissner's corpuscles. The Pacinian corpuscle is sensitive to pressure. Pruritus (itch) is a common symptom and may be produced by a variety of physical stimuli and disease processes. It seems to be closely related to pain as it travels in the C-fibres of sensory nerves and ascends in the spinothalamic tracts of the spinal cord in association with the pain fibres.

Benign cutaneous surgical conditions

Epidermoid cysts

Often called sebaceous cysts, these lesions are derived from the epidermis lining the hair follicle and sebaceous glands. They may occur anywhere on the skin but particularly on the head, face, neck and trunk. They are unilocular dermal cysts giving rise to visible and palpable cystic swellings which are fixed to the skin (Figure 16.5). There is usually a visible central punctum at the site of the follicle. Histologically, the cysts are made up of layers of epidermal cells interspersed with keratin layers. An epidermoid cyst may become inflamed and present with a tender indurated swelling.

Treatment involves excision along with an ellipse of overlying skin. It is important to excise the whole of the cyst to prevent recurrence. In the infected state, an epidermoid cyst should be incised to allow drainage and the remnant is excised at a subsequent stage when the inflammation has subsided.

True sebaceous cysts occur in a rare condition known as *steatocystoma multiplex*, which is characterized by the presence of multiple cysts containing oily sebum. Another type of cyst which may be mistaken for an epidermoid cyst arises from the epidermis of the external root sheath of the hair follicle. These are known as *pilar cysts* or *trichilemmal cysts*. They tend to occur in women and appear to be familial. Occasionally, the walls may rupture and the resulting proliferative reaction may mimic a squamous cell carcinoma (SCC).

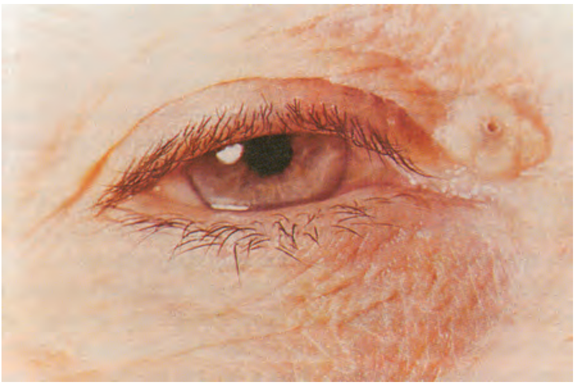

Figure 16.5 Typical epidermoid (commonly known as sebaceous) cyst, this example being situated at the inner canthus of the right eye. (Courtesy of Dr Sally Ibbotson, University of Dundee, UK.)

Molluscum contagiosum

This lesion is caused by the molluscum contagiosum virus, which is a member of the pox virus family. It is contagious but with low virulence in immune-competent patients. It tends to occur in children and young adults, in whom it is often sexually transmitted. Transmission may be direct (skin contact) or through fomites (infected towels and clothing). The incubation period averages 2–3 months. The virus multiplies in the deeper layers of the epidermis and destroys the low-lying tissue producing a central pore. The most typical clinical presentation is a crop of smooth firm, raised pink umbilicated lesions up to 1.0 cm in diameter with a central pus-like head. In adults, the lesions tend to be located on the thighs, buttocks, groin and lower abdomen and even on the genitalia, whereas in children they develop on the face, trunk, legs and arms. The usual form of treatment is curettage but cryotherapy or topical trichloroacetic acid or iodine or phenol can be effective. However, the lesions often resolve without treatment. In HIV patients, however, molluscum contagiosum often persists and takes an aggressive course.

Warts

Warts are exceedingly common, and it is estimated that about 10% of all individuals are affected, usually teenagers, but they may occur at any age. They originate as a result of epithelial hyperplasia triggered by a human papillomavirus (HPV), a group which consists of more than 100 related viruses. Some HPVs types are associated with the development of certain cancers and these are designated as oncogenic or carcinogenic HPVs, e.g. cervical, anal, oropharyngeal and penile cancers. The HPV causing skin warts is not oncogenic. Skin warts are of various types:

- common wart (*verruca vulgaris*): raised nodule with roughened surface, most common on hands, but can grow anywhere on the body
- flat wart (*verruca plana*): small smooth flattened wart, can occur in large numbers; most common on the face, neck, hands, wrists and knees

- filiform wart: finger-like wart, most common on the face, especially near the eyelids and lips
- plantar wart (*verruca pedis*): forms a hard, often painful, lump with multiple central black specks; usually on pressure points on the soles of the feet
- mosaic wart: a group of tightly clustered plantar-type warts, usually located on hands or soles of the feet
- genital (venereal) wart (*condyloma acuminatum, verruca acuminata*): occurs on the genitalia
- periungual wart: a cauliflower-like cluster of warts that occurs around the anus.

A wide range of local treatments is available for treating warts. In a systematic revue, Gibbs *et al*. (2002) concluded that no one treatment is strikingly effective and there is little good evidence on the efficacy of these treatments. Such evidence as exists suggests that there may be a beneficial effect from the use of topical salicylic acid and from contact immunotherapy with dinitrochlorobenzene. There is no good evidence to substantiate the efficacy of cryotherapy, although this treatment modality is often used. Likewise, the benefits and risks of 5-fluorouracil, bleomycin, interferons and photodynamic therapy remain to be determined.

Keloid and hypertrophic scars

A keloid is an abnormality of scarring encountered in certain individuals following trauma, including surgical skin incision. It is due to an overgrowth of granulation tissue (collagen type III) which is gradually replaced by collagen type I as the lesion matures. Keloids form firm, rubbery nodular lesions, which characteristically grow beyond the extent of the wound as distinct from the less severe but related condition of hypertrophic scar, which does not cause symptoms other than impaired cosmesis. Keloids are relatively uncommon in white-skinned individuals but are very common in the dark-skinned races, with a reported ratio of 12:1 between dark- and white-skinned individuals.

The distinction between hypertrophic scar and keloid on histology may be difficult because thickened hyalinized collagen, the hallmark of keloid, is not always detectable and -smooth muscle actin (-SMA) is expressed in both conditions (70% in hypertrophic scar and 45% in keloid). The features more commonly encountered in keloids, as reported in a comparative histopathological study (Lee *et al*. 2004), are:

- non-flattened epidermis
- non-fibrotic papillary dermis
- presence of hyalinized keloid collagen (detected in 55% of keloid specimens)
- prominent disarray of fibrous fascicles/nodules
- tongue-like advancing edge underneath normal-appearing epidermis and papillary dermis
- horizontal cellular fibrous band in the upper reticular dermis
- prominent fascia-like fibrous band.

The treatment of keloids is extremely difficult and often problematic. Surgical excision is best avoided as it merely results in further keloid scarring, although scalpel intralesional excision may be needed if non-surgical management has failed. In these cases, excision should be combined with intraoperative or postoperative triamcinolone as recurrence is inevitable with excision alone.

The conservative treatment includes intralesional corticosteroids, which is generally considered as first-line therapy in view of published evidence that the majority of patients obtain substantial improvement with flattening of keloids, although the recurrence rate is high (up to 50%) at 5 years. Silicone gel sheeting is used to treat symptoms (pain and itching) in patients with established keloids. It is also beneficial in the management of patients with evolving keloids. In some of the reported studies treatment with silicone gel sheeting appeared to improve elasticity of established abnormal scars. Cryosurgery is useful in combination with other treatments but it induces hypopigmentation, which limits its use in dark-skinned patients. Radiotherapy has been reported to be beneficial in reducing keloid recurrence after surgical excision. There is, however, concern regarding the potential long-term risks associated with this treatment and for this reason radiotherapy is used only when other therapies have failed. Interferon- injections have been used to reduce recurrence rates postoperatively although there is no firm evidence of their efficacy. Finally, pulsed dye laser treatment appears to induce keloid regression through suppression of keloid fibroblast proliferation and induction of apoptosis. Combination treatment with pulsed dye laser plus intralesional therapy with corticosteroids and/or fluorouracil may be superior to either approach alone.

Malignant and premalignant conditions of the skin

Cancer of the skin as an overall entity is by far the commonest tumour to affect humans. The three main types are SCC, basal cell carcinoma (BCC) and malignant melanoma. These will be dealt with in turn but, initially, the general aetiology and pathology of skin cancer will be considered followed by a description of the premalignant lesions.

Aetiology of skin cancer

There are two major aetiological factors, the HPVs and solar radiation. For some reason, it is usually only the skin of the perineum that is affected by malignant change unequivocally associated with HPV (see Anal intraepithelial neoplasia). However, papillomavirus particles have been found in SCC in other parts of the body.

Both premalignant and malignant lesions of the skin occur more frequently in those areas that are exposed to sunlight. The causative agent is ultraviolet (UV) light, which is classified in accordance with its wavelength (Table 16.1).

UVA (wavelength 320–420 nm) is probably the least damaging to skin but may have an additive effect to that of UVB (wavelength 290–320 nm). UVB is more damaging, and UVC (200–290 nm) is by far the most damaging. Fortunately, relatively little UVC reaches the Earth's surface as it is filtered by the ozone layer, but it can be produced by arc welders and sterilizing lamps. It should be noted that, although sunbeds

Table 16.1 Classification of ultraviolet (UV) light

Class	Wavelength (nm)	Source	Effect
UVA	320–400	Sunlight	Darkening of melanin; phototoxicity
UVB	290–320	Sunlight	Sunburn; carcinogenesis; melanin production
UVC	<290	Arc welders	Carcinogenesis; sterilizing lamps

generally emit UVA radiation, they are still potentially dangerous.

UV light causes dimerization of the adjacent pyrimidines in the epidermal DNA. This decreases the efficiency of the cellular repair mechanisms and thereby may lead to malignant transformation. Malignant and premalignant skin lesions are rare in black populations and common in Australia, New Zealand and South Africa, where the skin of the white migrant North Europeans is exposed to high levels of sunlight over prolonged periods. The absorptive effect of the atmospheric ozone layer is least at the Equator but increases with increasing longitude as the Sun's rays strike the ozone layer more obliquely and have a longer passage through it.

Pathology of solar damage

Solar radiation creates changes in the skin known as actinic change, which involves degeneration of collagen in the dermis and an increase in the amount of elastin. As a consequence, there is failure of the supportive dermal structure and the skin becomes wrinkled. In the epidermal layer actinic change affects all the cells. The epidermis becomes thin and atrophic, melanocytes become irregularly distributed and atypical and there is an increase in the number of suppressor T-lymphocytes.

The epidermal keratinocytes undergo hyperkeratinization and parakeratinization. In the early stages of the dysplastic change, excessive amounts of keratin are produced and the keratin fails to separate from the skin resulting in hyperkeratosis. Clinically, this forms scales. With further accumulation of damage, the pattern changes to the more dysplastic form, parakeratosis. Here the cells fail to mature and, as they reach the surface, they retain their nuclei. In addition, cellular atypia of the individual cells is seen with pleomorphism, hyperchromatism, irregular nuclei and an increase in the ratio of the nuclear to the cytoplasmic areas. Extreme dysplastic changes are described as carcinoma *in situ* and, when the basement membrane is breached, the lesion becomes an invasive cancer.

Actinic keratosis

Actinic keratosis is also known as senile keratosis or solar keratosis. It is most commonly seen in white-skinned individuals and presents clinically as a red scaly patch on the exposed skin of the elderly. The clinical course is slow with regression of some of the lesions and progression of others to malignancy. Histologically, the skin exhibits a variable degree of solar damage as described above. Although the most effective treatment for actinic keratosis is surgical excision, this may prove difficult in large and awkward areas. It may therefore be appropriate to treat the condition conservatively and only advise excision when there are suspicious clinical indications of malignancy, i.e. the onset of ulceration or bleeding.

Carcinoma *in situ*

Carcinoma *in situ* of the skin is sometimes known as *Bowen disease* and it may be difficult to distinguish it from actinic keratosis, as indeed it represents the more severe end of the spectrum of this condition. Histologically, the picture is identical to that of squamous cell carcinoma without penetration of the basement membrane. Clinically, it presents as a roughened reddened patch of skin, which persists over many months or years. Owing to the risk of invasive malignant change, it should be excised, unless there is a compelling reason to treat it expectantly for reasons of size or anatomical position.

Keratoacanthoma

Keratoacanthoma (KA), formerly regarded as a benign self-limiting lesion, is now considered as 'squamous cell carcinoma–keratoacanthoma' (SCC-KA) to reflect the difficulty which often arises in the histological differentiation, as well as the rare but potentially aggressive forms of the disease, especially when multiple. More usually, however, KA behaves as a relatively common low-grade malignant lesion, with an incidence of 104/100 000. It is more common in males (male to female ratio, 2:1), affects elderly patients over 60 years and is rare in dark-skinned individuals. KA originates in the pilosebaceous glands. It may also be a manifestation of the rare *Muir–Torre* syndrome, an autosomal dominant familial cancer syndrome. As the epidemiology is virtually identical to that of invasive SCC and Bowen disease, prolonged exposure to sunlight and chemical carcinogens (industrial workers exposed to pitch and tar) have been implicated, in addition to HPV and an immunocompromised state.

The clinical presentation of KA is that of a rapidly growing skin-coloured or reddish nodule with a central crater containing a keratin plug over a few weeks to months, followed by a slow spontaneous resolution over 4–6 months leaving a scar (Figure 16.6). The majority of KAs occur on sun-exposed areas, e.g. the face, neck and dorsum of the hands and forearms, and are usually solitary. Occasionally KA presents as multiple tumours characterized by rapid local enlargement, and may even metastasize to regional lymph nodes.

Treatment of KA is primarily surgical, with medical treatment being reserved for when surgical intervention is not feasible (multiple scattered lesions, poor surgical risk, etc.). KA should be excised with an adequate margin (3–5 mm) and subjected to detailed histology to exclude invasive SCC.

Medical (conservative) treatment is far from standardized and includes systemic retinoids (isotretinoin) and intralesional cytotoxic agents (methotrexate, 5-fluorouracil, bleomycin). Although successful in the majority, repeat intralesional injections are often needed. KAs are radiosensitive and respond well to low doses of radiation (<10 Gy). Radiation therapy is

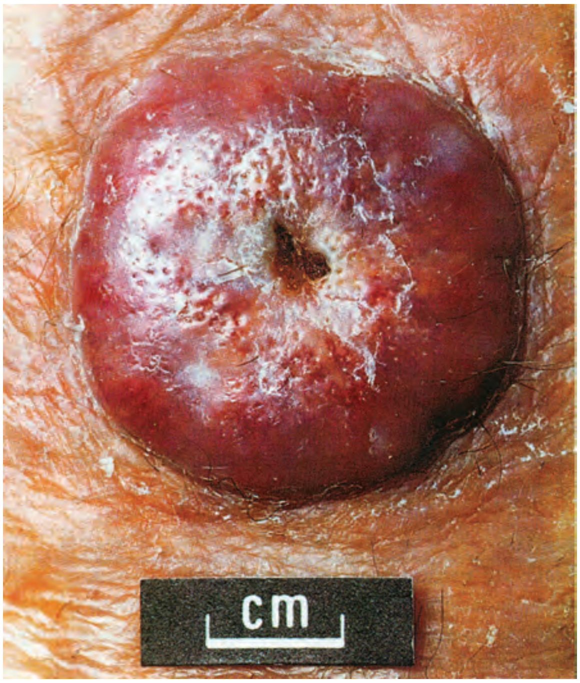

Figure 16.6 Keratoacanthoma. (Courtesy of Dr Sally Ibbotson, University of Dundee, UK.)

used in selected patients with large tumours in whom resection will result in cosmetic deformity and for tumours that recur after excision. Radiation therapy is also used for patients who are unfit for surgery and general anaesthesia. Laser and cryosurgical ablation are used in some centres for small KAs and for lesions which would pose problems with surgical excision by virtue of their location.

Squamous cell carcinoma of the skin

As with carcinoma *in situ*, SCC of the skin tends to occur in exposed areas of white-skinned individuals over the age of 50 years, particularly those who have spent considerable time outdoors. Fair-skinned individuals with light-coloured skin, blue/green eyes and blond or red hair are particularly susceptible.

Aetiology

Aside from prolonged exposure to sunlight, other less important aetiological factors include an inherited predisposition to skin cancer, smoking (SCC of the lip), thermal burn scars, long-standing leg ulcers (Marjolin's ulcer) and immunosuppression by drugs (ciclosporin, azathioprine in transplant recipients). Surveillance is nowadays recommended in all patients receiving long-term medication with immunosuppressive drugs. Infection with HPV causes mucosal SCCs and cuniculatum verrucous carcinoma of the skin of the face. However, HPV very rarely causes common cutaneous SCC. The actual risk of SCC following use of 'biological therapies' for inflammatory and haematological disease in recent years is not known, although there have been documented cases of rapid onset or reactivation of SCC in patients with a past history of the disease, especially in those with risk factors for recurrence. There is good evidence of the efficacy of protective clothing and effective sunblocks in the prevention of both actinic keratosis and SCC.

Pathology

SCC arises from the epidermal keratinocytes. Histologically, abnormal squamous cells are seen growing downwards from the epidermis into the dermis and subcutaneous tissue in strands or sheets. The tumour may be classified as well differentiated, moderately differentiated or poorly differentiated. Typically, the well-differentiated type will exhibit keratinization and formation of keratin pearls composed of concentric layers of cells with increasing keratinization towards the centre. The cells are large and polygonal with eosinophilic cytoplasm, and mitotic figures with few nucleoli. In contrast, the poorly differentiated tumours are made up of anaplastic cells with multiple mitosis and nucleoli and no keratinization. There is a four-part classification of SCC based on differentiation described by Broders. This describes grades 1, 2 and 3, which denote ratios of differentiated to undifferentiated cells of 3:1, 1:1 and 1:3, respectively. Grade 4 indicates a completely anaplastic tumour with no tendency to differentiation.

SCC spreads locally, via lymphatics and via the bloodstream. Local invasion is both horizontal and vertical and, in neglected tumours, can give rise to widespread destruction of the skin and underlying structures. Erosion of large blood vessels can be a terminal event. Lymphatic spread is to the regional lymph nodes in the first instance, and blood-borne spread is to the lungs, bone and brain. However, the ability of SCC for distant metastases is low and only about 3% of tumours will have distant metastases at the time of diagnosis. For some reason, SCCs that arise in chronic scars tend to behave more aggressively, but it is not clear whether this is a biological feature of the disease or whether tumours arising in scars tend to be neglected and present late.

Clinical features

Clinically there are two patterns of growth that are recognized, although these can overlap to a certain extent. The infiltrative type begins as a warty nodule that breaks down to form an ulcer with a rolled edge overlying the surrounding indurated skin (Figure 16.7). The protuberant type produces a raised cauliflower-like lesion (Figure 16.8). The degree of induration felt clinically gives an indication of the depth of invasion of the tumour, as does the extent of ulceration.

Diagnosis

The diagnosis tends to be evident clinically but must be confirmed by either incisional or, whenever possible, excisional biopsy.

Prognosis

The vast majority of SCCs (95%) can be cured by adequate surgical excision, although new tumours may develop subsequently and patients should be informed of this and followed up. Otherwise the best predictor of tumour behaviour in terms of metastatic disease is the vertical tumour thickness (Clark levels), but the surface area of the tumour also has implications for local recurrence. Tumours arising in apparently

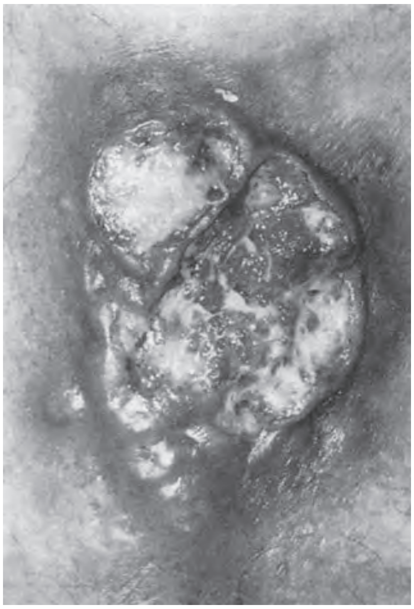

Figure 16.7 Infiltrative squamous cell carcinoma.

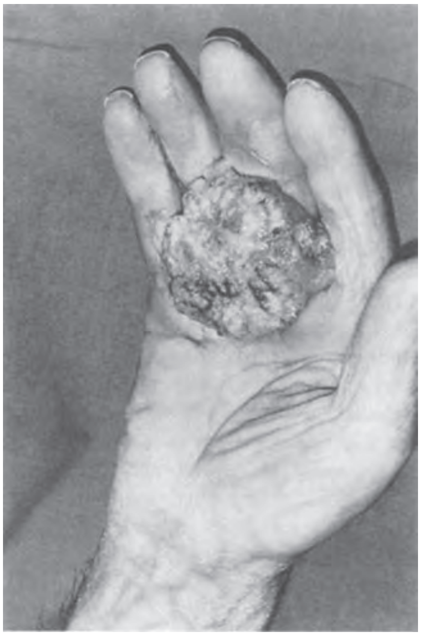

Figure 16.8 Protuberant squamous cell carcinoma.

normal skin have a poorer prognosis in terms of recurrence and distant spread than those arising in skin showing solar damage. Histological differentiation (Broders classification) is also a factor in prognosis as the poorly differentiated tumours have an increased tendency to metastasize. The anatomical site of the tumour is another prognostic factor as tumours of the trunk and limbs have a worse prognosis than those of the head and neck.

Factors which influence the metastatic potential of SCC are:

- *Anatomical site*: greatest potential in SCCs arising in areas of radiation or thermal injury, chronic sinuses/ulcers followed in *descending order* by (1) SCCs in non-sun-exposed sites (perineum, sacrum, sole of the foot), (2) SCC of the ear, (3) SCC of the lip, (4) SCC at sun-exposed areas excluding the lip and ear.
- *Size of tumour at presentation*: tumours >2.0 cm in diameter are twice as likely to recur locally and three times as likely (30%) to metastasize as smaller tumours.
- *Tumour thickness/level of invasion*: tumours >4 mm in depth or extending beyond the subcutaneous tissue (Clark level V) are more likely to recur and metastasize, whereas tumours <2 mm thick rarely metastasize.
- *Histological differentiation and subtype*: poorly differentiated tumours (Broders grades 3 and 4) carry a poorer prognosis with twice the local recurrence rate and three times the metastasis rate than the better differentiated types. Perineural involvement and lymphatic or vascular invasion are associated with an increased risk of recurrence and distant spread. The acantholytic, spindle and desmoplastic subtypes have a poorer prognosis than verrucose lesions.
- *Host immunosuppression*: by drugs or disease.

The Clark levels of invasion are the same as those used for malignant melanoma and are described below.

Treatment

Surgical excision

Surgical treatment remains the treatment of choice for the majority of cutaneous SCCs. Aside from proven efficacy, it allows histological examination of the extent of differentiation of the tumour and objective evidence that the excision has been complete (tumour-free margins). The underlying important consideration which determines the clinical outcome is completed removal of the tumour including the 'in transit' metastases in the environs of large lesions. As previously mentioned, prior diagnosis should be made by excisional biopsy whenever possible and this may serve as treatment if the tumour is completely excised with clear margins. Small lesions may be excised under local anaesthetic, in which case the incision should be planned and marked prior to infiltration with local anaesthetic to avoid mistakes created by the inevitable distortion of the skin.

For low risk SCCs <2.0 cm diameter, surgical excision with a minimum of 4 mm circumferential margin is appropriate and will result in complete removal of the primary in 95% of cases. Tumours >2.0 cm, poorly or undifferentiated tumours, tumours extending into the subcutaneous tissue, and tumours of the ear, lip, scalp or eyelids require a wider margin (minimum of 6 mm). When removing the lesion, it is important to remember that deep clearance is as important as lateral/circumferential clearance and, for this reason, it is important to palpate and inspect the deep margin during the excision. In the limbs, the possibility of extension along fascial planes must be considered and possible perineural spread also taken into account. A history of pain or unusual sensations associated with the tumour may suggest perineural spread.

Irrespective of site, it is essential that a margin of normal tissue is excised on all aspects of the tumour, and, if the tumour is adherent to tendon or bone, this tissue must also be excised. Problems of reconstruction must not compromise the complete clearance of the tumour, otherwise surgical excision will fail. After excision, it is important to mark the specimen in order to enable the histopathologist to orientate the specimen. With this in mind, the specimen should always be accompanied by a diagram showing its site and orientation.

Radiotherapy

Although surgery is the treatment of choice for the majority of SCCs, these tumours are radiosensitive and radiotherapy has an important role in its management. In practice radiotherapy is reserved for tumours which are inoperable by virtue of involvement of vital structures and for postoperative treatment of tumours that have been inadequately excised because of anatomical considerations. Having said this, radiotherapy may be used as the primary treatment modality for all SCCs with the following reservations:

- pretreatment biopsy is essential
- radiation of the exposed skin in young people may increase the risk of future carcinoma and is thus usually contraindicated in this age group
- areas of chronic friction or poor vascularity, e.g. the shoulders, back of the hand, abdominal wall and pretibial region, should not be irradiated as this will lead to chronic skin damage
- treatment of skin around the eye may lead to radiation keratitis.

Because of its superior cosmetic results, radiotherapy is often used instead of surgical excision in SCCs of the lower eyelid, the inner canthus of the eye, the lip and tip of the nose with reported cure rates of >90%.

Other treatment modalities

These include Mohs micrographic surgery, cryotherapy, photodynamic therapy, curettage and cautery and topical therapy. Mohs micrographic surgery consists of microscopically controlled precise excision of the tumour in increasingly deeper layers until the microscopy shows no tumour cells. Nowadays, the fresh tissue modification (without application of zinc chloride paste to fix the tumour *in situ*) is used with excellent results in terms of low recurrence and metastatic rates, such that it is recommended as the treatment of choice for high-risk SCCs, particularly at difficult sites where wide surgical margins may not be possible without inducing deformity of functional impairment. Curettage and cautery is reserved for very small (<1.0 cm), well-differentiated, primary, slow-growing tumours on sun-exposed sites. The lesion is first curetted (for debulking) and then cautery (electrodessication) applied to the wound. The problem with this treatment is that curettage provides poorly orientated material for histological examination and assessment of the completeness of removal is not possible. Good short-tem cure rates have been reported with cryotherapy for small histologically confirmed SCCs. Cryotherapy is contraindicated for recurrent and high-risk tumours. There is no level 1 evidence that other treatments such as photodynamic therapy and topical treatment with imiquimod, 5-fluorouracil paste and interferon- are effective in the long term.

Recurrent disease

If histological examination of the excised specimen reveals involvement of the resection margins, the risk of recurrence exceeds 50%. A second procedure with wider and deeper excision should therefore be undertaken immediately unless this is contraindicated by involvement of vital structures. In this case, radiotherapy is indicated. If recurrence occurs after a lesion has been excised with adequate (clear) histological margins, this indicates deep infiltration along tissue planes. This tends to occur particularly in lesions of the ear and requires a wide excision or radiotherapy. When wide excision is performed, intraoperative frozen section will help to define the extent of excision.

Treatment of metastatic disease

When metastatic deposits in the regional lymph nodes are detected, *en bloc* resection of the lymph node group is indicated and postoperative radiotherapy should be considered for poorly differentiated tumours. Currently there is no evidence for the use of prophylactic block dissection of regional lymph nodes in high-risk large tumours. Some recommend sentinel node biopsy in these cases but again the benefit of this approach remains uncertain.

Metastatic lesions of the bone and brain may be treated by radiotherapy to reduce local symptoms but widespread disease will require chemotherapy. Randomized studies have established the combination of cisplatin and infusional 5-fluorouracil and paclitaxel is effective in palliation (pain relief and improved quality of life) but does not materially improve survival. Phase II studies of a platinum/taxane combination with a third drug have reported response rates exceeding 50%, including 15% complete responses. A number of non-platinum agents are also active including gefitinib and the newer antifolates which target or restore deficient p53. Overall, the 5-year survival in patients with metastatic disease at presentation is 25%. The 10-year survival is 13%, and the 15-year survival is 8%.

Basal cell carcinoma (rodent ulcer)

BCC is the commonest skin malignancy in white-skinned individuals (60% of cutaneous tumours) and is the most common cancer in Europe, Australasia and the USA. The age-standardized incidence of BCC varies considerably from country to country, e.g. 114 per 100 000 population in Wales, 146 per 100 000 in Minnesota, USA, 726 per 100 000 in Australia, etc. The incidence is increasing each year, such that the estimated lifetime risk of BCC in the white populations of North America is 33–39% and 23–28% for males and females, respectively. It is virtually unknown in dark-skinned individuals. BCC arises from epithelial cells and is thought that the cells of origin are from the follicular basal lining of the hair follicle rather than the cells from the basal layer of the epidermis.

Aetiology

The most significant aetiological factors are genetic predisposition and exposure to UV radiation. Increasing age, male sex, skin type I (skin that always burns and never tans), blond hair with blue/green eyes, freckles and sunburn in childhood and adolescence (as opposed to adults), immune suppression, ionizing radiation, burns and arsenic exposure are other recognized risk factors. Multiple BCCs are a feature of the rare *basal cell naevus (Gorlin–Goltz) syndrome*, an autosomal dominant familial disorder characterized by pitting of the palms and soles, jaw cysts, spine/rib anomalies, calcification of the falx cerebri, cataracts and the development of multiple BCCs. Other conditions associated with an increased risk of BCC include albinism and xeroderma pigmentosum. Susceptibility to the development of BCC is determined by a complex interaction between duration, intensity of exposure to UV radiation and certain polymorphic genes.

Pathology

BCCs behave as slow-growing, locally invasive malignant skin tumours which infiltrate local tissues but rarely if ever metastasize. However, untreated they cause local destruction of tissues. BCCs occur on areas of chronic sun exposure, e.g. face, head and neck. Histologically, the tumour consists of clumps of basophilic cells surrounded by a connective tissue stroma. At the periphery of the tumour, columnar cells form a palisade which is the hallmark of the tumour. Mucin is found in the stroma rather than elastin in contradistinction to SCCs. The ratio of cells to stroma varies according to the five recognized types of BCC: noduloulcerative, superficial spreading, morphoeic, pigmented and fibroepithelioma of Pinkus.

Noduloulcerative basal cell carcinoma (cystic basal cell carcinoma, rodent ulcer)

This forms a well-circumscribed tumour with islands of basal cells embedded in a fibroblastic stroma. Centrally the cells are arranged randomly, but peripherally the cells form palisades. The basal cells may show differentiation towards the adnexal structures of the skin or may demonstrate squamous metaplasia.

Superficial spreading basal cell carcinoma

In this variant, there are nests of basiloid cells with peripheral palisading at the level of the basal layer of the epidermis with atrophy of the epidermis above this.

Morphoeic basal cell carcinoma

This type, which accounts for 5% of cases, is the most aggressive. Histologically, it is characterized by the presence of a dense fibrous dermal stroma with scanty strands and groups of cells embedded within it. The tumour cell strands may stream from the under surface of the tumour into the deeper tissues without definite margins. Proliferation of the stroma may also occur in the horizontal plane beneath apparently normal epidermis. This makes for difficulty in judging the margins of the tumour with the naked eye and is responsible for the high incidence of recurrence of this type of BCC. Some of these tumours may be very large at presentation and cause significant disfigurement requiring lengthy plastic surgical reconstruction.

Pigmented basal cell carcinoma

This is similar in histological appearance to the noduloulcerative type but contains melanocytes.

Fibroepithelioma of Pinkus

In this variant, strands of basiloid cells extend into the deeper fibrous stroma but there is no palisading.

Clinical features

Sporadic BCC is rarely encountered before the age of 20 years but increases thereafter with age. All types of BCC develop in the sun-exposed areas with 80% occurring on the head and neck, with the rest mainly on the trunk and lower limbs. The small early lesions are either translucent or of pearly colour and have raised areas with telangiectasia. Otherwise, the clinical features vary with the type. Patients treated for BCCs have an increased risk of developing further (new) lesions. This risk, variously reported at 33–77%, depends on the number of lesions present and location of tumour in the trunk. Additionally, patients with BCCs are at an increased risk of developing malignant melanoma, presumably related to the exposure to UV radiation.

Noduloulcerative basal cell carcinoma

This is by far the commonest form, accounting for approximately 50% of all BCCs. Clinically, it presents as a slowly growing nodule with waxy or pearly appearance associated with telangiectasia. Later in the course of the disease, the skin ulcerates to form a typical rodent ulcer (Figure 16.9).

Superficial spreading basal cell carcinoma

This is also described as superficial cicatrizing or 'field fire' BCC. It presents as a scaling erythematous lesion, usually on the trunk. It does not become indurated, nor does it ulcerate. Instead, it spreads radially while appearing to heal in the centre. The central scar area contains sweat glands but the hair follicles are destroyed producing characteristic alopecia. The tumour is frequently multifocal and is commonly advanced at presentation owing to the insidious nature of its development.

Morphoeic basal cell carcinoma

This presents as a dense greyish yellow plaque that increases in size gradually. Around the eyelids, contraction of the fibrous stroma may result in distortion. The lesion may ulcerate.

Pigmented basal cell carcinoma

Clinically, this type of BCC is similar to the noduloulcerative variety except for a pearly black sheen.

Fibroepithelioma of Pinkus

This presents as a papilloma without scaling or ulceration.

It is important to distinguish between high- and low-risk BCCs, based on their likelihood of recurrence after treatment. Factors indicating higher risk include histological type (morphoeic), size at presentation (>2.0 cm), site (central face), perineural and deep invasion below the dermis, immune suppression and genetic disorders (Gorlin syndrome).

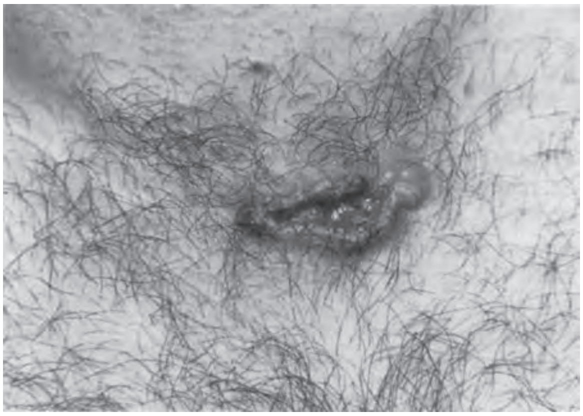

Figure 16.9 Typical rodent ulcer (noduloulcerative basal cell carcinoma).

Diagnosis

The diagnosis of BCC is clinical in the first instance but it must always be confirmed by histology; whenever possible this should be by excision biopsy.

Treatment

The treatment options for BCC are:

- surgical: usually excision with primary closure or with flaps or grafts for large lesions precluding primary closure
- Mohs micrographic surgery
- curettage and cautery
- radiotherapy
- cryotherapy
- photodynamic therapy
- topical fluorouracil
- topical imiquimod.

The choice of treatment in the individual case depends on the size and site of the tumour, its histological nature, the condition of the patient and, in recurrent tumours, the methods previously used.

Surgical excision

This is the standard treatment for the majority of BCCs. A simple excision is usually carried out as an ellipse around the tumour with a margin of 4 mm for noduloulcerative lesions. The excision is planned along Langer's lines to ensure healing with minimal scarring/deformity. In morphoeic and recurrent lesions, the clearance should be significantly larger at 1.0 cm. As with SCC, the excised specimen should be marked and be accompanied by an appropriate diagram to allow the pathologist to orientate the specimen. After excision in most cases, primary closure is possible but large lesions (primary or recurrent) often require partial or full thickness skin grafting. On the face, large lesions may require flap reconstruction by a plastic surgeon after excision. The 5-year cure rate following appropriate surgical excision is 95% or higher.

Mohs microangiographic surgery

When expertise is available for this technique, it is ideal for the treatment of tumours of the central face, morphoeic lesions and recurrent BCCs as it results in very high cure rates (99% for primary lesions and 95% for recurrent BCCs), while providing maximal preservation of normal tissues.

Curettage and cautery

Noduloulcerative BCCs can be treated by curettage and cautery with the wound being allowed to heal by secondary intention. The rationale behind this method is that the soft tumour tissue is scraped out while the firmer more resistant normal skin is left behind. Although curettage and cautery gives cure rates which approximate those of surgical excision, the wound takes much longer to heal and there is no tissue available for histological examination. Curettage is definitely contraindicated for lesions >1.0 cm in diameter, for morphoeic lesions, recurrent tumours and tumours at high-risk sites (central face) as the risk of residual tumour is high.

Cryotherapy

Cryotherapy using a liquid nitrogen probe at minus 50°C for between 30 and 120 seconds effectively destroys BCCs with equivalent cure rates to surgical excision, but, as with curettage and cautery, the wound is left to granulate and heal by secondary intention and no tissue is available for histological examination to confirm complete ablation. Cryotherapy is used selectively, usually for small multiple BCCs.

Topical photodynamic therapy

This is an established technique which has witnessed considerable progress in recent years with the advent of technology based on organic light-emitting diodes (OLEDs). Topical photodynamic therapy is most effective for superficial BCCs, and for these lesions it results in high cure rates with excellent cosmesis. It uses a photosensitizer drug, -aminolaevulinic acid, in a 20% emulsion applied to the tumour, which then takes it up and thereby becomes photosensitized. As a result, it is ablated when exposed to light in the wavelength range of 620–670 nm. The recent OLED-based system has revolutionized photodynamic therapy as, following the application of the sensitizer, a plaster covering containing OLEDs provides the appropriate light irradiation at home (Figure 16.10). The reported average cure rates with photodynamic therapy for BCCs is 87%, but this is lower for nodular lesions (53%), presumably because of the thickness of these tumours adversely affecting the penetration of the light into the deeper layers of the tumour.

Radiotherapy

The overall cure rate of BCC using radiotherapy is about 90% which is of the same order as all other methods used. This option may thus seem attractive as operation is avoided. It does, however

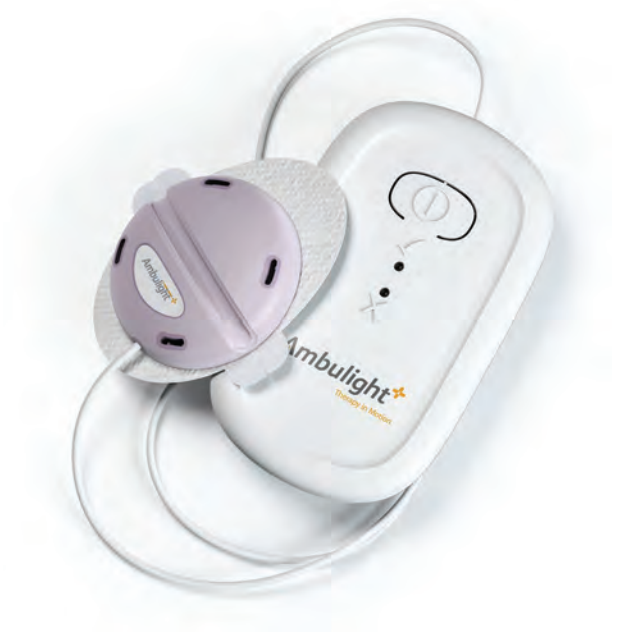

Figure 16.10 Organic light-emitting diode plaster for outpatient photodynamic therapy of superficial basal cell carcinoma. (Courtesy of Professor J Ferguson, Ninewells Hospital and Medical School, Dundee, UK.)

require multiple visits to the hospital as the exposure required is 4000–6000 Gy over several fractions to obtain the best results. It also causes skin atrophy and alopecia. Previous radiotherapy to the area is a contraindication. Additionally, radiotherapy is not recommended for young patients as the late cosmetic results are inferior to those of surgery. In practice, radiotherapy is reserved for elderly patients with extensive lesions in whom major surgery is not appropriate.

Benign pigmented naevi (moles)

Naevi are extremely common and have little clinical significance in themselves. However, they may mimic malignant melanoma or they may be cosmetically unacceptable to the patient. A small percentage of naevi do, however, carry the risk of malignant change.

Aetiology and pathology

Melanocytes, which are responsible for skin pigmentation, arise from the neural crest in the first weeks of embryonic development and then migrate to the skin as well as the meninges, uveal tract and ectodermal mucosa. In the skin, melanocytes are distributed throughout the dermis and epidermis. At birth, most cutaneous melanocytes are present in the basal layer of the epidermis but, over the first three decades of life, some will migrate to the dermis. In the dermis, melanocytes lose their ability to undergo mitosis and therefore have no malignant potential.

Melanocytes may clump together in the basal layer of the epidermis to form a *simple lentigo* or *mole*, which is commonly seen in infants. This may be regarded as the first stage in the progression towards a mature intradermal naevus. As the child grows, the melanocytes aggregate at the dermoepidermal junction. These are called *junctional naevi*. The melanocytes gradually become incorporated into the dermis by fibroblast migration. When this has taken place, naevi consist of a combination of junctional and intradermal aggregates of melanocytes and are termed *compound naevi*. Finally, as the naevus matures, all the melanocytes aggregate in the dermis and an *intradermal naevus* is formed. Thus junctional naevi are common in children and have virtually no malignant potential. In adults, they are rare but do carry a risk of malignant transformation and they are usually found on the palms of the hands and the soles of the feet.

Clinical features

The junctional naevus is either a macule or papule and is brown, smooth and hairless. It may occur anywhere, but when these lesions are seen on the palms or the soles in adults, they may be premalignant. The intradermal type of naevus is a papule which is often hairy and well defined. It may be brown or flesh coloured and is most commonly encountered on the face and the neck.

Diagnosis

The diagnosis is usually self-evident but excision biopsy and histological examination are necessary for definite diagnosis.

Treatment

The only treatment for a naevus is excision but this should only be done when the lesion causes inconvenience to the patient or because of concerns regarding possible malignant change. The latter is suggested by rapid growth, deepening of the pigmentation or bleeding (see below).

Malignant melanoma

Malignant melanoma is the most aggressive of all cutaneous cancers with a marked tendency to spread by both lymphatic and vascular pathways. It predominantly affects white-skinned races, particularly those who are exposed to intense sunlight. The highest incidence in the world is in Queensland, Australia (33 per 100 000). The disease is extremely rare in black-skinned races and, when it does occur, it is found almost exclusively on the sole of the foot, the subungual region or on the mucous membranes. Malignant melanoma is very rare in children and is more common in women than in men in a ratio of 1.5:1. Although predominantly a cutaneous disease, malignant melanoma may rarely originate in mucous membranes (e.g. colorectum, small bowel and oesophagus), and other sites, e.g. choroid plexus of the eye. Not infrequently in these cases, it presents with distant visceral metastases from an unknown primary.

Aetiology and epidemiology

The aetiological factors in malignant melanoma include sun exposure, racial/genetic predisposition, premalignant states and recurrent trauma. The worldwide very significant increase in the incidence of malignant melanoma has been attributed to an increased exposure to UV radiation with the vast increase in charter holidays in the sun by white-skinned residents of wealthy countries. However, recent studies by a Swedish group has established a good time correlation between the roll out of FM/TV broadcasting networks that occurred many years before the boom in holiday charter sun travel. On the basis of this evidence, the authors argue that the increased incidence and mortality of melanoma cannot be solely explained by increased exposure to UV radiation from the sun, as the continuous disturbance of cell repair mechanisms by body-resonant electromagnetic fields may amplify the carcinogenic effects of UV-induced cell damage (Hallberg and Johansson 2004). However, this remains unproven and the Agency for Research on Cancer has concluded that solar radiation remains the main cause of melanoma. In this respect, a review of all case–control studies has concluded that intermittent unaccustomed exposure is more important than age at sunburn. In addition to sunburn (mainly due to UVB radiation), there has been accumulating evidence implicating UVA (and sun beds) in the pathogenesis of melanoma.

The most important premalignant state is the junctional or compound naevus as it appears that melanocytes that remain in the epidermis have distinct malignant potential, the reason for which remains unclear. A minority of malignant melanomas are associated with congenital giant naevi or the *dysplastic naevus syndrome*. Congenital giant naevi are defined as naevi occupying >1% of the body surface area. They may be very large and sometimes cover the trunk, upper arms and upper thighs (bathing trunk naevus). The reported risk of malignant change is such lesions varies from 2% to 28% according to the reported series. Fifty per cent of melanomas which develop in giant congenital naevi do so in the first 5 years of life. The dysplastic naevus syndrome is a familial condition inherited as autosomal dominant with variable penetrance. It is characterized by multiple pale, non-homogeneous naevi with an irregular edge. Most commonly, they occur on the back and start to develop around puberty. The risk of developing malignant melanoma in these individuals is of the order of several magnitudes higher than that of the normal population.

The established risk factors for malignant melanoma are summarized in Table 16.2.

Familial melanoma other than the dysplastic naevus syndrome accounts for 2% of melanomas associated in some cases with two mutated genes (*CDKN2A* and *CDK4*), although these account for a small percentage of familial melanoma. *CDKN2A* codes for two separate proteins (p16 and p14ARF). Both *CDKN2A* and *CDK4* genes control cell mitotic activity. Although families with mutations in *CDKN2A* have an increased risk of melanoma, this varies widely with the geographic region in which they live, presumably because of other factors involved in the aetiology including extent of exposure to sunlight. Mutations in other genes, e.g. *MC1R*, which regulates pigment production by melanocytes and is associated with freckling and red hair, appears to increase the risk of melanoma in individuals both with and without *CDKN2A* mutation.

Pathology

Mutations of the proto-oncogene *BRAF* occur in 50% of malignant melanomas, with the V600E mutation accounting for >90%. This mutation obviates the need for phosphorylation of the T599 and S602 residues – an essential step for the normal activation of *BRAF*. This mutation thus leads to a continuous stimulation of the MAP kinase cascade and hence cell proliferation and dedifferentiation. However, the role of activating *BRAF* mutations with respect to course and stage of melanoma has not been defined, although a recent study has demonstrated that the *BRAF*^{V600E}-dependent expression of a newly identified potential effector gene, *BAALC* (discovered in malignant melanoma cell lines), may be involved as a downstream effector of *BRAF* mutations during the development of malignant melanoma.

Table 16.2 Established risk factors for malignant melanoma

Risk factor	Comment
Number of common moles >2 mm	Risk increases with number of moles >10
Previous history of melanoma	
Family history of melanoma	
Red or light-coloured hair	
Presence of atypical moles	Have irregular borders/pigmentation and >5 mm
Presence of actinic lentigines	Flat brown skin lesion associated with sun exposure
Giant congenital naevi	≥20 cm in diameter
Skin that does not tan easily	
Female sex	Age-standardized female to male ratio 1.5:1.0
Age	Rare in children, thereafter rises to peak in the elderly

Malignant melanomas are classified into four groups in accordance with their clinical presentation:

1. lentigo maligna
2. superficial spreading
3. nodular
4. acral lentiginous.

Superficial spreading melanoma

This is the commonest type of malignant melanoma and typically presents as a change in a pre-existing naevus on the trunk or limbs of an individual aged between 40 and 50 years (Figure 16.11). It appears as a flat, pigmented lesion with an irregular edge and non-homogeneous pigmentation. Histologically, the tumour cells often excite a localized lymphocytic response that appears to induce regression of parts of the tumour. Patients often complain of increases in growth, change in sensation or colour, crusting, bleeding or inflammation. The duration of these symptoms varies from patient to patient from a few months to several years.

Nodular melanoma

This is the second most common melanoma. Again usually arising in a pre-existing naevus, it has the appearance of a nodule growing from a pigmented area of skin usually on the head, neck or trunk of an individual aged between 50 and 70 years (Figure 16.12). Histologically, the tumour has a strong vertical growth component with relatively little radial growth. It usually has a shorter presentation because of a greater tendency to bleed or ulcerate.

Lentigo maligna melanoma

This is a slow-growing, flat, pigmented lesion, sometimes known as Hutchinson's melanotic freckle. It tends to exist for a

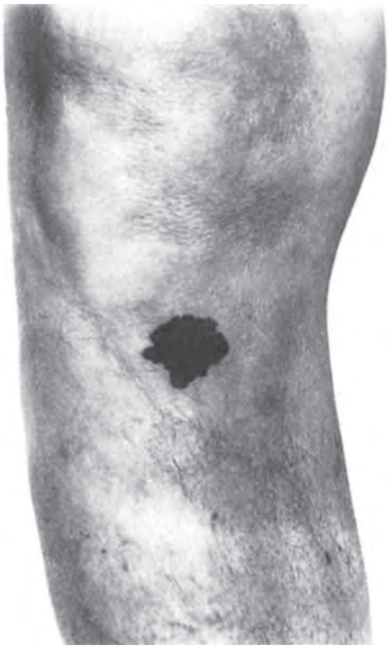

Figure 16.11 Superficial spreading melanoma in the subpatellar region.

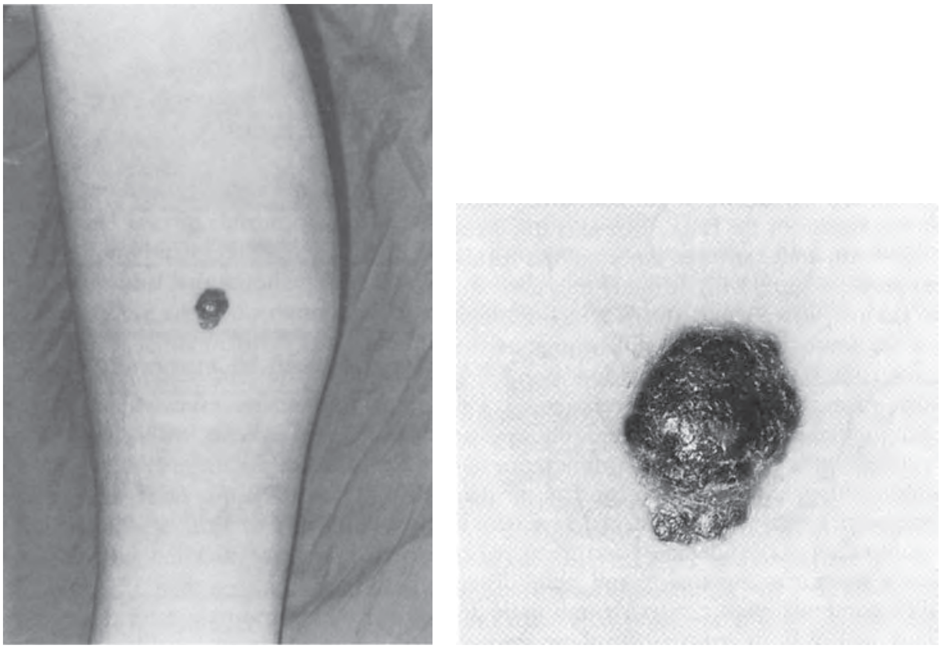

Figure 16.12 (a) Nodular melanoma of the arm; (b) close-up view.

long time in a premalignant state. It is relatively non-aggressive and rarely metastasizes. Lentigo maligna typically develops in sun-damaged skin, usually on the face of elderly individuals.

Acral lentiginous melanoma

This is the least common melanoma. It is used to describe melanomas arising in the nail beds or on the palmar or plantar skin. They tend to grow slowly and seldom metastasize.

Clinical features

The clinical features of a malignant melanoma vary according to the classification previously described in the pathology section. The most important principle to appreciate, however, is that melanoma may develop either in pre-existing naevi or as a *de novo* pigmented lesion in normal skin. The changes in a naevus that suggest malignancy include increase in size, loss of homogeneity with areas of darker or lighter pigmentation, irregularity of outline, nodularity, changes in sensation, crusting, bleeding, ulceration and inflammation. Itching may also be a feature and occasionally the patient may notice satellite lesions.

Diagnosis

Suspicious lesions should be dealt with urgently by excision biopsy which removes the entire lesion with a 2 mm surround of normal skin and underlying subcutaneous fat. Incisional biopsy should be avoided as malignancy may be missed and some clinicians believe that it may encourage metastatic spread, although evidence for this is lacking. Complete excision not only ensures a good histological specimen, enabling a definite diagnosis, but is also essential for the proper staging of the tumour (Clark levels). Another important consideration is the presence/absence of regional lymph node metastases and a careful palpation of the regional nodes is an essential part of the clinical examination.

Prognosis

The prognosis of a malignant melanoma is most accurately assessed by the histological depth of the tumour. In turn, this is measured by the depth of penetration (Breslow thickness) and the Clark levels of skin invasion by the tumour. There is substantial evidence that Breslow thickness is the single most important prognostic variable. However, the Clark level of invasion yields additional prognostic information in patients with a Breslow thickness of <1.5 mm. In particular, Clark level IV in lesions <1.5 mm are associated with significantly higher metastases.

Nodular melanoma is more prone to recurrence than superficial spreading melanomas, although when matched for stage and tumour thickness they have equivalent survival rates. Radial growth phase of a melanoma is a good indication that tumours with this growth characteristic are much less prone to metastases and are associated with a significantly better long-term survival than tumours with vertical growth phase. Ulceration is a well-established bad prognostic factor and is associated with an increased risk of visceral and bony metastases. Additionally, there is an established correlation between extent of ulceration and an increasingly unfavourable prognosis. The association between increased survival and the presence of tumour-infiltrating lymphocytes within the vertical growth phase component remains unproven. Histological evidence of lymphatic invasion is associated with in-transit metastases and early (within 12 months) locoregional cutaneous recurrence. Likewise, the presence of satellites also increases the risk of both local recurrence and metastatic spread. Various models have been used to predict survival in the individual patient. The most commonly used is the Cochran model, which predicts 3- to 10-year survival and is based on clinical data (age, sex and anatomical site) in combination with the Breslow thickness and the breadth of epidermal ulceration. The same model can be modified to calculate risk of recurrence by inclusion of histogenetic subtype and the regional lymph node status.

Breslow thickness

The Breslow thickness is measured from the granular layer of the epidermis to the deepest melanoma cell of the lesion in a fixed specimen. Breslow separated melanomas into three bands according to the prognostic significance of the depth of penetration. Tumours <0.76 mm in depth were accompanied by a 100% long-term survival; those between 0.76 mm and 1.5 mm have an unfavourable prognosis; and tumours >1.5 mm are uniformly associated with a bad prognosis. Thus prognosis deteriorates with increasing tumour thickness. However, in thin tumours which have stimulated an immune response resulting in the regression of tumour cells (superficial spreading melanoma), measurement of the Breslow thickness may be unreliable. In these cases, survival will be less than predicted for the apparent thickness.

Clark levels

Clark classified five levels of invasion of the skin by malignant melanoma in terms of the histological layers of the skin. The system requires accurate histological assessment of the penetration of the tumour through the defined layers of the dermis. It is subject to some interobserver variability and, for this reason, it is somewhat less accurate than Breslow thickness, which remains the gold standard in determining prognosis in the individual patient. The Clark levels are:

Level I	Tumour cells confined to the epidermis above the basement membrane.
Level II	Tumour cells present in the papillary dermis.
Level III	Tumour cells penetrating through the full depth of the papillary dermis to the level of the reticular dermis.
Level IV	Tumour cells in the reticular dermis.
Level V	Tumour cells in the subcutaneous fat.

Staging

In addition to the Breslow thickness and the Clark level of skin involvement, the staging of melanoma has to take into account metastatic spread (nodal and distant metastases). The simplest staging system is the McNeer and Dasgupta staging:

Stage 1	Primary tumour only with no evidence of metastases.
Stage 2	Primary lesion with metastatic spread to the regional lymph nodes detected on clinical examination.
Stage 3	Primary lesion with metastases to more than one lymph node group or distant metastases.

However, more detailed systems that enable better prognostic information and better management are used nowadays. This includes the American Joint Committee on Cancer (AJCC) and the tumour–node–metastasis (TNM) classification. The AJCC staging is as follows:

Stage 1A	Localized disease <0.76 mm or Clark level II.
Stage 1B	Localized disease 0.76–1.5 mm or Clark level III.
Stage IIA	Localized disease 1.5–4.0 mm or Clark level IV.
Stage IIB	Localized disease ≥4.1 mm or Clarke level V.
Stage III	Melanoma with involvement of regional lymph nodes.
Stage IV	Melanoma with advanced regional node involvement, multiple regional node group involvement or distant metastases.

The best characterization of the stage of the melanoma in the individual patient is, however, provided by the TNM system (Tables 16.3–16.5), which aside from indicating the appropriate management also enables reliable prognosis, certainly in terms of survival rate.

Treatment

The treatment of malignant melanoma is essentially surgical. The initial excision biopsy should be carried out with a sufficient margin to ensure complete local clearance. Following histological confirmation of the diagnosis and measurement of Breslow thickness, further treatment may be planned. The basic principle is wide excision to prevent local recurrence caused by micrometastases present in the skin at the time of the primary excision, but there is still some controversy surrounding the

Table 16.3 Tumour (T) classification

Breslow thickness	Ulceration	Stage	5 year survival
T1 ≤1.0 mm	a: Without ulceration and level II/III	1A	95%
	b: With ulceration or level IV or V	1B	90%
T2 1.01–2.0 mm	a: Without ulceration	IIA	90%
	b: With ulceration	IIB	78%
T3 2.01–4.0 mm	a: Without ulceration	IIA	78%
	b: With ulceration	IIB	65%
T4 >4.0 mm	a: Without ulceration	IIB	65%
	b: With ulceration	IIC	45%

Table 16.4 Node (N) classification

No. of metastatic nodes	Nodal metastatic mass	Stage	5 year survival
N1: 1 node	a: Micrometastases	IIIA	70%
	b: Macrometastases	IIIB	59%
N2: 2 or 3 nodes	a: Micrometastases	IIIA/B	63%
	b: Macrometastases	IIIB/C	59%
N3: 4 or more nodes or matted nodes or a combination of in-transit metastases/ satellites/ ulceration with nodes		IIIC	27%

Table 16.5 Metastasis (M) classification

Site	Lactate dehydrogenase	Stage	5 year survival
M1a: Distant skin, subcutaneous or nodal metastases	Normal	IV	15–20%
M1b: Lung metastases	Normal	IV	5–10%
M1c: All other metastases/ visceral		IV	8–10%

margin required to ensure complete clearance. Studies on comparison of 1 cm and 3 cm margins for tumours up to 2 mm thick have documented no overall difference in survival between the two groups. A 1.0 cm margin is thus considered adequate for melanomas <1 mm thick. For lesions between 1 and 2 mm thick a width excision of 1–2 cm is, however, considered necessary. The AJCC recommends the following:

- For pTis (melanoma *in situ*): a surgical excision margin of 2–5 mm to achieve complete histological excision.
- For pT1 (melanoma 0–1 mm thickness): a surgical excision margin of 1.0 cm.
- For pT2 (melanoma 1–2 mm thickness): a surgical excision margin of 1.0–2.0 cm.
- For pT3 (melanoma 2–4 mm thickness): a surgical excision margin of 2.0 cm.
- For pT4 (melanoma >4 mm thickness): a surgical excision margin of 2.0 cm.

However, a randomized controlled trial (RCT) (Meirion *et al.* 2004) involving 900 patients with melanoma undergoing excision randomly assigned to 1.0 cm or 3.0 cm margins showed that excision with a 1.0 cm margin was associated with significantly increased (168 recurrences) locoregional recurrences compared with the group with 3 cm margins (142 recurrences). In this RCT, there were 128 deaths attributable to melanoma in the group with 1 cm margins, as compared with 105 in the group with 3 cm margins, but this did not reach significance. Thus, a 1.0 cm margin of clearance is inadvisable for high-risk melanomas (defined by a tumour thickness of at least 2.0 mm) as it is associated with a significantly greater risk of regional recurrence than is obtained by a 3.0 cm margin.

Obviously the width of excision at sites of aesthetic and functional importance requires full clinical consideration but must not compromise complete clearance. The extent of the deep excision margin is equally important in all cases and should always include adipose tissue down to, but not including, the deep fascia. Following excision, the majority of wounds can be closed by primary skin closure but wide excisions will require plastic surgical reconstruction.

There is some controversy surrounding the treatment of regional lymph nodes in patients with stage I disease, i.e. those with localized disease with no clinically involved nodes. Reports on elective regional lymph node dissection in such patients have shown that tumour may be present in 5–25%. For this reason, some surgeons will perform an elective regional lymph node clearance in those patients with tumours thicker than 1.5 mm, even when the regional lymph nodes are impalpable. For patients with clinical lymph node involvement but no apparent distant metastases, it is generally agreed that block excision of regional lymph nodes should be performed. Following this, the 5 year survival is related to the original Breslow thickness, with 80% survival in patients with melanomas <3.5 mm and 27% survival in those with tumours with thickness >3.5 mm.

Probe-directed sentinel node dissection/biopsy is now well established in the management of patients with malignant melanoma. In this technique, patients with clinical stage I and II melanomas (i.e. without palpable lymph nodes) undergo intraoperative mapping of the regional lymph nodes. This is done by preoperative intradermal injection in the region of the tumour (or excision area) with ^{99m}Tc-labelled sulphur colloid or human serum albumin. The draining lymph nodes are then detected by a hand-held gamma probe (Figure 16.13) and the 'hot' node(s) identified and excised. If these sentinel nodes are proved by histology to contain tumour deposits, a block dissection of the regional node is carried out. There is good evidence that sentinel lymph node biopsy accurately determines the presence/absence of metastasis within the regional lymph nodes and is a useful staging tool in melanomas >1 mm. In thick melanomas (>4 mm) sentinel node biopsy can identify a subset of good prognosis melanomas which are node negative.

In patients with palpable nodes, fine needle aspiration (FNA) cytology should be used in the first instance to confirm the diagnosis of metastatic disease before block dissection is performed. Biopsy is performed if the FNA is inconclusive. In the groin, the block dissection should include the superficial inguinal nodes and the deeper obturator and iliac nodes (radical ilioinguinal) as this offers a survival advantage over the superficial inguinal dissection, although it is accompanied by increased morbidity and thus should be carried out by experts. The 10 year survival after complete ilioinguinal node dissection depends on the number of nodes involved and varies between 20% and 45%. Head and neck melanomas have the most variable pattern of lymph node metastasis and require a variety of types of neck dissection that may include the parotid or the posterior occipital chain nodes. There is no evidence that adjuvant radiotherapy after radical block dissection improves survival.

Other forms of treatment

These include isolated limb perfusion with melphalan and immunotherapy as adjuvant therapy for patients with stage II and III disease

Isolated limb perfusion

This is a surgical technique that effectively isolates the limb circulation enabling high-dose chemotherapy with melphalan to the limb within minimal systemic leakage and toxicity. It is used for the treatment of major limb recurrences. Isolated

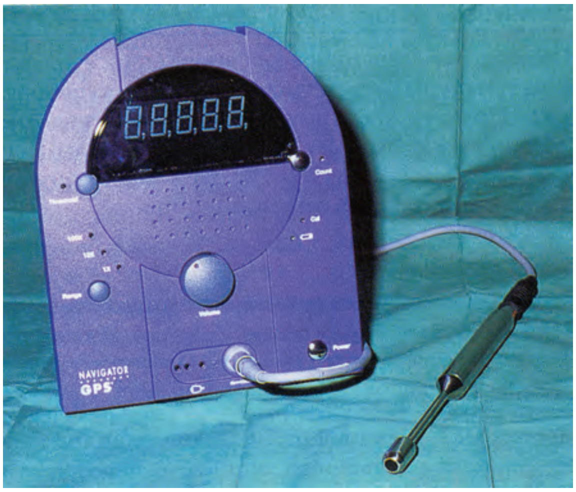

Figure 16.13 Hand-held gamma probe used for sentinel node biopsy.

limb perfusion is a highly specialized treatment that is carried out in regional centres only. A large prospective multicentre RCT showed that prophylactic isolated limb perfusion with melphalan is not indicated in high-risk primary limb melanoma.

Immunotherapy

This is based on the established observation that many primary melanomas undergo partial regression and, occasionally, complete regression. The two approaches proposed in patients with stage II or III disease are non-specific immune stimulation with interferon- and tumour-specific vaccines. Although several studies with interferon- have documented longer disease-free intervals after surgery, no trial has reported a significant increase in overall survival and, especially in view of the toxicity including marrow depression with adjuvant interferon, the current recommendation is that interferon therapy should not be used in patients with stage II or III disease other than in a trial setting.

Melanoma tumour vaccines are still in the research phase. One RCT (the Vaccinia Melanoma Oncolysate Trial) did not show an advantage for the vaccine. Another large RCT compared vaccinia melanoma cell lysates with no immunotherapy and found that vaccinia melanoma cell lysates did not significantly improve overall survival or relapse-free survival. Thus, as with interferon, melanoma vaccines are not in established routine practice for stage II or III disease but recruitment of suitable patients into vaccine trials is recommended.

Management of stage IV disease

This includes surgical excision (metastasectomy), chemotherapy and radiotherapy. Metastasectomy is a good option for patients with distant skin, node or visceral metastases. Surgical excision of single or localized metastases improves survival. However, the proportion of patients suitable for excision is limited to 10–25% of patients, with the 5-year survival varying from 14% to 33% in reported series, depending on the site (skin and lung being favourable), the number of metastases and the disease-free interval. Surgery is also indicated for spinal cord compression, and these patients require urgent referral to a neurosurgical centre as they do not benefit from chemotherapy or radiotherapy.

Dacarbazine is the standard single agent of choice in stage IV melanoma. Multiple drug regimens, including those with tamoxifen and interferon- , do not improve survival compared with single agent dacarbazine, which has an overall response rate of 20%. A meta-analysis comparing dacarbazine with combination chemotherapy, with or without immunotherapy, found no statistically significant benefit for multiple drug regimens compared with dacarbazine alone. Interferon- combined with dacarbazine does increase the response rate to 50% but does not improve survival. In a RCT, the Dartmouth regimen (dacarbazine, cisplatin, carmustine and tamoxifen) was compared with single agent dacarbazine. This showed significantly greater toxicity with the combination regimen though the response rate was higher (18.5% versus 10.2%), but again was not accompanied by a survival advantage. More recently, an oral preparation of dacarbazine (temozolomide) has been introduced and shown to have equivalent efficacy and better central nervous system penetration.

Radiotherapy is used for palliation of pain from bony deposits. Single-dose radiotherapy of at least 8 Gy provides effective palliation. In patients with cerebral metastases with good performance status and favourable response to corticosteroids, surgical resection is indicated in the absence of systemic disease. In patients with inoperable cerebral metastases, radiotherapy with systemic corticosteroids is used for palliation.

Tumours of fibrous tissue

Fibroma

This is a benign encapsulated fibrous nodule which may either form a soft subcutaneous nodule (fibroma mole) or a pedunculated lesion of the oral mucosa (fibroma durum). Both are treated by excision. A third variety, the pleomorphic fibroma, presents in adult patients as a slow-growing, dome-shaped papule most commonly in the limbs followed by the trunk, and head and neck. Histologically, it forms a well-circumscribed lesion composed of dense collagenous tissue with scant spindle, stellate and pleomorphic multinucleated giant cells with few if any mitotic figures. The stroma may exhibit myxoid change. Again treatment is by local excision.

Benign fibrous histiocytoma

This condition is also known as sclerosing haemangioma or dermatofibroma and forms a benign lesion usually in the arms and legs in adults. The lesions seldom grow beyond 1.0 cm and histologically they are made up of thin-walled capillary vessels surrounded by fibroblasts and histiocytes. Treatment is by local excision.

Malignant fibrous histiocytoma

Malignant fibrous histiocytoma (MFH) is the most common soft-tissue sarcoma occurring in late adult life and accounts for 20–24% of soft-tissue sarcomas. MFH originates either from the deep fascia or skeletal muscle usually in the limbs (70–75%), but may arise in the retroperitoneum where it usually presents late. MFH has also been reported in internal organs, e.g. lung, kidney, bladder, stomach, small intestine, and other sites including the orbit and central nervous system.

Pathology

The histogenesis of MFH is uncertain. The tumour contains both fibroblast and histiocyte-like cells in varying proportions, together with spindle and rounded cells. The several histological subtypes of MFH are:

1. *Storiform/pleomorphic MFH*: undifferentiated high-grade pleomorphic sarcoma in the World Health Organization (WHO) classification (most common subtype).
2. *Myxoid MFH*: myxofibrosarcoma in the WHO classification.
3. *Giant cell MFH*: undifferentiated pleomorphic sarcoma with giant cells in the WHO classification.

4 *Inflammatory MFH*: undifferentiated pleomorphic sarcoma with prominent inflammation in the WHO classification.
5 *Angiomatoid MFH*: tumour of uncertain differentiation (generally affects children and young adults and shows indolent behaviour with low metastatic potential).

Clinical features

The peak incidence of MFH is in the fifth and sixth decades but varies considerably. Although rare in children, the angiomatoid subtype may occur in patients younger than 20 years. MFH is more common in males with an male to female ratio of 2:1. It presents with an enlarging, painless soft-tissue mass most commonly in the muscle compartment of the thigh. Rapid enlargement is seen in pregnant females. Rarely, the patient may exhibit symptoms of episodic hypoglycaemia or has/develops a haematopoietic disorder (Hodgkin and non-Hodgkin lymphomas, multiple myeloma). Retroperitoneal MFH presents with constitutional symptoms, including fever, malaise and weight loss. In these patients, the tumour is usually large at presentation and may cause displacement of the organs: bowel, kidney, ureter and/or bladder. Distant metastases occur most commonly to the lung (90%) and less frequently to bone (8%). MRI is the imaging modality of choice for the diagnosis and staging of MFH because of its ability to provide superior contrast between tumour and muscle. CT is used for patients in whom MRI is not possible for any reason. As no single imaging technique can provide a specific histological diagnosis, biopsy is essential for the definite diagnosis.

The overall 5-year survival of patients with MFH ranges from 36% to 58% but is considerably worse for retroperitoneal tumours (15–20%). Otherwise, prognosis depends on the clinical stage, tumour grade, histological subtype, size of tumour and presence of distant metastases. Whereas patients with low-grade MFH have 10-year survival of 90%, this falls to 20% with high-grade lesions.

Treatment

Surgery is the mainstay of treatment. For MFH of the extremity, the surgical options are twofold: limb-sparing resection and amputation. As these result in equivalent survival rates, currently limb-sparing surgery is overwhelmingly the favoured treatment but is only indicated if it allows complete removal with reasonable residual limb function. With limb preservation, the resection for MFH may be either *wide* (removal of the entire tumour with margin of normal tissue) or *radical* (the entire compartment containing the tumour is removed).

External beam radiotherapy is administered routinely in all high-grade tumours as one RCT confirmed abolition of local recurrence compared with a 20% local recurrence in limb salvage surgery alone. The role of chemotherapy in the treatment of MFH remains uncertain, and currently chemotherapy is reserved for patients with metastatic disease.

Desmoid tumour (aggressive fibromatosis)

The term desmoid is derived from the Greek word *desmos*, which means a band or a tendon, and desmoid tumours arise from fascial sheaths or musculoaponeurotic structures. They are also known as aggressive fibromatosis, which better describes their cellularity and aggressive local behaviour. They originate from myofibroblasts in myoaponeurotic structures throughout the body. Desmoid tumours are infiltrative, usually well-differentiated tumours but have a marked tendency for recurrence. Although most commonly originating from the fascia of the rectus abdominis in women after childbirth and in incisional scars after previous abdominal surgery, desmoid tumours may arise in any skeletal muscle compartment. Desmoid tumours do not usually involve the overlying skin.

Sporadic desmoid tumours are rare and account for 0.03% of all neoplasms. Desmoid tumours are much commoner in patients with familial adenomatous polyposis (FAP) of the colon, the prevalence in these patients being variously reported at 9–13%. This genetic predisposition of patients with FAP to desmoid tumours is independent of the *APC* mutation.

Clinical features

Desmoid tumours are uncommon. The estimated incidence in the general population is two to four per million people per year. They occur in patients aged between 15 and 60 years. Desmoids are commoner in females than in males (female to male ratio of 1.2:1.0). The average age of reported cases is 41 years, with an age range of 10–60 years. The commonest sites of desmoid tumours are the anterior abdominal wall and shoulder girdle. Retroperitoneal tumours are more common in familial polyposis coli. There is usually a history of trauma (surgical intervention is present in 25% of cases). A biopsy is considered necessary for establishing the diagnosis.

From a clinical standpoint, desmoids commonly form smooth, firm, initially painless, mobile tumours arising in operation scars, e.g. after Caesarean section. They do not usually affect the overlying skin and their development should alert the surgeon to the possibility of FAP and hence the need for a detailed family history. Both intra- and extra-abdominal (limbs, scrotum) desmoids are rare. Intra-abdominal desmoid tumours remain asymptomatic until they reach a large size and then present with evidence of compression of adjacent organs: intestinal tract, ureter or vascular tree.

Aetiology

The exact cause of desmoid tumours is not known but trauma, hormonal and genetic factors appear to be involved. The role of hormonal factors is suggested as these tumours most commonly arise in young women during or after pregnancy and may regress with oral contraception, with tamoxifen treatment and during menopause. The estimated risk of developing a desmoid tumour in patients with FAP is between 4% and 20%. The desmoid tumours that occur in patients with FAP frequently develop in areas of previous surgical procedures, often in the scar of a Caesarean section. Trauma related to pregnancy and surgery and exposure to elevated hormone levels may both be contributory.

Treatment

The treatment of desmoid tumours consists of surgical excision, which must ensure tumour-free margins to reduce the marked tendency for recurrence (up to 50%). Medical therapy may be considered as an initial alternative, particularly for tumours that involve the intestines, blood vessels, nerves or organs. Other treatment modalities that are used in selected patients include radiotherapy and chemotherapy.

Medical therapy

Mostly this is with non-steroidal anti-inflammatory drugs, e.g. sulindac usually in combination with an antioestrogen (tamoxifen). Although this usually results in detectable symptomatic improvement, significant shrinkage occurs in only a small minority of patients. Desmoids may respond to the tyrosine kinase inhibitor imatinib, presumably because of expression of one of imatinib's molecular targets – the platelet-derived growth factor receptor. Antifibrotic agents, e.g. pirfenidone, have been used recently and although promising the reported experience is still very limited.

Radiotherapy

This is an effective alternative option to surgery for some patients and may be used as an adjunct to surgical excision. Radiotherapy is, however, contraindicated in intra-abdominal desmoids in view of their large size at the time of presentation and involvement of vital structures.

Chemotherapy

Chemotherapy may be effective in patients with unresectable tumours. It is used if tumours do not respond to tamoxifen and/or sulindac. Low-dose chemotherapy with methotrexate and vinblastine produces good response rates, particularly in children. Liposomal doxorubicin has shown promising response rates. Low-dose chemotherapy is usually administered for a year and then stopped. In view of systemic toxicity, aggressive high-dose chemotherapy with doxorubicin and dacarbazine is reserved for patients unresponsive to other therapies or with very rapidly growing/symptomatic tumours.

Other options

Other treatment options include intralesional therapy with acetic acid and radiofrequency ablation but these have been limited to a few centres without sufficient reported data to adjudicate their efficacy in shrinking the tumour (see also Chapter 21).

Fibrosarcoma

Fibrosarcoma (Figure 16.14) is a malignant neoplasm of mesenchymal cell origin in which histologically the predominant cells are fibroblasts. It forms 5% of all primary bone sarcomas, is locally invasive and prone to distant metastases. The tumour affects men and women with equal frequency and can occur at any age, but most commonly presents between the third and sixth decades. In older patients, fibrosarcoma may originate from a pre-existing benign lesion, e.g. chronic osteomyelitis, burn scars, in areas of previous irradiation and fibrous dysplasia.

On histology the tumour is classified as low or high grade. Low-grade fibrosarcomas have abundant collagenous stroma, few cells and mitotic figures. These are the better differentiated tumours and have a relatively good prognosis. In contrast, high-grade fibrosarcomas have abnormal fibroblasts arranged in a herringbone pattern with giant cells and mitotic figures and exhibit a poor prognosis. The prefix A (stage I) is used for tumours that remain within the anatomical compartment at the time of presentation, and B (stage II) when the fibrosarcoma involves adjacent compartments. Stage III is used to describe tumours of any grade that have metastasized. The majority of fibrosarcomas present at stage IIB. Distant spread from fibrosarcoma is to other bones, lymph nodes, brain, subcutaneous tissue, muscle and visceral organs, but rarely to the lung.

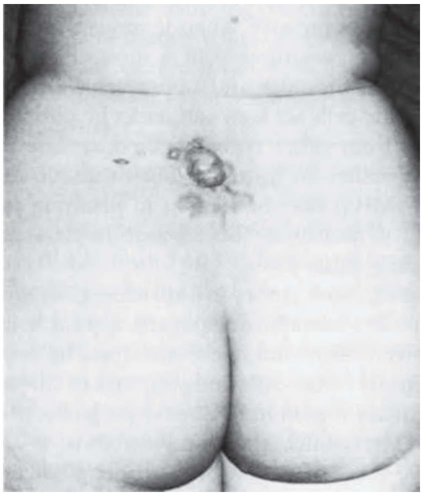

Figure 16.14 Fibrosarcoma.

Surgical resection is the standard treatment for fibrosarcoma. Chemotherapy is administered to patients with stage IIB or III disease usually before surgery (neoadjuvant chemotherapy). Radiotherapy is only used for palliation. Surgery consists of amputation or limb salvage surgery, which is possible with advances in adjuvant chemotherapy, surgical technique and implant development. Amputation is, however, indicated for unresectable lesions, local recurrence, failure of previous reconstruction and for certain tumour locations which preclude functional reconstruction. Although amputation avoids the complications associated with limb salvage (non-union, implant infection and implant failure) and has a lower local recurrence rate, it does not impart a survival advantage over limb salvage surgery.

Prognosis in fibrosarcoma is largely dependent on the histological grade. Survival rates from 50% to 80% have been reported in low-grade and surface fibrosarcomas. Other factors associated with a poor survival include age over 40 years and advanced stage of disease at presentation.

Dermatofibrosarcoma protuberans is a rare form of fibrosarcoma which presents clinically as one or more red or bluish dermal nodules usually on the trunk or shoulders. These tumours tend to occur in young adults and although they grow slowly they may suddenly start to enlarge and ulcerate. They are extremely locally aggressive but metastatic disease is relatively rare. On histology there are non-collagenous fibroblasts arranged in bundles around a central acellular area producing a characteristic cartwheel appearance. Treatment is by wide local excision.

Tumours of muscle

Rhabdomyoma

There are very rare benign lesions of striated muscle and consist of two types:

- true benign tumours:
  - adult
  - fetal
  - genital
- hamartomas:
  - cardiac rhabdomyoma
  - rhabdomyomatous mesenchymal hamartoma of skin.

The adult rhabdomyoma occurs predominantly in the head and neck region including the tongue of men aged 25–40 years as a round or polypoid mass. Fetal rhabdomyoma occurs in children aged between birth and 3 years also in the head and neck. The genital type affects the vagina or vulva of middle-aged women and may cause dyspareunia.

Cardiac rhabdomyoma arises in fetal life and involves both ventricles and interventricular septum. It presents in children and may be associated with tuberous sclerosis of the brain, sebaceous adenomas and hamartomas in other organs. Rhabdomyomatous mesenchymal hamartoma presents in newborns and infants as a lesion in the subcutis, which on histology exhibits skeletal muscle bundles, fibrous tissue, fat and nerves.

Treatment of rhabdomyomas is by local excision.

Rhabdomyosarcoma

Rhabdomyosarcoma is a malignant mesenchymal tumour that arises from primitive muscle cells. It is a disease of children and adolescents, with the vast majority of tumours (90%) occurring below 15 years, the disease being very rare in adults. Several distinct histological types of rhabdomyosarcoma that influence the clinical course and prognosis of the disease are recognized. The cause of rhabdomyosarcoma is unknown, although genetic factors are probably involved as several genetic syndromes are associated with increased prevalence of the disease, e.g. neurofibromatosis, *Li–Fraumeni* syndrome (germline mutation of the tumour suppressor gene *p53*), *Gorlin's basal cell naevus syndrome, Beckwith–Wiedemann syndrome* and *Costello syndrome.*

Pathology and types of rhabdomyosarcoma

Several distinct histological types are recognized and these influence the prognosis. The most common type accounting for 55% of cases is *embryonal rhabdomyosarcoma*, which carries the best prognosis and is frequently found in the head and neck and in the genitourinary organs. *Botryoid* (resembling grapes) *rhabdomyosarcoma* is a subtype of rhabdomyosarcoma that affects hollow organs, e.g. urinary bladder and the vagina in young girls. *Spindle rhabdomyosarcoma* is the usual type affecting the testicular region in young boys. Other types include *alveolar rhabdomyosarcoma*, which has septa and thus resembles pulmonary alveoli, and *undifferentiated sarcoma*. The botryoid variant arises in mucosal cavities, e.g. bladder, vagina, nasopharynx and middle ear, whereas the alveolar type is most commonly encountered in the extremities. The two types associated with a poor prognosis are the alveolar and undifferentiated rhabdomyosarcoma. Distant metastases occur predominantly in the lungs, bone marrow, lymph nodes, breasts and brain.

Clinical features

The overall annual incidence of rhabdomyosarcoma is six cases per 1 000 000. The disease is more common in males, with a male to female ratio of 1.4:1. The most common sites of the disease are the head and neck (28%), followed by limbs (24%) and genitourinary tract (18%). Other less common sites include the trunk (11%), orbit (7%) and the retroperitoneum (6%). Children aged 2–6 years tend to develop rhabdomyosarcoma either in the head or the genitourinary system. In contrast, in adolescents rhabdomyosarcoma affects the limbs, trunk and testicular/scrotal regions.

Rhabdomyosarcoma usually presents as an expanding mass, the location of which determines the symptoms in the individual patient. Thus, orbital tumours cause proptosis and dysconjugate gaze; vaginal rhabdomyosarcoma presents as a protruding polypoid mass; it is a painless testicular/paratesticular mass in young boys; and is an initially painless enlarging mass of the extremities in adolescents of either sex, etc. Metastatic disease presents usually with bone pain or respiratory difficulty/breathlessness from pulmonary metastatic disease and pleural effusion. In advanced disease, anaemia, thrombocytopenia and neutropenia are usually present and, for this reason, disseminated rhabdomyosarcoma may mimic leukaemia.

The clinical staging of rhabdomyosarcoma determines the treatment in the individual case. The current clinical system of staging is based on extent of tumour and on residual disease after resection (Table 16.6).

Approximately 60–70% of newly diagnosed patients with non-metastatic disease can be cured with combined modality therapy. Despite aggressive multimodality treatment, <20% of patients with metastatic rhabdomyosarcoma are currently cured of their disease. Analysis of data from the Surveillance, Epidemiology, and End Results (SEER) programme indicates that mortality is related to age, site and histology, the 5-year survival being highest in children aged 1–4 years (77%) and

Table 16.6 Clinical system of staging of rhabdomyosarcoma

Clinical group	Extent of disease
IA	Tumour confined to the site of origin; resected completely
IB	Tumour extending beyond the site of origin but resected completely
IIA	Tumour with microscopic localized disease after resection
IIB	Extensive tumour + regional node spread, resected completely
IIC	Extensive tumour + positive regional nodes with microscopic residual disease
IIIA	Extensive tumour with positive lymph nodes, gross residual disease after biopsy only
IIIB	Locally extensive residual disease after ≥50% debulking
IV	Any tumour with distant metastases

worst in infants and adolescents. Orbital and genitourinary sites are associated with good 5 year survival (80%), whereas with tumours of the extremities, retroperitoneum and trunk survival is lower and averages 50%.

Treatment

The treatment of rhabdomyosarcoma depends on the stage of the disease, but is always multimodal with surgery, radiotherapy and prolonged chemotherapy.

Surgery

Complete surgical resection is recommended provided it is not mutilating. When complete resection is not possible, neoadjuvant chemotherapy is initiated after the procurement of a biopsy and this is often combined with radiotherapy. Second-look surgery is undertaken in patients who do not achieve a complete remission, with resection of residual disease. However, it is not known whether this improves survival.

Radiotherapy

Radiation therapy is used for sites such as the head and neck or pelvis, where complete surgical excision is not possible. For residual microscopic disease, doses of 4000–4500 cGy are used but a higher dose (5000 cGy) is considered necessary for gross residual disease and for tumours >5 cm.

Chemotherapy

This is necessary as even localized rhabdomyosarcoma usually has micrometastatic disease. The development of adjuvant and neoadjuvant therapy has increased survival in patients with localized disease to approximately 60%. The cytotoxic drugs that are active and used in different combination chemotherapy regimens are vincristine, actinomycin D, doxorubicin, cyclophosphamide, ifosfamide and etoposide. Although vincristine, actinomycin D and cyclophosphamide is the gold standard combination chemotherapy regimen for rhabdomyosarcoma, other combinations are used. Patients with metastatic disease have a poor prognosis despite aggressive therapy.

Tumours of adipose tissue

Lipoma

Lipomas are benign tumours of adipose tissue and they are among the commonest of all benign neoplasms. They may occur in any organ as fat is present throughout the body but they are most often found in the subcutaneous tissue of the neck and shoulders, chest and thigh. The incidence of lipomas increases over the age of 40 and they are more commonly found in women than in men. Histologically, lipomas are usually simple but there are several other types that are defined by their histological appearance. Fibroblastic or spindle cell lipomas are made up of fat cells and fibroblasts in a myxomatous stroma. These are benign but may be difficult to distinguish from liposarcomas on histology. Angiolipomas are characterized by a dense vascular plexus.

Clinically, a lipoma presents as a slow-growing asymptomatic mass in the subcutaneous tissue. Occasionally, deeper lipomas may cause nerve compression and are then associated with paraesthesia, pain and other functional problems. On examination, they are typically circumscribed, non-tender and are characteristically mobile, as they are not attached to skin. Small lipomas may be difficult to palpate as they slip from under the examining fingers. Angiolipomas are characterized by pain, and *Dercum disease* (adiposa dolorosa) is a syndrome in which diffuse adipose tissue is deposited around the ankles, knees and elbows in menopausal women. This is often associated with pain.

Although most lipomas are subcutaneous, they may infiltrate fascia, muscle, periosteum or bone. They may recur after excision, but do not behave like malignant tumours. The treatment of a single lesion is excision in order to obtain histological diagnosis. Patients who have multiple lipomas should only have those lesions excised that are causing problems. If these are confirmed histologically as lipomas, it is safe to assume that the other lesions are similar.

Liposarcoma

These malignant tumours of adipose tissue are rare but must always be considered in the differential diagnosis when a lipoma is suspected. Unlike lipomas, liposarcomas usually arise from deeper tissues. They occur most frequently in older patients and are commoner in men than in women. The commonest sites are the limbs and the retroperitoneum. Histologically, liposarcomas are classified according to their malignant potential into five subtypes:

1. well differentiated
2. myxoid
3. fibroblastic
4. lipoblastic
5. pleomorphic.

The *well-differentiated* subtype is made up of mature adipocytes which show some pleomorphism and occasional mitotic figures. These tumours have a good prognosis. They do not metastasize but are invasive and tend to recur locally. The second subtype, *myxoid liposarcoma*, consists of pleomorphic adipocytes and preadipocytes and fibroblast-like cells or prolipoblasts. This subtype is commonly found in the groin, thigh, trunk, popliteal fossa and the retroperitoneum. It is most commonly seen in the fifth and sixth decades of life. These tumours may metastasize and have a 50% risk of local recurrence after excision. The *fibroblastic* subtype is made up largely of prolipoblasts with a few preadipocytes. It presents clinically very much as the myxoid liposarcoma but has a poor prognosis with a 62% recurrence rate after surgical excision. *Lipoblastic liposarcoma* is made up of round cells with preadipocytes and lipoblasts in a myxoid stroma. This tumour shows a similar malignant potential to the fibroblastic type. The *pleomorphic liposarcoma* is made up of undifferentiated cells with a high mitotic rate. The tissue of origin is demonstrated by the presence of occasional preadipocytes, lipoblasts or intracytoplasmic hyalin globules. This tumour has a strong tendency to metastasize and is associated with a very poor prognosis.

Treatment of liposarcoma is by wide excision, and for the less differentiated types radiotherapy should be considered either as adjuvant treatment or as an alternative when surgical excision is impossible or incomplete.

Tumours of the lymphatic system

Lymphangioma

Lymphangiomas are thought to arise from failure of the lymphatics to connect to the venous system, from abnormal budding of lymphatic tissue or from sequestered lymphatic rests during embryonic growth. There is some evidence that vascular endothelial growth factor C and its receptors may be involved in the development of lymphangiomas. Whatever the exact cause, the abnormal 'lymphatic rests' penetrate adjacent structures and fascial planes during embryonic development, and, as their lining retains secretory function, they form cystic lesions that do not communicate with the venous system. The nature of the tissues that the developing lymphangiomas permeate determines their eventual type: *capillary, cavernous or cystic*. Thus, cystic hygromas (see below) tend to occur in loose areolar tissues, whereas in muscle lymphangiomas tend to be of the capillary or cavernous types.

Giguere *et al*. have proposed categorization of lymphangiomas based on the size of the cystic component, as follows:

- macrocystic: cystic spaces of at least 2 cm
- microcystic: spaces <2 cm
- mixed lesions.

Lymphangioma simplex arises in the skin or mucosa and is common on the tongue. Several cystic lesions may occur together and this is called *lymphangioma circumscripta*. Treatment is usually by excision, although recurrence is relatively common. Electrocoagulation and argon laser therapy have also been used to good effect. The *cavernous lymphangiomas* are more extensive than lymphangioma simplex. They occur at any time between birth and about 20 months of age. They resemble cavernous haemangioma but lack the blue colour seen with this lesion. Initially, they are soft but after repeated infections they become fibrotic. Some may resolve spontaneously and if this occurs it happens usually before the age of 8 years. If they persist after this age then treatment should be by wide surgical excision if this is possible.

Lymphangiomas may also be acquired as a result of trauma, including surgery and inflammatory conditions leading to obstruction/destruction of the lymphatic channels. Acquired lymphangiomas give rise to swelling of the limb from lymphoedema.

Cystic hygroma

Cystic lymphangioma, more commonly referred to as cystic hygroma, is a cystic lymphatic lesion that may occur at any site, but 75% of lesions affect the head and neck with a left-sided predilection usually in the posterior triangle. The next most common site of cystic hygroma is the axilla (20%). Other less frequent sites include the mediastinum, groin and retroperitoneum. Morbidity depends on the anatomical location and is related to cosmetic disfigurement, bleeding into the cyst causing sudden enlargement, infection and compression of vital structures, e.g. airway, nerves and vessels.

Clinical features

The incidence of cystic hygroma is estimated to be one case per 6000–16 000 live births. Most cystic hygromas (50–65%) are present at birth, and the majority (80–90%) present within the first 2 years of life. Signs and symptoms of cystic hygroma vary, depending on location. Most commonly, cystic hygromas are located below the mylohyoid muscle either in the anterior or posterior triangles of the neck.

de Serres *et al*. have proposed the system shown in Table 16.7 for staging of cystic hygroma of the head and neck, which has practical importance in terms of associated morbidity.

Cystic hygromas are typically soft, painless, compressible masses which transilluminate vividly. At presentation, the cysts are typically large and thick walled with little involvement of surrounding tissues and a normal/slightly bluish tinged overlying skin. Although most cystic hygromas are multicystic, in 10% of cases they consist of a unilocular cyst. Cysts can range from 1 mm to several centimetres in size. They are filled with clear to straw-coloured protein fluid and are surrounded by a fibrofatty stroma that contains lymphoid aggregates or smooth muscle.

Cystic hygromas may enlarge and present after an upper respiratory or secondary infection and, more rarely, intracystic haemorrhage. Less commonly, children with cystic hygroma may display symptoms of obstructive sleep apnoea from lesions located in the supraglottic/paraglottic regions. These children may present acutely with stridor and cyanosis. Other symptoms include feeding difficulties and failure to thrive. Cystic hygroma is reported to be more common in patients with Turner, Down and Klinefelter syndromes, although these are not aetiologically related.

The imaging tests used in the diagnosis of cystic hygroma are ultrasonography and MRI. CT scanning should be avoided because of the radiation hazard in infants and children.

Treatment

Expectant treatment is indicated only in patients without symptoms and a static condition; otherwise, active treatment is necessary. The medical treatment of cystic hygroma consists of aspiration and instillation of sclerosing agents, e.g. OK-432 (Picibanil; an inactive strain of group A *Streptococcus pyogenes*), ethanol, sodium tetradecyl sulphate and doxycycline. OK-432 works best for large unilocular cysts. Fibrin sealant has also been reported recently to give good results

However, only surgical resection offers the potential for cure. In the absence of urgent symptoms, surgery can be delayed until the child is aged 2 years. Complete removal offers the best

Table 16.7 Staging of cystic hygroma of the head and neck (after de Serres *et al.*)

Stage	Complication rate
Stage I: unilateral infrahyoid	17%
Stage II: unilateral suprahyoid	41%
Stage III: unilateral and both infrahyoid and suprahyoid	67%
Stage IV: bilateral suprahyoid	80%
Stage V: bilateral infrahyoid and suprahyoid	100%

chance of cure. If this is not possible because of risk of damage to vital structures, as much as possible of the lesion is removed, accepting an increased risk of recurrence. Complications of surgical excision of cystic hygroma include damage to cranial nerves, chylous fistula, chylothorax, haemorrhage and recurrence. Most recurrences occur within the first year.

Lymphangiosarcoma

Lymphangiosarcoma is a rare (fewer than 250 cases reported in the literature) malignant neoplasm arising from the endothelium of blood vessels or lymphatics in patients with longstanding congenital or acquired lymphoedema. The vast majority of cases have been reported in association with postmastectomy lymphoedema, when is usually referred to as Stewart–Treves syndrome. Rarely, the disease may develop in patients with congenital hereditary and non-hereditary lymphoedema. Hereditary lymphoedema is of two distinct types: the lymphoedema is present at birth or develops in early childhood (Milroy disease), and late onset disease, which may develop between the first decade of life and late puberty (Meige syndrome). Very rarely, lymphangiosarcoma may develop in patients with non-hereditary types of lymphoedema including filariasis.

In the Stewart–Treves syndrome, lymphangiosarcoma develops in the grossly oedematous upper limb some 10–20 years after radical mastectomy. The tumour forms purplish papules or nodules which may coalesce or undergo necrosis and ulceration. The prognosis is poor because of the tendency to both local recurrence and distant metastases, especially to the lungs. The treatment consists of neoadjuvant radiotherapy followed by ablative surgery. Lymphangiosarcoma is not responsive to chemotherapy. The overall reported 5 year survival is 20%.

Vascular tumours

The majority of vascular tumours are benign. Previous classifications were based on their clinical appearance, the architecture of the vascular channels and the embryology. However, Mullikan has introduced a classification based on cellular activity, which has been generally accepted because of its important clinical implications. Vascular abnormalities can be divided into true haemangiomas and vascular malformations. The term *haemangioma* should be restricted to those lesions which grow by proliferation of endothelial cells. Clinically, they are absent at birth and tend to grow rapidly in a proliferative phase for the first year of life. During this time their growth is disproportionately high with respect to the child's growth. The lesions then enter an involutional phase during which they regress spontaneously. *Pyogenic granulomas* are included in this category. *Vascular malformations* on the other hand are structural abnormalities that result from embryonic defects in morphogenesis. These grow in parallel with the patient's growth and do not regress. Many lesions which were formally termed cavernous haemangiomas fall into this group.

Haemangiomas

Haemangiomas constitute the commonest tumour of childhood and affect 10–12% of white children at 1 year old. They occur predominantly in the head and neck but are also found on the trunk and limbs (Figure 16.15). The diagnosis is based on clinical grounds and relies on a history of a lesion arising soon after birth and growing initially at a rate higher than the child's growth.

A superficial haemangioma or *strawberry naevus* is bright red and raised with a characteristic appearance. As it begins to involute, generally in the second year of life, it develops a pitted appearance. Deeper lesions may appear blue through the overlying skin. Because of rapid enlargement, haemangiomas may give rise to a number of complications. About 5% ulcerate and a few develop infection. The resulting tissue destruction can be severe and these are referred to as wildfire haemangiomas.

Occasionally the anatomical position of a haemangioma may cause problems, e.g. haemangiomas of the respiratory or alimentary tracts may give rise to obstruction and haemangiomas on the eyelid may result in amblyopia and failure to develop binocular vision. Bleeding may occur locally or, rarely, the patient may develop platelet thrombi within the haemangioma, leading to a consumptive thrombocytopenia (*Kasabach–Meritt syndrome*). These patients require steroid therapy. In general, the treatment of haemangioma should be expectant, although occasionally, when there is severe bleeding or infection, excision may be required.

Pyogenic granuloma (lobular capillary haemangioma)

Inaptly named 'pyogenic granuloma', nowadays this condition is referred to as lobular capillary haemangioma as it is neither infectious nor granulomatous in origin, although its aetiology remains unknown. Instead it consists of a localized proliferative vascular lesion common in children and young adults, typically

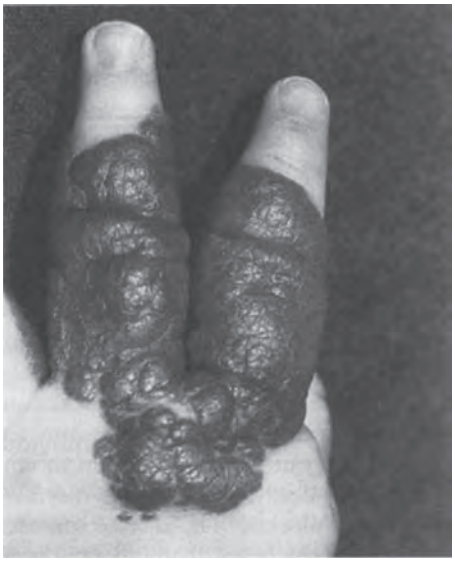

Figure 16.15 Haemangioma.

found on the face or limbs. There may be a history of trauma but usually it arises spontaneously and forms a cherry-red pedunculated lesion that often ulcerates and may become infected or bleed. The condition may also arise in pregnancy (pregnancy tumour) and, less commonly, with oral contraception either in the gingiva or elsewhere in the oral mucosa. As with other types of haemangioma it may involute if treated expectantly, but, if bleeding or infection occurs, the lesion may be treated by silver nitrate cautery, electrocoagulation or surgical excision.

Vascular malformations

As indicated above, vascular malformations (hamartomas) are structural abnormalities which are determined during embryological development. This may result in a capillary, venous, lymphatic or combined abnormality. Any of these can produce a low-flow malformation. In some cases, however, an arteriovenous fistula may develop, leading to a high-flow malformation.

Port-wine stain

The port-wine stain is a low-flow capillary malformation, sometimes called a capillary haemangioma or *naevus flammeus*. It presents at or soon after birth as a flat area of discoloration. Initially it is pink or scarlet but with age it deepens to purple. It grows in parallel with the patient's growth, but with increasing age it may become macular, giving a cobblestone type of appearance. On histological examination, it is made up of mature vascular endothelium. Port-wine stains on the trunk and limbs may be associated with lymphatic or venous abnormalities (*Klippel Trénaunay syndrome*). Port-wine stains of the face may be associated with underlying abnormalities of the meningeal and choroid plexus vasculature, resulting in focal seizures (*Sturge–Weber syndrome*). Port-wine stains are best treated using photocoagulation with a tuneable dye laser. This lightens the colour of the lesion and reduces the cobblestone effect in older lesions. Very rarely, excision and skin grafting may be necessary.

Capillary lymphatic malformations

These lesions, also known as *lymphangioma circumscriptum* or *verrucous haemangiomas*, are commonly found on the limbs and trunk. They present at birth as clearly demarcated raised red areas. With age they become hyperkeratotic, giving them a warty appearance. On histology they are made up of dermal and subcutaneous vessels and lymphatics. Treatment, when necessary, is by surgical excision and it is important to remove any deep extensions of the lesion to prevent recurrence.

Angiokeratoma

Angiokeratomata are abnormalities of the microvasculature presenting as dark red/purple spots up to 1.0 cm in diameter and sometimes with a rough scaly surface and composed of dilated capillaries. There are four types: (1) sporadic, (2) angiokeratoma of Fordyce, (3) angiokeratoma circumscriptum and (4) Fabry syndrome (*angiokeratoma corpus diffusum*). The sporadic type (angiokeratomata of Mibelli) forms solitary lesions on the hands and feet in patients over 40 years old. The angiokeratomata of Fordyce are found in linear groups most commonly on the scrotum, but also on the shaft of the penis, labia major, vulva, inner thigh and lower abdomen. Angiokeratoma circumscriptum often presents as a birth mark but may develop later in life. It is commoner in females and usually consists of a localized cluster of lesions in the leg or trunk. Fabry disease is a rare, serious, inherited sex-linked recessive disorder of glycolipid metabolism (deficiency of -galactosidase A), which results in abnormal deposits of glycophospholipids in the blood vessels and internal organs. Aside from multiple angiokeratoma, these patients often develop fever and painful hands and feet (acroparaesthesias) and corneal and lenticular changes. They are prone to develop renal failure, strokes and hypertensive cardiovascular disease.

Telangiectasia

The telangiectasia lesion is known as a spider naevus and consists of a dilated vessel with radiating branches. It is commonly found on the face, arms and chest and, because of its vascular nature, it blanches on pressure over the central feeding vessel. Spider naevi are found in pregnancy and in liver cirrhosis, in which they are thought to be related to high oestrogen levels. Hereditary haemorrhagic telangiectasia (Osler–Weber–Rendu disease) is characterized by multiple telangiectasia and is complicated by widespread bleeding and the late development of arteriovenous pulmonary malformations. Individual spider naevi rarely require treatment but, if removal is required for cosmetic reason, thermocoagulation may be used.

Venous malformations

Venous malformations are also known as cavernous haemangiomas. Clinically they are soft, compressible and non-pulsatile and may present in any site. They are often dark blue, but in deep tissue when they are covered by skin they may have a normal colour. If combined with a capillary malformation they may be dark red. The adjacent bone may become distorted or hypertrophied in response to the blood flow through the lesion. Phlebothrombosis may develop within the abnormality, giving rise to pain and induration of the lesion. Minor injury may lead to rapid enlargement of the vessels or the formation of the arteriovenous fistula. Treatment of venous malformations must be planned by delineating the extent of the abnormal vessels. Angiography can confirm the venous nature of the lesion and define feeding vessels, and MRI may be useful to define the extent of the lesion, which is not seen on angiography. Treatment depends on the size of the lesion and its anatomical site, but may consist of intravascular coagulation, selective arterial embolization of feeding vessels or surgical resection.

Arteriovascular malformations

Compared with low-flow abnormalities, high-flow vascular malformations are rare. They tend to occur on the head and neck and limbs and may arise from an innocent low-flow capillary vascular malformation. Trauma or the hormonal changes of puberty and pregnancy may precipitate the formation of arteriovenous communications in such a lesion. Clinically they present as a raised, warm lesion with a palpable thrill and a bruit on auscultation. The overlying skin may become ischaemic and the lesion may haemorrhage spontaneously or as a result of relatively minor trauma. The high flow may cause gigantism of the limb or the digit and the pulsatile flow may erode bony structures. There may also be a systemic effect as the shunt effect of the fistula may give rise to cardiac failure. Treatment of an arteriovascular malformation generally involves surgical excision, although preoperative embolization may help to reduce intraoperative blood loss.

Malignant vascular tumours

Haemangiopericytoma

Haemangiopericytoma is a rare tumour that usually occurs in adult life (fifth decade) and less commonly in children (10% of cases). Haemangiopericytoma arises from pluripotential cells (pericytes) in the walls of capillaries. Multiple molecular genetic changes are involved in the oncogenesis of haemangiopericytoma, including activation of certain oncogenes of the insulin-like growth factor family.

Clinically, haemangiopericytoma forms a deep soft-tissue tumour (usually muscle, rarely subcutaneous or dermal), which may occur anywhere including the brain, but the most common sites are the lower limbs, pelvis and head and neck regions. Clinical presentation is with a slowly enlarging painless mass, with pain becoming a feature only in advanced disease. Rarely haemangiopericytoma may present with hypoglycaemia owing to the inappropriate secretion by the tumour of an insulin-like growth factor. Prognosis is worse in adults with haemangiopericytoma, with the development of systemic metastases (commonly lungs and bones) and a 5 year survival of 50%.

Treatment

Haemangiopericytoma is treated by complete surgical excision, which remains the mainstay of treatment. Preoperative ligation or vascular embolization of the afferent vessels is indicated for large tumours, largely to reduce blood loss during removal. Chemotherapy and radiotherapy are indicated in patients in whom complete resection is not possible and in large locally invasive tumours. Adjuvant postoperative radiotherapy (50 Gy) is recommended even in patients with complete excision in view of the reported improved local control.

Kaposi's sarcoma

Kaposi's sarcoma (KS), first described in 1872 by the Hungarian dermatologist Moritz Kaposi, used to be a rare vascular tumour affecting elderly men of Italian or Eastern European Jewish ancestry. However, nowadays, the neoplasm is encountered in several other populations – young and adult black African males, patients on long-term immune suppression after allograft transplantation and homosexual HIV-negative males – in addition to the fulminant form of KS, associated with HIV disease and referred to as epidemic KS. Although the histopathology of the different clinical types in these various patient groups is essentially the same, the clinical manifestations, course of the disease and prognosis differ considerably from one group to the other. The human herpes gamma virus type 8 (HHV-8), also known as KS herpes virus (KSHV), is present in all biopsies of KS irrespective of type and is absent in non-involved tissue, indicating an aetiological role for HHV-8.

Kaposi's sarcoma-associated herpesvirus

In view of its aetiological importance to the development of KS and, indeed, other lymphoproliferative disorders, it is necessary to outline the nature, epidemiology, transmission and pathological consequences of human infection with this virus. It was first isolated by Chang *et al.* in 1994 from a KS skin lesion from a patient with AIDS. The virus is now referred to as KSHV or HHV-8. Since then, it has been documented that virtually all KS lesions, irrespective of clinical subtype, are infected with KSHV. Hence, there is little doubt that this virus is the primary factor in the aetiology of KS. However, an important cofactor in the development of clinical KS is immunosuppression of the host. In this sense, therefore, KS differs from other neoplasms in that reactivation of KSHV in the immunocompromised host is necessary for its development. It remains uncertain whether the KS lesions are composed of neoplastic cells harbouring specific cytogenetic alterations (mutations, rearrangements and amplifications) or are, in essence, the result of HHV-8-induced abnormal intracellular signalling pathways that modulate the expression of cellular genes associated with cell cycle regulation, apoptosis, inflammatory response and angiogenesis. According to this viewpoint, these are not true tumours but represent a reactive angioproliferative disorder. KSHV is also associated with the development of other lymphoproliferative disorders, e.g. body cavity-related -cell lymphoma and some plasma cell forms of multicentric Castleman disease.

KSHV is transmitted by sexual and other means. Sexual transmission is more common with homosexual (anal recipients) than heterosexual contact, and the prevalence of KSHV infection increases with the number of male sexual partners. Other modes of transmission predominate in African countries, where infection can occur during childhood through maternal–infant transmission (during labour or delivery or transplacental). Other non-sexual routes of transmission operate in children; the exact modes are not known, although KSHV has been detected in the saliva of infected persons. Clinical disease in transplant patients results predominantly from reactivation of the virus. One study on 220 transplant recipients reported antibodies against KSHV (seroconversion) in 25 patients within the first year after transplantation. The risk of transmission of KSHV through blood products is not known.

The KSHV infection rates parallel the incidence of KS, being low in the USA, many parts of Europe and Asia, intermediate in Mediterranean countries and highest in Central Africa. The seroprevalence of KSHV among blood donors ranges from 10% in the USA to >50% in many African countries, with intermediate rates in Italy and other Mediterranean countries.

Most primary KSHV infections are asymptomatic since healthy immunocompetent adults are able to suppress the KSHV infection, whereas the infection becomes clinically symptomatic in the presence of immunodeficiency. In HIV seropositive patients, the incubation period for disorders caused by KSHV infection depends on the immune status of the patient. In patients with AIDS infected with KSHV, the ability of human leucocyte antigen class I-restricted cytotoxic T-lymphocytes to respond to KSHV proteins becomes lost as the immunodeficiency worsens, at which point KS develops. Both KS and -cell body cavity lymphoma respond dramatically to active antiretroviral therapy in patients with AIDS. Additionally, KS in transplanted patients often regresses when immunosuppressive regimens are discontinued or reduced.

Clinical types of Kaposi's sarcoma

The types or variants of KS that are recognized are shown in Table 16.8.

Classic Kaposi's sarcoma

This is a rare disease with a predilection for males (reported male to female ratio of 15:1). The usual age at onset is between 50 and 70 years, the disease presenting with one or more firm asymptomatic red, purple or brown patches, plaques or nodular skin lesions. Classic KS is often localized to one or both lower limbs, initially around the ankles and soles of the feet but gradually progresses up the arms and legs. On histology, the tumour is composed of spindle-shaped cells surrounding hyperaemic vascular clefts, often in association with extravasated erythrocytes, haemosiderin and fibrosis. Classic KS runs a relatively benign, indolent course for several years with slow enlargement and gradual emergence of new lesions. Venous stasis and lymphoedema may precede or follow the appearance of the skin lesions. Systemic lesions (usually in the gastrointestinal tract) may develop in longstanding cases. These visceral lesions are usually asymptomatic although occasionally they may cause gastrointestinal bleeding. Some published series have reported the development of a second primary malignancy, usually a body cavity lymphoma.

Treatment

In patients who are immunocompetent and have single or few localized lesions, treatment is by surgical excision as this provides an adequate outcome but requires prolonged follow-up because of the risk of recurrence (40%). In contrast multifocal disease is unsuitable for surgical treatment in view of high recurrence rates. Patients with several lesions limited to a localized area are best treated with single doses of radiotherapy (8–12 Gy) as this treatment modality gives good control with reported symptomatic relief in the majority, partial regression in 85% and a complete response in 50%.

Patients with extensive or recurrent KS are treated either with a combination of surgery and chemoradiotherapy or with chemotherapy alone as this can result in complete remission lasting several years. The active cytotoxic agents used are vinblastine, bleomycin, doxorubicin, and dacarbazine alone or in combination. Intralesional injection of interferon 2b in a dose of 1×10^6 to 3×10^6 units is an alternative in view of reported good response rates. Its advantage over chemotherapy and radiotherapy is the avoidance of systemic toxicity.

Table 16.8 Types or variants of Kaposi's sarcoma

Clinical type	Population at risk	Prognosis
Classic	Elderly males of Eastern European/Mediterranean origin	Long survival
Endemic	African children and adults	Survival months to years
Immunosuppression	Organ transplant recipients	Survival months to years
Epidemic/AIDS associated	HIV-infected patients – homosexual and bisexual males	Survival weeks/months

Endemic (African) Kaposi's sarcoma

First reported in 1950, KS is a common neoplasm endemic in native populations in equatorial Africa. Nowadays, two types are recognized: endemic KS in HIV-negative patients and KS in HIV-positive patients. Together, these two types account for most of the soft-tissue tumours in central Africa. Adult endemic KS may occur either as an indolent neoplasm identical to the classic disease with nodules or plaques in oedematous limbs or as an aggressive fungating and exophytic lesion that invades the subcutaneous tissue and bone. Both types are again much more common in males but present at significantly lower age group (median age 45) than the classic disease, and a small percentage (8%) have concurrent lymphoma. A third type, the lymphadenopathic form of KS seen in Africa, occurs usually in prepubescent children. It is characterized by generalized lymphadenopathy, which is often associated with visceral organ involvement and a very poor prognosis with death in most patients within 3 years of diagnosis.

Treatment

Endemic KS is treated by chemotherapy using the same cytotoxic agents used in classic disease with reported response rates of up to 80%.

Immunosuppressive treatment-related Kaposi's sarcoma

This is encountered in organ transplant patients on immunosuppressive therapy in whom the incidence is estimated at 150–200 times that of the general population. The French Collaborative Transplantation Research Group reported a 0.5% overall risk of KS in 7923 organ transplant recipients. The male predominance persists but is much less marked than in classic KS, with reported male to female ratios ranging from 2:1 to 4:1. The average time to develop KS after transplantation is 29–31 months (range 3–124 months). In general, this type of KS tends to be aggressive, involving lymph nodes, mucosa and visceral organs in about 50% of patients. Some patients have concurrent lymphoma, tuberculosis or transfusion-related HIV infection. These KS tumours may regress following reduction or changes in immunosuppressive therapy. Clinical management of transplant patients who develop KS is difficult and requires a balance between the risk of death from generalized KS and the risk of graft rejection if the immunosuppressive therapy is discontinued.

Treatment

The options in transplant patients who develop KS include (1) withdrawal or reduction of immunosuppressive therapy, (2) radiotherapy and (3) chemotherapy. In most studies the withdrawal/reduction of immune suppression results in graft rejection in approximately 50%. Total withdrawal, which often results in complete response, is an acceptable risk only in renal transplant patients in view of the availability of dialysis (in the event of graft rejection), but obviously not in patients with cardiac or liver transplants in whom the immunosuppressive drugs can only be reduced or modified. In these patients, chemotherapy, single or combination with the cytotoxic agents used for classic KS (doxorubicin, bleomycin and vincristine) with or without radiotherapy, is used. There is a good reason to institute chemoprevention in transplant patients who are seropositive for KSHV. The problem is that the current antiviral drugs that are active against KSHV (ganciclovir, foscarnet and cidofovir) are too toxic for long-term chemoprevention.

Epidemic Kaposi's sarcoma

The proportion of HIV disease patients with KS has steadily decreased since the AIDS epidemic was first identified in 1981. About 48% of AIDS patients in 1981 had KS as their presenting AIDS diagnosis. By 1987, this had decreased to less than 20%. This is attributed to the introduction of highly active antiretroviral therapy (HAART), which delayed or prevented the emergence of drug-resistant HIV strains, thereby substantially reducing the viral load – the risk of opportunistic infections accounting for the decline of KS incidence in AIDS patients. In epidemic KS, the lesions may involve the skin, oral mucosa, lymph nodes and visceral organs (gastrointestinal tract, lung, liver and spleen). Eventually, most patients with epidemic KS develop disseminated disease. The disease often progresses rapidly from a few localized or mucocutaneous lesions to more numerous lesions and generalized skin disease with lymph node, gastrointestinal tract disease and other organ involvement. Pleuropulmonary KS is an ominous sign and usually cause death directly attributed to KS. Also, many patients with epidemic KS die of one or more complicating opportunistic infections. Several reports have documented KS in homosexual HIV-negative men. These patients have an indolent and cutaneous form of the disease, which causes new lesions to appear every few years. The lesions occur most commonly on the extremities and genitalia but can occur elsewhere in the skin.

Treatment

In AIDS patients who present with KS, the initial treatment is with HAART. If the patient responds to this with restoration of immune competence, this will have a beneficial effect on the KS lesions and certainly halt the progression of the disease. A good response to HAART may induce shrinkage of the KS lesions and reduce the KSHV viral load. However, not all patients respond to HAART; this varies considerably from patient to patient. For this reason, specific local or systemic therapy for KS is usually instituted as well.

Radiotherapy is used for lesions limited to areas of the skin or oral mucosa. Systemic chemotherapy is indicated for patients with widespread mucocutaneous disease, lymphoedema or visceral disease. The most active drugs include liposomal anthracyclines, paclitaxel, vinca alkaloids and bleomycin. Interferon- (subcutaneous, intralesional or intravenous) is also effective for epidemic cutaneous KS. The best results with this biological agent (when used singly) are reported with daily intramuscular or intravenous injections of interferon- in a dose of 30×10^6 units. The common side effects include fever, chills, fatigue and muscle pain. One RCT has shown that the combination of zidovudine and interferon- (1×10^6 units subcutaneously per day) produces a higher response rate (31% versus 8%) than interferon- alone.

A more recent therapeutic approach for epidemic KS is with use of inhibitors of angiogenesis (vascular endothelial growth factor and thalidomide) and retinoids (all-*trans* retinoic acid). Early results are promising but this therapy remains experimental.

CHAPTER 17

Disorders of the breast

ALASTAIR M. THOMPSON, STACY L. MOULDER-THOMPSON, ANDREW EVANS AND JOHN A. DEWAR

Introduction

Many women develop breast symptoms during their lifetime, most of which are benign, self-limiting and resolve in time. Some symptoms should be referred to a breast specialist (Box 17.1) whereas others can be managed in the community (Box 17.2).

Breast conditions can be subdivided into benign and malignant diseases. Whatever the underlying pathological process, a concise history and examination followed by appropriate imaging and pathological investigation is required.

Organization of services

Ideally, breast clinics should be established and served by staff trained in breast disease: surgeons, breast physicians, radiologists, diagnostic radiographers and breast care nurses, with specialist pathology, oncology and reconstuctive surgery back-up.

Patients attending for diagnostic purposes should be seen by a clinician trained in the management of breast conditions. Based on evidence that patients with breast cancer managed in a breast unit/centre have a better outcome, patients with breast cancer should be managed by a multidisciplinary team within a designated breast unit.

While delay in being seen at a breast clinic is associated with marked anxiety, delays in onset of treatment of <3 months are unlikely to be associated with a measurable difference in survival.

BOX 17.1 Patient referral: conditions that require referral to a breast specialist

- Lump
  - Any new discrete lump
  - New lump in pre-existing nodularity
  - Asymmetrical nodularity that persists at review after menstruation
  - Abscess or breast inflammation which does not settle after one course of antibiotics
  - Cyst persistently refilling or recurrent cyst (if the patient has recurrent multiple cysts and General Medical Practitioner has the necessary skills, then aspiration is acceptable)
- Pain
  - If associated with a lump
  - Unilateral persistent pain in postmenopausal women
- Nipple discharge
- All women aged 50 and over
- Women under 50 with:
  - Blood-stained discharge; or
  - Bilateral discharge sufficient to stain clothes; or
  - Persistent single duct discharge
- Nipple retraction or distortion, nipple eczema
- Change in skin contour

BOX 17.2 Patient referral: conditions that can be initially managed in general practice

- Young women (<35 years) with tender, lumpy breasts and older women with symmetrical nodularity, provided that they have no localized abnormality
- Women with minor and moderate degrees of breast pain who do not have a discrete palpable lesion
- Women aged under 50 years who have nipple discharge that is from more than one duct or is intermittent and is neither bloodstained nor troublesome

Hence, in the UK, it has been suggested that >80% of urgent referrals are seen within 5 working days and the remainder within 10 working days (after receipt of referral).

History

The history for a patient with breast symptoms can be subdivided into:

- history of the presenting problem
- hormonal history
- gynaecological history
- family history
- other medical/surgical history
- breast imaging history.

History of the presenting problem

Having established the age and the sex of the patient, the answers to the questions shown in Box 17.3 should be recorded.

The categories shown in Box 17.4 identify women who have three times (or more) the population risk of developing breast cancer.

Hormonal and gynaecological history

This should include age at menarche and (when appropriate) menopause, number and timing of pregnancies, use of oral contraception and hormone replacement therapy (and whether oestrogen and/or progesterone containing, duration and timing of usage).

BOX 17.3 History for breast conditions

- Is there a lump?
- Where is the lump?
- How big is it?
- When was it first noted?
- Is it a single/are they multiple lump(s)?
- Have there been any previous lumps?
- Does it change with menses?
- Is it tender/mobile/hard/soft?
- Are there any lumps elsewhere?
- Are there any associated features?
- Skin changes
- Nipple indrawing
- Nipple discharge – single or multiple ducts; blood stained or not
- Are there any problems in the other breast, axilla, supraclavicular fossae or neck?

BOX 17.4 Familial breast cancer: criteria for identifying women who have three times (or more) the population risk of developing breast cancer

A woman who has

- one first-degree relative with bilateral breast cancer or breast and ovarian cancer, or
- one first-degree relative with breast cancer diagnosed under the age of 40 or one first-degree male relative with breast cancer diagnosed at any age, or
- two first- or second-degree relatives with breast cancer diagnosed under the age of 60 or ovarian cancer at any age on the same side of the family, or
- three first- or second-degree relatives with breast or ovarian cancer on the same side of the family

In this context, a first-degree female relative is mother, sister or daughter. A second-degree female relative is grandmother, granddaughter, aunt or niece.

Family history

A history of cancers diagnosed in the wider family and the age at diagnoses and type of cancer in each family member should be ascertained. Breast, ovarian, prostate and colon cancers are of particular relevance in familial predisposition to breast cancer.

Other medical/surgical history

Here the aim is to assess the patient's general medical, mental and social health, especially as regards fitness for surgery, possible radiotherapy or chemotherapy and breast reconstruction. In particular, it is essential to know about medications, whether the patient smokes and any history of venous thrombosis. A history of previous radiation therapy to the chest (e.g. for lymphoma) should be recorded.

The patient's age (Figure 17.1) and the history will indicate the likely diagnosis but a systematic breast examination is necessary to pick up additional features.

Breast imaging history

Knowing when patients last had breast imaging will influence the choice of imaging required. Unless there is serious clinical suspicion of malignancy, repeating a mammogram within 12 months of a previous mammography is often not necessary.

Examination

Examination includes the key steps outlined below.

The patient (naked to the waist) is examined in the presence of a chaperone.

With the patient sitting, the breast should be inspected for changes in contour due to skin or nipple tethering, which may be emphasized by asking the patient to raise her arms above her head and lean slightly forward. Tethering of a lesion to the chest wall can be assessed by asking the patient to put her hands on

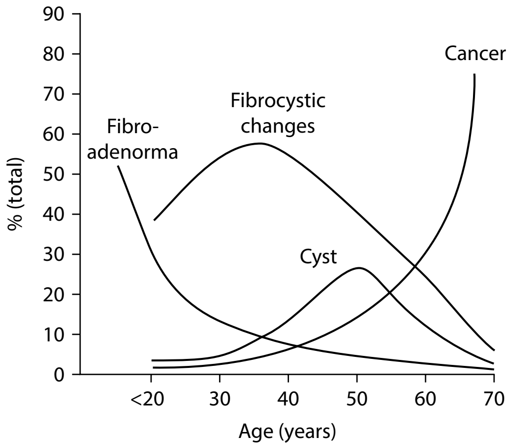

Figure 17.1 Incidence of breast lesions in women presenting to a breast clinic: fibroadenoma, fibrocystic changes, cyst and cancer as a percentage of breast lumps in patients presenting to a breast clinic compared with patient age.

her hips and press onto both hips, thus contracting the pectoral muscles. Next, with the patient lying comfortably with her hands behind her head, the normal breast should be examined first. Each breast should be examined, including the axillary tail, with the flattened fingers of the hand.

Any lump should be assessed for size (measured with calipers), shape, consistency, tenderness, mobility and fixity to the overlying skin/underlying chest wall.

Both axillae should be examined thoroughly for palpable nodes ensuring that the anterior, medial, posterior and apical node groups are palpated. The size, number and fixity of nodes should be recorded. Although clinical assessment of axillary nodes may not reflect their pathological status, for patients with breast cancer the clinical tumour–node–metastasis (TNM) system requires an assessment of node involvement.

The supraclavicular and infraclavicular fossae and cervical region should also be examined for palpable lymph nodes.

Any other symptomatic regions should be examined as required for signs (in a patient with breast cancer) of metastatic disease.

The examination findings must be recorded in sketch or written form, as part of good clinical practice and for medicolegal reasons.

Imaging

Most symptomatic problems in women under 40 who require imaging are best imaged using ultrasound. Ultrasound is excellent at discriminating cysts from solid lesions. Ultrasound is also highly accurate at benign/malignant differentiation of solid lesions. However, virtually all symptomatic solid lesions in women over the age of 25 years require a histological diagnosis. Most women attending a clinic over the age of 40 should have mammography unless they have had a mammogram within the last 12 months. All women with clinical findings suspicious of malignancy require mammography. Women with breast lesions thought to be malignant require axillary ultrasound with sampling of nodes abnormal on ultrasound. Most palpable lesions are best sampled under ultrasound guidance, which is more accurate than clinically guided biopsies.

Initial assessment, investigation and staging of breast symptoms

Methods of assessment of a breast abnormality include clinical history and examination, imaging and core biopsy sampling of the lesion for histological assessment. These three investigations collectively constitute *triple assessment*. There is strong evidence that triple assessment provides more accurate diagnosis than fewer tests. Clinical examination, mammography, ultrasound and core biopsy range in sensitivity to detect malignancy from 85% to 95%.

All patients should have a full clinical examination. When a localized abnormality is present, patients should have imaging usually followed by core biopsy. A lesion considered malignant on either clinical examination or imaging alone should have histopathological confirmation of malignancy before any definitive surgical procedure, e.g. mastectomy or axillary clearance. Clearly there are medicolegal implications if appropriate assessment is not performed prior to mastectomy if the subsequent definitive pathology turns out to be non-malignant.

Benign breast conditions

Aberrations of normal development and involution

The cyclical variations in oestrogen and progesterone result in increased mitosis of breast epithelial cells around days 22–24 of the menstrual cycle, but apoptosis restores the tissue balance across the cycle.

Benign proliferations in the breast are often considered as aberrations of normal development and involution.

Localized benign nodularity

Localized benign nodularity, previously termed fibroadenosis or fibrocystic disease, occurs commonly in young women, often with bilateral nodularity that is usually accentuated premenstrually. Any focal nodularity should disperse after two menses (approximately 6 weeks). Lumpy, normal breast tissue is usually managed in general practice following repeat examination, with reassurance, but any persistent localized abnormality requires referral for triple assessment. Many benign masses disappear completely spontaneously over time.

Fibroadenoma (Figure 17.2)

There is a spectrum of aberrations of normal development and involution that ranges from a single fibroadenoma (termed a juvenile fibroadenoma in teenage girls) through giant fibroadenoma to phylloides tumour. A fibroadenoma forms from a breast lobule, a smooth, non-tender, mobile lump, usually in a young woman. It may be single, lobulated or multiple and does not show any changes in size with menstruation.

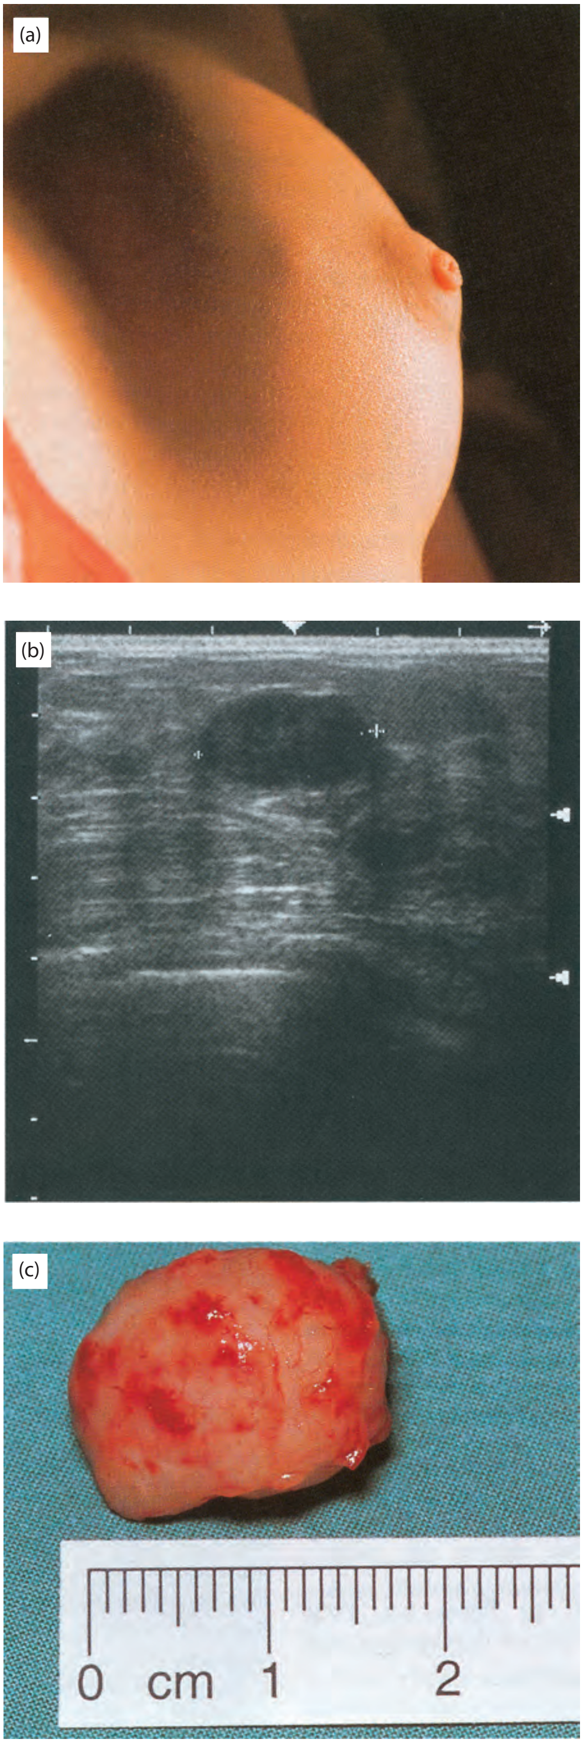

Figure 17.2 Fibroadenoma: (a) clinical appearance; (b) ultrasound appearance as a homogeneous, well-defined, oval mass; (c) surgical specimen.

Following diagnostic triple assessment the fibroadenoma can be excised if >4 cm or at the patient's request. Percutaneous vacuum biopsy represents an alternative to surgery for the removal of fibroadenomas <3 cm in size. Fibroadenomas are best sampled using core biopsy rather than cytology as, occasionally, papillomas and phylloides tumours may mimic fibroadenomas and these lesions are best diagnosed on core rather than cytology. A giant fibroadenoma should be excised as its increasing size may distort the shape of the breast. Phylloides tumours progressively increase in size, and range between a benign appearance and more sarcoma-like appearance with an increasing number of mitotic figures on histology. Local recurrence is common, if excision is incomplete, and therefore a phylloides tumour should be excised with a >1 mm margin of normal tissue to prevent local recurrence; even then further recurrence may require mastectomy; metastasis is very rare.

Cyst (Figure 17.3)

Rare before the age of 30 years, the incidence of cysts declines after the menopause. However, 7% of women develop a symptomatic cyst at some point during their life. Cysts may be single, multiple, unilateral or bilateral and range in size from 2 mm to several centimetres. Whereas ultrasound may be particularly useful in demonstrating the site and number of cysts, aspiration yields clear or turbid fluid ranging in colour from white to dark green; a cyst may disperse spontaneously; approximately 10% of symptomatic cysts recur and require reaspiration. Worrisome cysts are those that contain fresh blood, those in which there is a residual mass after aspiration and those that have a solid filling defect on ultrasound. Residual masses or intracystic filling defects should undergo core biopsy. Cysts which recur repeatedly also require histological assessment as a carcinoma in the wall of the cyst may be present. Endocrine agents such as danazol have been used to reduce the formation of further cysts in those prone to multiple cyst formation.

Duct papilloma

A duct papilloma classically presents as a blood-stained nipple discharge from a single duct; pressure on the areolar margin overlying the duct papilloma results in expression of a blood-stained discharge. The discharge can be tested for blood using a urinary testing stick. Papillomas can sometimes be seen on imaging as intraductal masses and then biopsied or even removed using a vacuum biopsy device under imaging control. Under general anaesthetic a lachrymal probe should be inserted into the duct and the single duct excised through a circumareolar incision and sent to pathology. Rarely, the symptoms of a blood-stained nipple discharge may be due to ductal carcinoma *in situ* (DCIS).

Epithelial hyperplasia

Epithelial hyperplasia (previously termed epitheliosis or papillomatosis) is usually an incidental finding on biopsy and

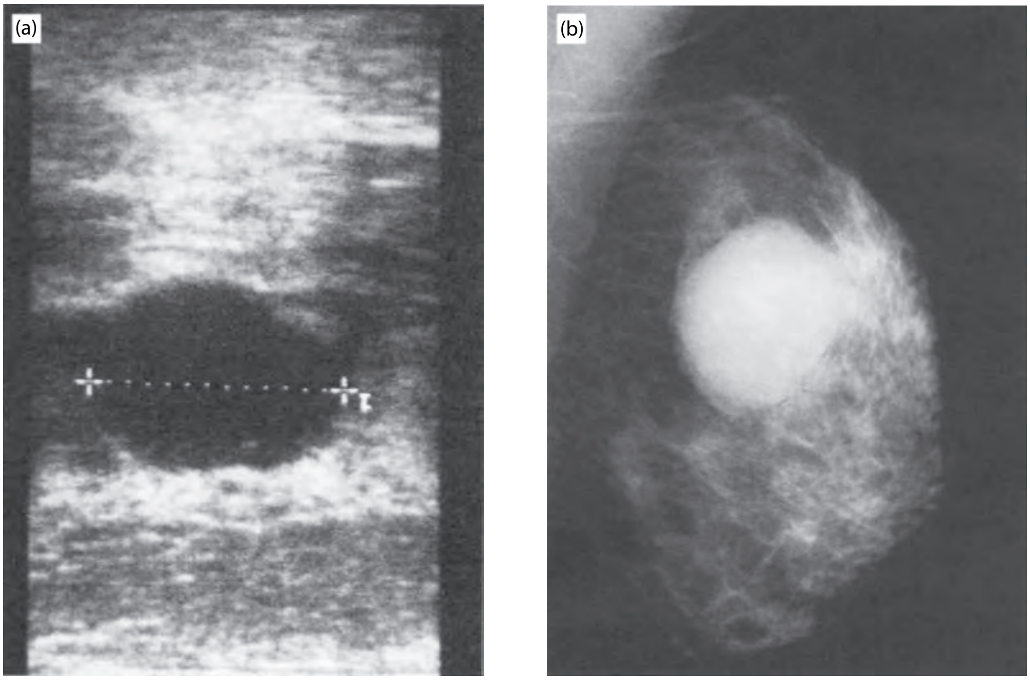

Figure 17.3 Cyst: radiological appearances using (a) ultrasound, showing an anechoic lesion with distal bright up; (b) mammogram of a breast cyst showing a large well-defined, oval mass.

can be graded as mild, moderate or florid. Cellular atypia (atypical hyperplasia) increases the risk of breast cancer two- to fourfold.

Sclerosing lesions

Usually detected on mammography as areas of architectural distortion, radial scars (which if >2 cm are also known as complex sclerosing lesions) require either surgical biopsy or vacuum biopsy excision to exclude cancer, which is present in about 15% of cases.

Inflammatory/infectious processes

Abscess (Figure 17.4)

Abscess formation may occur in the breast tissues or in the skin overlying the breast (in an epidermoid cyst) or in the inframammary fold. The typical symptoms of pain, redness and swelling are present.

A breast abscess is commonly lactational, occurring in a young breastfeeding woman, and usually staphylococcal in origin. Non-lactational abscesses tend to occur in middle-aged women who smoke and are secondary to streptococci and anaerobic bacteria. Periareolar infection, occurring in women in their thirties, results from active periductal inflammation (periductal mastitis). Periareolar abscess formation may proceed to a fistula (see below). Peripheral non-lactating breast abscess may be associated with diabetes, steroid therapy or rheumatoid arthritis. There may be multiple peripheral abscesses requiring drainage and antibiotics. At an early stage, abscess formation may be aborted by the use of appropriate antibiotics (such as amoxicillin, safe in breastfeeding mothers, with its antianaerobic and anti-staphylococcal action). Once an abscess is established, antibiotics are required for the surrounding cellulitis plus drainage either under local anaesthetic using a 19 G needle or by formal incision and drainage under local or general anaesthesia. Repeat drainage under ultrasound control helps prevent the need for surgical drainage in most cases. Inserting a drain, as described in older surgical texts, is *not* required. A breast abscess may require more than one drainage procedure (particularly if needle aspiration is used) and may be complicated by fistula formation. Tuberculosis and actinomycosis are rarer but recognized causes of breast abscess.

Inflammatory breast cancer should be excluded in patients with a solid inflammatory lesion or an apparent abscess that does not respond to appropriate treatment with ultrasound-guided drainage.

Fistula (Figure 17.5)

A fistula between the epithelium of a breast duct and the skin may follow on as a consequence of an abscess with the discharge site/fistula usually opening at the areolar margin. Excision of the fistula through a circumareolar incision including the duct up to the back of the nipple under antibiotic cover is the treatment of choice, rather than laying open the length of the fistula with the resultant scarring and deformity.

Duct ectasia (periductal mastitis)

These represent a spectrum of inflammatory process in which the subareolar ectatic, enlarged, ducts are surrounded by a mild inflammatory infiltrate commonly found in smokers. The ectatic

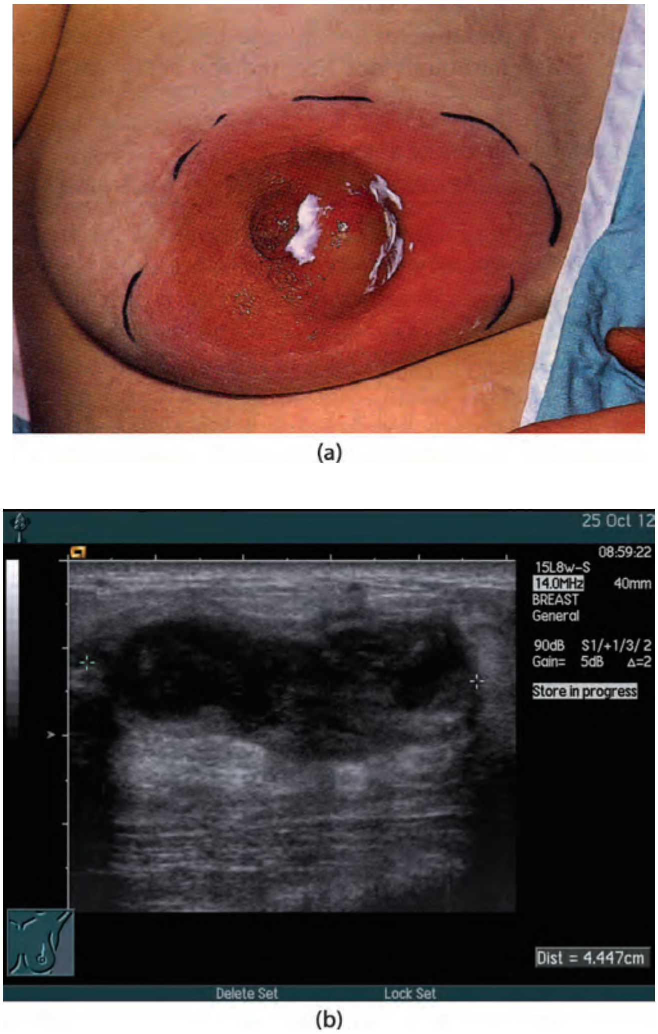

Figure 17.4 (a) Breast abscess in a breastfeeding mother demonstrating erythema marked to determine whether it is a spreading, pointing abscess adjacent to the areola with local anaesthetic cream in place prior to needle aspiration. (b) Ultrasound image of an abscess showing an ill-defined fluid collection with surrounding oedema.

duct may result in a retracted slit-shaped nipple (in contrast to the nipple retraction seen with an underlying cancer). Creamy discharge from multiple bilateral ducts is a feature of duct ectasia and is distinct from the single blood-stained discharge of a duct papilloma/intraduct carcinoma. Duct ectasia often shows characteristic 'lead pipe' and 'broken needle' calcifications on mammography.

Fat necrosis

Fat necrosis in the breast usually appears in postmenopausal women following trauma to the breast (such as a seat belt injury) as a localized inflammatory response. Fat necrosis may be suggested from the history but should be diagnosed using triple assessment including core biopsy as a small cancer may clinically and radiologically mimic fat necrosis. Sometimes fat necrosis, which often has a characteristic ultrasound appearance, can be confirmed by aspiration of associated oil cysts. Treatment is by reassurance or, if suspicion remains or the patient requests, excisional biopsy.

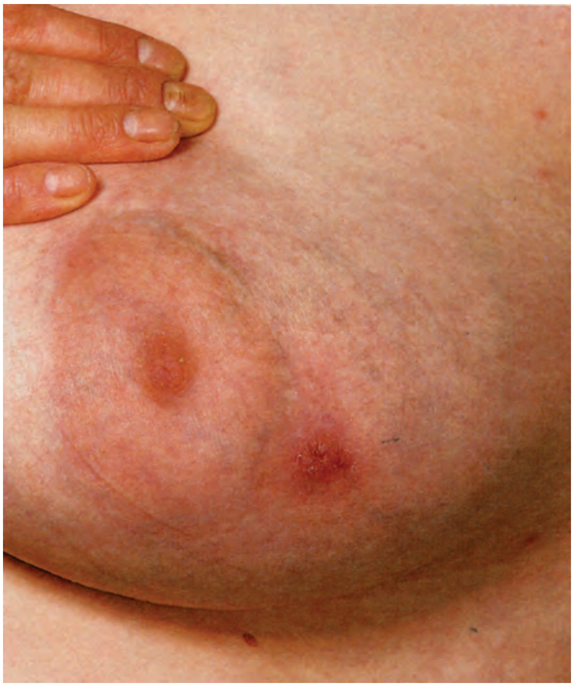

Figure 17.5 Fistula as a consequence of a breast abscess; note the classical position at the areolar margin.

Hormonal changes

Nipple discharge

Single or multiple duct discharge producing a clear, creamy, green or black fluid is a common physiological finding but also occurs from ectatic ducts. Physiological nipple discharge from multiple ducts, usually bilateral, is not uncommon in premenopausal women. Following triple assessment, including mammography to detect underlying DCIS, a careful drug history (particularly for psychotropic drugs, which may cause hyperprolactinaemia) and measurement of serum prolactin to exclude a (rare) pituitary prolactin-secreting tumour, surgical intervention (duct excision or disconnection) is only required if blood can be detected on stick testing raising the suspicion of an underlying papilloma or rarely a carcinoma, or if there is a profuse discharge causing patient distress.

Breast pain (mastalgia)

Breast discomfort or pain at some time is reported by two-thirds of women; mastalgia can be defined as breast pain of sufficient severity for a woman to seek medical advice. While breast pain is very rarely a symptom of breast cancer, appropriate reassurance is required.

Mastalgia may be unilateral, bilateral, unifocal or multifocal, cyclical (worse before the menses) or acyclical. It is important to exclude concomitant pathology. Cyclical mastalgia is worst in the days before the menses, usually affects the outer half of the breast, occurs in women often in their thirties and may persist for months or years. Cyclical mastalgia ceases with the menopause. Acyclical mastalgia may be continuous or have a random pattern and is more common in women in their forties. Hormone replacement therapy or a change in oral contraceptive pill may exacerbate mastalgia, at least initially. Following triple assessment of any focal abnormalities to exclude malignancy, conservative measures include reassurance and explanation, simple analgesia (e.g. paracetamol), dietary modification (avoiding caffeine in tea, coffee and soft drinks; avoiding fatty foods), wearing a correctly fitting supportive bra especially at night, stopping smoking and regular exercise. Keeping a breast pain chart (Figure 17.6) can be helpful for the patient to record the timing and severity of the pain and for the clinician to establish any pattern of pain.

Although mastalgia is self-limiting, it may persist for months or years. For cyclical mastalgia, medication such as gammalinoleic acid (oil of evening primrose) given for a minimum of 3 months' duration in an adequate dose (80 mg t.i.d.) shows a response similar to placebo in 40% of patients. If the pain is persistent and severe, medical therapy such as 100–200 mg danazol or bromocriptine have similar response rates, but one-third of women experience side effects. Tamoxifen 20 mg/day (although not licensed for breast pain) or ovarian suppression (by a luteinizing hormone-releasing hormone analogue) in premenopausal women is increasingly used for refractory mastalgia; psychological referral for the management of the pain may be required. Rarely, mastectomy is performed to remove the painful breast, but should be considered only when chest wall disease has been excluded, other measures have been exhausted and following patient counselling, as surgery tends to make mastalgia worse not better.

Acyclical mastalgia may respond to the conservative measures used for cyclical pain. A persistent localized painful area may respond empirically to local anaesthesia/steroid injection.

Chest wall pain, musculoskeletal pain (e.g. Bornholm myalgia), costochondritis (particularly of the second rib/cartilage joint – Tietze syndrome), thrombophlebitis of the chest wall veins (Mondor's condition; Figure 17.7), intra-abdominal (gall stones) or intrathoracic (cardiac, pleural) pain may all present as 'breast pain' in clinical practice. Exclusion of significant breast pathology, reassurance and non-steroidal anti-inflammatory drugs can provide symptomatic relief.

Other conditions

An accessory nipple, accessory breast tissue (which occurs along the axillary–groin milk lines) or, conversely, breast hypoplasia (which may be associated with pectoral/upper limb abnormalities – Poland syndrome) are developmental abnormalities of variations in the site and the volume of breast tissue. Surgical treatment is only required when swollen accessory breast tissue is symptomatic. Rarely, hamartoma, angioma or neurofibroma may occur in the breast.

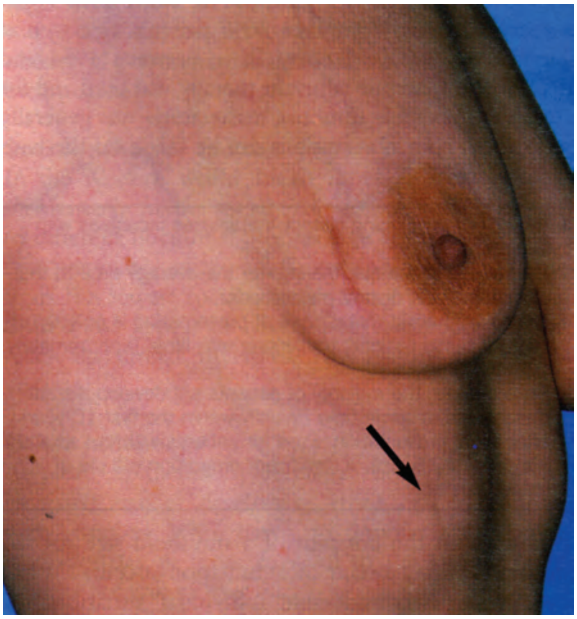

Figure 17.7 Mondor's disease (thrombophlebitis) inferior to the breast on the chest wall and a benign breast biopsy scar in the skin lines.

Lipoma

Lipomata are not uncommon in the breast and can mimic other breast lumps including carcinoma. They usually have a characteristic appearance on ultrasound and infrequently require biopsy for confirmation.

Epidermoid cyst

This lies within the skin of the breast, usually adjacent to the sternum or an inframammary fold. The classic punctum is often visible and the cyst may become inflamed/infected and discharge cheesy material. This lesion may be left *in situ* if not complicated by recurrent infection.

Each day mark whether you have bad pain, no pain or just a little pain, using the symbols shown.

◩ Mild Pain ■ Severe Pain ☐ No Pain

Please put a **P** in the space provided on the day your period starts

Surgery for benign breast conditions

Many benign breast conditions are self-limiting and following triple assessment the patient may require simple reassurance, conservative measures or a course of medication. Follow-up of patients with benign breast conditions is not usually required in the hospital setting. A benign lump may be excised (under local or general anaesthetic) at the request of the patient. Surgical scars should be placed circumferentially, in the line of skin tension (Figure 17.7) or at the areolar margin, at the peripheral margins of the breast or in the skin lines of the axilla.

Gynaecomastia (Figure 17.8)

Gynaecomastia, the growth of breast tissue in males, is a benign, reversible condition affecting 3% of the male population at any one time. Teenage boys undergoing puberty (pubertal gynaecomastia) and elderly men (senescent gynaecomastia) are most commonly affected and between them account for half of the patients with gynaecomastia. Gynaecomastia secondary to drug therapy, liver disease, primary hypogonadism (e.g. Klinefelter syndrome), testicular tumours, hyperthyroidism or renal disease should be excluded. Withdrawal of the causative drug (cimetidine, digoxin, spironolactone, anabolic steroids, oestrogen) should result in symptom resolution.

Clinical examination, revealing a usually tender, palpable lump deep to the areolar and often, surprisingly, unilateral, may be supplemented by mammography, ultrasound and core biopsy if male breast cancer is suspected. In young men, the testes should be examined to exclude testicular tumours and human chorionic gonadotrophin and oestrogen levels measured. Surgical excision (through a circumareolar incision), danazol or tamoxifen have all been used for the treatment of gynaecomastia.

Female breast cancer

Breast cancer is the most common cancer in women and is second only to lung cancer in cancer-related deaths. Fortunately, mortality rates are declining in breast cancer – a change attributed to an ongoing multidisciplinary approach to the management of the disease. This approach includes the use of diagnostic imaging for early detection in appropriate patients. Upon the pathological or histological diagnosis of breast cancer, most patients undergo surgical resection and further pathological evaluation of breast and lymph node tissue followed by additional therapies such as radiation therapy and/or systemic therapy as indicated to reduce the risk of disease recurrence. Such an approach has been enhanced by the ability to identify high-risk patients who may especially benefit from increased clinical and radiographic surveillance to detect early disease or breast cancer prevention strategies which involve prophylactic surgery or drug administration.

Histology of breast cancer

Breast cancers originate from the epithelium of the terminal duct lobular unit. Those encompassed within the basement membrane are classified as *in situ,* and have characteristic patterns, as do invasive cancers that disseminate beyond the basement membrane.

Invasive cancers are now classified as no special type (NST; or not otherwise specified) (Figure 17.9) or special types: lobular, tubular, medullary, mucoid and papillary, which may have characteristic histopathological features and some of which have a better prognosis. Prognosis is related to lymph node involvement, tumour size and tumour grade: I, II, III based on gland formation, nuclear pleomorphism, and frequency of mitoses originally described by Scarff, Bloom and Richardson. These prognostic factors may be scored and combined to give a prognostic score. For invasive cancer, some 80% are NST, 10% lobular and the remainder (10%) tubular, medullary, mucoid, papillary or other even rarer types. The frequency of special type tumours is higher in women with screen-detected cancer. Lymphatic or vascular invasion on histological assessment is also a marker for both local and systemic recurrence. Patients with perineural invasion or extensive (>25%) *in situ* cancer within the tumour mass are more likely to develop local recurrence.

Paget's disease is an eczematous infiltration of large breast cancer cells into the nipple/areolar skin that occurs in approximately 2% of presenting cancers. It is symptomatic of an underlying high-grade ductal carcinoma *in situ* (DCIS) lesion which may have an invasive component. Diagnosis is from nipple or punch biopsy after triple assessment, which may reveal an underlying cancer.

Metastatic spread from breast carcinoma is via lymphatic channels to regional lymph nodes (Figure 17.10), predominantly in the axilla. Even in the absence of detectable lymph node metastasis,

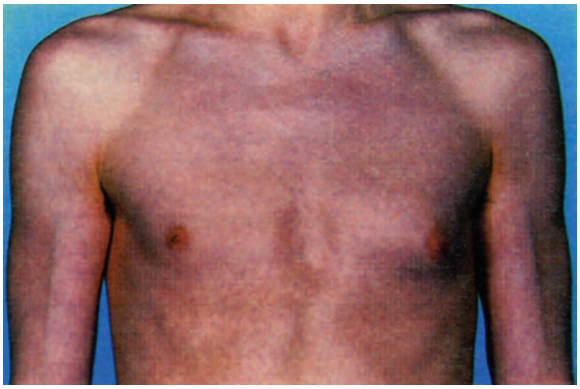

Figure 17.8 Unilateral (left) gynaecomastia in a teenage boy.

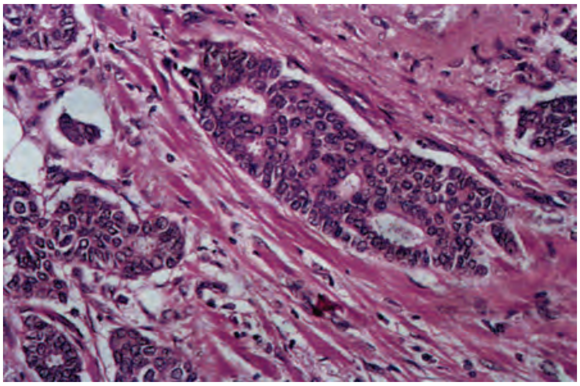

Figure 17.9 Haematoxylin and eosin-stained section of invasive breast cancer.

lymphatic or vascular invasion in the breast tissue is suggestive of the propensity of the cancer to spread to distant metastatic sites.

Synoptic reporting is proving increasingly acceptable to standardize and optimize communication, with the format determined locally for macroscopic and microscopic details. An illustrative example is provided in Box 17.5.

Carcinoma *in situ*

A spectrum of preinvasive neoplastic change in the breast includes DCIS (15% of symptomatic, 20% of screen-detected 'cancers'), lobular carcinoma *in situ* (LCIS; <1% symptomatic and 1% of screen-detected lesions) and hyperplastic appearances (ductal or lobular atypia), which can cause diagnostic difficulties.

DCIS (Figure 17.11) covers a heterogeneous group of lesions and is classified by histological pattern, grade (high, intermediate or low) and the presence of necrosis. However, no internationally agreed classification system exists. High-quality mammography is required to determine the extent of disease (but may still underestimate the volume of breast involved), although DCIS can be present without mammographic signs. The majority of cases are now detected in screening programmes, although the natural history of the disease is not fully understood.

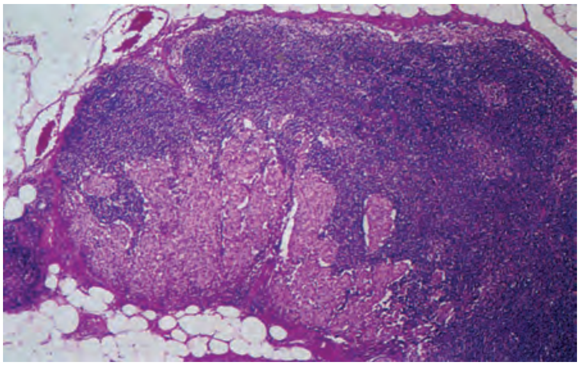

Figure 17.10 Haematoxylin and eosin-stained section of an axillary lymph node showing extensive node involvement with invasive breast cancer.

BOX 17.5 Synoptic pathology report

- Invasive cancer: invasive carcinoma, no special type
- Grade: III (glands 3, nuclei 3, mitosis 2)
- Size: 27 mm
- *In situ* cancer: present – comedo type
- Grade: high
- Extent: extensive, within main lesion
- Calcification: yes; associated with *in situ* cancer
- Margins: nearest is medial at 5 mm, all others >10 mm
- Multifocal: no
- Vascular/lymphatic invasion: yes, at the edge of the cancer in two blocks
- Lymph nodes: number confirmed 5; number positive 1 (microscopic tumour deposit)
- Oestrogen receptor (specify scoring system): Allred 6/8, HER2: positive 3^+ FISH amplified
- Summary: right breast wide local excision – invasive carcinoma grade 3 with one lymph node metastasis

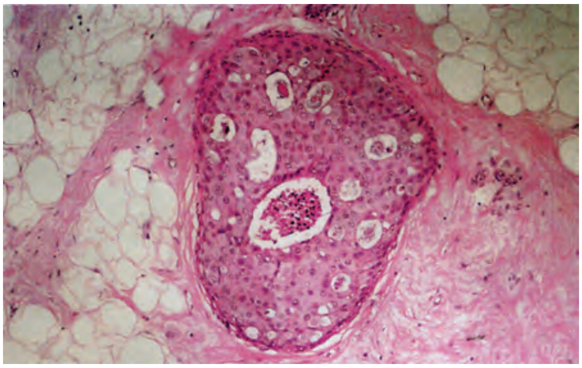

Figure 17.11 Haematoxylin and eosin-stained section demonstrating ductal carcinoma *in situ* (of cribriform type).

DCIS, characterized by ducts expanded by large irregular cells with large irregular nuclei, may be classified in a variety of ways: comedo DCIS has high-grade cytology, extensive necrosis and branched calcifications; non-comedo DCIS (cribriform, solid or micropapillary) has low-grade cytology, lacks necrosis and calcification is inconsistent. As one might expect, there are patients with intermediate histology. DCIS is increasing in the frequency of detection, largely because of screening techniques. The risk of developing invasive cancer at the site of low-grade DCIS is about 10% over a 10 year period. The natural history of high-grade DCIS is more aggressive with a median time to relapse of 76 months. The average age of diagnosis is 55 and most women are postmenopausal. The biology remains poorly understood (e.g. 60% of DCIS is HER2 protein expressing (see below), but, unlike invasive cancer, this is not a poor prognostic sign).

Atypical ductal hyperplasia

Atypical ductal hyperplasia (ADH) forms part of a spectrum with DCIS – membrane-bound spaces of 2–3 mm with cellular atypia. ADH holds a fourfold risk of developing breast cancer, which is additive with any family history of breast cancer.

Lobular carcinoma *in situ*

LCIS, usually an incidental histological finding, is an expansion of the breast lobule by smaller, regular cells with regular row/oval nuclei. The risk of developing invasive breast cancer is about 25% (and contralateral breast cancer about 10%) at 20 years; since most women (70%) with LCIS are premenopausal (mean age 45 years) this may be significant.

Lobular neoplasia, identified on core biopsy, carries an upgrade rate at surgical excision to DCIS or invasive carcinoma of around 15%. Such lesions are therefore usually excised.

Other malignancies in the breast

Primary lymphoma affecting nodes within the breast or in the axilla is perhaps the most common non-breast malignancy and is treated, following staging, with or without local excision/tumour biopsy, by conventional antilymphoma regimens. Sarcoma is treated by excision with the widest possible margin at mastectomy followed by postoperative radiotherapy.

While primary breast cancer is by far the most common breast malignancy, secondary spread from other organs such as bronchogenic carcinoma, melanoma or from the gynaecological organs is recognized. Usually, the cellular morphology of the lesion gives clues to its origin (which may be suggested from a past history of, for example, leiomyosarcoma of the uterus), and the use of special stains suggesting the lesion is not breast cancer [e.g. oestrogen receptor (ER) negative] or positive molecular markers (e.g. for lung cancer) give clues to the primary.

Molecular characterization of breast cancer

There appears to be a wide range of molecular abnormalities in breast cancer which probably interact with the cellular environment and play a role in the aetiology, development, invasion and metastasis of breast cancer. Using whole genome scanning techniques, such as comparative genomic hybridization or genetic profiling (with microarray or chip-based technology for gene expression or gene deletion), it is clear that individual cancers vary markedly from each other. In clinical practice, few genes or their protein products are of genuine widespread clinical utility but include the ER gene protein product and a cell surface receptor HER2. Some provide information when the importance in clinical decision-making (PgR, pS2/PNR2, *p53*) remains unclear, whereas others (Ki67 or PCNA as a proliferation marker, percentage of cells in S phase, DNA content of tumour) relate to the biological aggressiveness of the cancer.

Oestrogen receptor

ER expression, historically measured by radioimmunoassay or the dextran-coated charcoal method on cell lysates, is now assessed by immunohistochemistry on formalin-fixed paraffin-embedded tissue sections (Figure 17.12), for which there are a variety of scoring systems. Two forms of ER exist: ER-α (detected and measured clinically in breast cancer samples) and ER-β (of uncertain clinical significance in breast cancer); tumours with moderate or high ER expression are much more likely to respond to endocrine therapy than those with no or low ER expression. In addition, ER expression correlates with survival, at least in the first 5 years following diagnosis. However, only two-thirds of patients with ER expression appear to have intact, functioning downstream effector pathways, so some centres also measure progesterone receptor (PgR) and/or the insulin-like growth factor peptide pS2 in immunohistochemical sections. Expression of PgR and/or pS2 along with ER suggests that the cancer is more likely to respond to endocrine therapy.

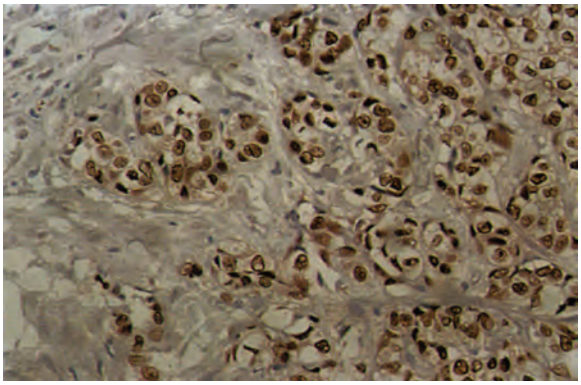

Figure 17.12 Oestrogen receptor staining of breast cancer.

Human epithelial growth factor receptors

HER2 (erbB2, neu) is a transmembrane growth factor receptor, expressed in 15% of invasive breast cancers (and, for reasons which are unclear, up to 60% of DCIS), and is associated with poor prognosis in invasive breast cancer. It is one of a family of growth factor receptors [including epidermal growth factor receptor (EGFR), erbB3, erbB4], but unlike most other molecular markers now forms a target for ‘biological therapy’. For patients in whom amplified HER2 can be detected (i.e. multiple copies for the gene best detected by fluorescence *in situ* hybridization) and is overexpressed (on immunohistochemistry), humanized mouse antibody [trastuzumab (Herceptin)] was the first new ‘biological’ therapy to enter clinical use. What is perhaps of greatest clinical significance is that this therapy may be most effective in HER2-positive and node-positive patients with invasive breast cancer whose disease is relatively insensitive to chemotherapy or endocrine therapy. A number of targeted therapies to HER2 extracellular or intracellular domains or HER2 and EGFR (targeting EGFR–HER2 dimers which drive HER2 downstream effects) have subsequently emerged.

p53

p53 has acquired the nickname ‘guardian of the genome’ owing to its essential role in the cellular response to injury with subsequent cell cycle arrest or apoptosis. In breast cancer, mutant *p53* has been associated with poor prognosis and resistance to treatment by chemotherapy. Thus, detection of *p53* mutation may be important in clinical therapeutic decision-making and is the subject of clinical trials. Unfortunately, immunohistochemistry for *p53* in breast cancer is less reliable than other methods of detecting *p53* mutation and this has held back the application of *p53* research in the clinical arena.

Triple negative and basal phenotype breast cancer

Cancers which are negative for ER, PgR and HER2 are termed triple negative. Most triple negative cancers express basal cytokeratins such as CK5/6 and CK14. Triple negative and basal breast cancers have a poor prognosis even when detected at small sizes.

Triple negative and basal breast cancers are more frequently found in *BRCA1* carriers and women of African Caribbean or African American ethnicity. Basal breast cancers present at a younger age than luminal (ER positive) breast cancers. Targeted therapy is currently not available but the use of poly ADP ribose polymerase (PARP) inhibitors is being investigated in this patient group.

Other genes

Several other genes [multiple drug resistance (*mdr*) glycoprotein], oncogenes (c-*myc*), apoptotic pathway genes (*bcl2*, *bax*), tumour suppressor genes (*Rb*), growth factors (transforming growth factor α and β families, insulin-like growth factors), growth factor receptors (EGFR), proteases (cathepsin D) and cell cycle-related genes (*p21*, cyclin D) have been among the many studied in breast cancer. Each has its enthusiasts, but to date they have added little to clinical practice.

Gene signatures

Combining a series of genes into a predictive and/or prognostic profile has resulted in the generation of some dozen or so molecular tests. Many are based on the RNA extracted from frozen or formalin-fixed paraffin-embedded tissues whereas others have used immunohistochemistry predictors. While these technologies remain the subject of clinical trials, they aim to predict which patients may not need chemotherapy (the MINDACT trial based on frozen material and the MammaPrint diagnostic platform) or which ER-positive patients may benefit from chemotherapy (the TAILORx trial using the Oncotype DX test and formalin-fixed, paraffin embedded material). The clinical use of these technologies has not been well established worldwide and their cost together with the need for further evidence of their utility has held back the introduction of such tests into everyday clinical practice.

Epidemiology of breast cancer

It is estimated that the world burden of breast cancer is some 1 million women newly diagnosed each year. The extent of the breast cancer problem can be illustrated based on the data from the UK. Breast cancer is the most common incident cancer among women, with some 48 000 new registrations, and accounts for 25% of the female cancer burden excluding non-melanoma skin cancer. For women, the lifetime risk of developing breast cancer is 11%; it is the commonest cause of death in women aged 40–50 years.

Breast cancer is the second most common cause of death from cancer in women (after lung cancer). Survival has improved over the past 20 years in, for example, Scotland, with 56% 5 year relative survival having been reported for those diagnosed between 1968 and 1972, compared with 70% for those diagnosed between 1988 and 1992, rising to 90% for women diagnosed in 2004. However, even allowing for pathological stage, there is evidence of variation between different patient groups.

The rising incidence of breast cancer may be due to the increasingly aged population together with earlier detection (including DCIS, which may never develop into invasive cancer) through screening programmes in addition to the factors listed below. This increasing incidence may be offset by the improved survival secondary to the effect of early detection of small cancers prior to metastasis and the use of adjuvant endocrine therapy, radiotherapy, chemotherapy and biologically targeted therapy.

Aetiological factors in breast cancer

Although the aetiology of breast cancer is multifactorial and may differ between individual women and racial groups, it is clear that breast cancer has a genetic basis upon which internal hormonal influences, diet and external environmental factors act.

Endocrine influences on breast epithelium result in stimulation, then involution, of breast tissue. The number of cycles of stimulation/involution together with the stimulatory effect of exogenous steroid hormones (oestrogen, progesterone) may additively increase the risk of breast cancer.

Age

The risk of breast cancer increases with age, although there is a flattening of the age–incidence curve after the menopause. The median age for breast cancer in Western countries is 60 years.

Hormonal influences

These include:

- Age at menarche (younger age increases the risk).
- Age at menopause (menopause at age 55 doubles the risk compared with menopause at age 45).
- Number of pregnancies (higher number is protective).
- Age at first pregnancy (if over 30, the risk is double that at <20 years at first pregnancy).
- Breastfeeding history (breastfeeding is protective).
- Oral contraceptive use (high oestrogen pills increase risk, whereas low oestrogen/progesterone pills are safer; use before age of 20 increases the risk; note that oral contraceptive use decreases the risk of ovarian cancer). Risk is elevated during and for 10 years after use.
- Hormone replacement therapy (HRT). A recent analysis of pooled published data on HRT and the risk of breast cancer has shown that the relative risk for each year of use is 1.023 and for 5 years or more of use the relative risk is 1.350. For women under the age of 50 this risk is equivalent to having normal menses and therefore women under 50 are at no increased risk. Five years after cessation of HRT, the risk returns to normal levels. A baseline mammogram prior to commencement of HRT is not recommended. Some studies have suggested that cancers diagnosed in women on HRT may be at an earlier stage but the Million Women Study has shown increased breast cancer mortality in current users of HRT. Breast cancer risk from HRT should be balanced against the potential benefits of HRT, including control of menopausal symptoms and osteoporosis.
- Oophorectomy in premenopausal women greatly reduces the risk of breast cancer, the benefit being greatest when oophorectomy is conducted at a young age, presumably by reducing the cyclical oestrogenic stimulation of breast tissue.

Family history

A family history of breast, ovarian, colon, prostate or other cancers is associated with increased risk of breast cancer.

When a family member has had breast or ovarian cancer, their age at onset should be recorded as well as whether the cancer was unilateral/bilateral, the menopausal status of the family member and the relationship to the individual consulting – first-degree relative (mother, sister or daughter); second-degree relative; or maternal or paternal side. There are now guidelines (Box 17.4) for patients to attend risk assessment clinics for screening which, when conducted at centres with expertise and interest in the field, can detect cancers with similar success to breast screening programmes conducted in postmenopausal women.

Mammographic density

Women whose mammogram shows 75–100% dense tissue are at four to five times increased risk of breast cancer compared with women with <10% dense breast tissue. Decreasing breast density in middle life has recently been shown to be associated with a decreased risk of breast cancer.

Diet

Dietary influences on breast cancer risk are most startling when noting the increased risk of breast cancer in Japanese women moving to the USA. Some evidence suggests that soya and phyto-oestrogens are protective, but eating saturated fat and red meat, drinking alcohol (for which there is a dose–response relationship), obesity in postmenopausal women and smoking all increase the risks of breast cancer.

Socioeconomic factors

In the Western world, breast cancer has an increased incidence in higher socioeconomic groups of women, possibly related to different hormonal profiles (age at menarche, age at first pregnancy, etc.) in different social classes. Women from the lowest socioeconomic groups present with later stage disease and appear to have a poorer outcome, despite receiving similar therapies. The reasons for this are unclear.

Other important influences

Atypical epithelial hyperplasia holds a fourfold increased risk of developing breast cancer compared with women who have no proliferative changes. Therapeutic radiation for lymphoma, given as thoracic irradiation in teenage or young women, significantly increases the risk of breast cancer. Smoking now appears to increase the risk of breast cancer.

Familial predisposition

About 5–10% of breast cancers in the West are attributed to a genetic predisposition – there are multiple genes of limited penetrance, inherited in an autosomal dominant fashion.

However, *BRCA1* (17q) and *BRCA2* (13q) account for many of the high penetrant larger families with multiple (four or more) breast and other cancers in close relatives. Within certain populations, the particular mutation identified (e.g. *BRCA2* deletion at position 999 in half of familial cancers in Iceland) demonstrates the genetic lines of inheritance. However, population screening for mutations in *BRCA1* and *BRCA2* is not, at present, realistic given the large size of these genes and the scatter of mutational sites. Inheritance of mutant *p53* (Li–Fraumeni syndrome) or *PTEN* (Cowden syndrome) is even less common. These four genes have comparatively high penetrance resulting in multiple cancer sites within each family and sometimes within each individual. The breast cancers usually occur before the age of 65 years and may be bilateral. Based on a detailed family history, risk estimates can be computed using established tables to help inform women of whether their risk is sufficient to warrant intervention. Other genes such as ataxia telangiectasia (*ATM*), *FGFR2* and other low penetrative genes probably account for many of the smaller families (two or three cases) in which *BRCA1* and *BRCA2* have been excluded.

Early detection and prevention of breast cancer

Based on the concept that detecting and treating precancerous lesions and small cancers (before they have metastasized to the regional nodes and/or further afield) could save lives, breast screening and, more recently, (chemo)prevention of breast cancer in high-risk groups have been implemented.

Breast screening

There is currently no evidence to support the view that clinical breast examination by a doctor, nurse or patient should be considered as a primary screening technique. However, since the majority of breast cancers are found by women themselves, women should be encouraged to become aware of the feel and shape of their breasts, so that they are familiar with what is normal for them and to report any change from normal to a medical practitioner.

National breast screening programmes, such as in the UK, performed by mammography, aim to reach >70% of the target population and require considerable organization and a built-in quality assurance programme. Digital two-view mammography (craniocaudal and oblique), with double reading of films performed every 2–3 years, should maximize the detection of small (<15 mm) breast cancers.

The UK National Health Service Breast Screening Programme (NHSBSP) aims to detect 7.3 cancers/1000 women screened of both the first (prevalent) attendence at age 50–52 and on average at subsequent incident rounds. Eighty percent of the cancers detected will be invasive, 20% non-invasive, of which nearly all are DCIS. More than 50% of the cancers detected should be <15mm in pathological size.

Some two-thirds of screen-detected abnormalities prove to be insignificant on further mammographic/ultrasound review. For the remainder, triple assessment is required, and, since two-thirds are impalpable, ultrasound- or mammographic-guided biopsy with core or vacuum (wide bore core) biopsy should establish the diagnosis. Mass lesions and distortions should initially be biopsied using core biopsy whereas vacuum biopsy is the biopsy method of choice for calcifications. Lesions of uncertain malignant potential (papillomas and radial scars) but without cellular atypia have a low upgrade rate and can be removed using vacuum excision, whereas lesions with cellular atypia have higher upgrade rates and should be removed at surgery. For invasive malignant lesions a preoperative diagnosis rate of 95% should be achieved. Preoperative diagnosis rates for DCIS are lower at around 85%.

Screen-detected cancers are, in general, smaller, better differentiated, more likely to be of special type and node negative than symptomatic cancers; these features agree with the concept of detecting 'early' cancers, when the chances of metastasis are less and mortality is lower. Thus, population screening by mammography can reduce mortality from breast cancer by up to 25% in those who attend.

In the UK, women in the 50–70 years age range are invited every 3 years for screening through the NHSBSP aiming to achieve a 29% reduction in mortality. Meta-analyses of the international screening mammography trials also show statistically significant mortality reduction of 18–29% in the 40–49 years age group. The efficacy of screening women in their forties in the UK has been evaluated in the UK Co-ordinating Committee on Cancer Research (UKCCCR) Age trial. This study showed a non-significant 17% mortality reduction. Thus, with evidence that screening can be effective in the 40–70 years age group, there is the potential for reducing the mortality of breast cancer by using population-based screening. Unfortunately, this approach cannot be adopted throughout the world, owing to constraints on resources or the pattern of clinical care in some countries.

Radiation risk and mammography

It is thought that ionizing radiation increases the risk of breast cancer development after a latent period of 10 years, that the risk is cumulative and that the risk is greatest for adolescent exposure. This is based on the increased incidence of breast cancer in women who have had therapeutic thoracic radiotherapy for lymphoma, and decreases with increasing age at exposure. In those aged over 50 years, the risk of cancer induction is, very approximately, 1:100 000 per single view mammographic examination. The average dose per examination (single view per breast) is approximately 1–2 mGy, the dose being dependent on breast thickness and exposure factors used.

Women at increased risk of breast cancer

It is estimated that some 5% of all cases of breast cancer are attributable to inheritance of a gene conferring a high lifetime risk of breast cancer. A characteristic of many cases of genetically determined breast cancer is early age of onset. Several genes predisposing to breast cancer have been identified including *BRCA1*, *BRCA2*, *ATM* and *p53*.

Some women with histologically identifiable lesions, e.g. LCIS or severe atypical hyperplasia, are at a higher relative risk (of about two- to fourfold) of breast cancer. The risk is further increased when there is a positive family history. Thus, women with LCIS or ADH should have annual or biennial mammography. DCIS is considered below.

Only those women judged to be at substantially increased risk (Box 17.4) should be considered at present for detailed genetic assessment and follow-up in specialist clinics. In families with four or more relatives affected with either breast or ovarian cancer in three generations and one living affected individual, direct gene testing might be appropriate.

Management of women at high risk of breast cancer

For some families, the risk decreases with age and this should be reflected in their management. Women at high risk of breast cancer have three options: increased frequency of screening, including the use of MRI; chemoprevention; or prophylactic surgery.

Increased frequency of screening

Regular clinical and mammographic examination has been offered to young women at high risk of breast cancer without controlled trials. The efficacy of screening of young, high-risk women is at present uncertain, but a recent review by the UK Familial Breast Cancer Group suggested targeted screening may be as efficacious in this age group as in the NHSBSP.

In the UK, it is suggested that mammography should start at the age of 35 years, or 5 years younger than the youngest affected family member, whichever is younger. For women at high risk of breast cancer:

- <40 years: biennial mammography and annual clinical examination
- 40–50 years: annual mammography and clinical examination
- >50 years: depending on the risk, either discharge to NHSBSP or continue more frequent screening.

In the UK, known gene carriers (or women at equivalent risk) who do not opt for prophylactic surgery are eligible for annual MRI screening. MRI screening in this patient group has been shown to have superior performance in detecting small node-negative breast cancers than ultrasound or mammography. Women with *BRCA1* mutations have a high frequency of basal phenotype tumours. Basal cancers, unlike other types of breast cancer, may not have improved survival if detected early, so the use of MRI screening in *BRCA1* carriers remains unproven.

Prophylactic surgery

Some women at very high risk (>35% lifetime risk) of breast cancer may wish to consider prophylactic bilateral mastectomy, usually with reconstruction. If subcutaneous mastectomy is considered, the risk from residual ductal tissue deep to the nipple or in the tail of the breast must be recognized as any familial genetic defect would theoretically be carried by all remaining cells. The consequent reduction in the incidence of breast cancer by 90% in such high-risk women is considered worthwhile.

Management of women with autosomal dominant inheritance who develop breast cancer

Causal mutations can be identified in some 20% of high-risk breast cancer families. Genetic testing must involve formal pre- and post-testing counselling in person by a clinical geneticist. Predictive tests should only be undertaken in diagnostic laboratories with appropriate quality control.

Women who carry a mutant *BRCA1* or *BRCA2* gene and develop early breast cancer have a risk of developing cancer in the contralateral breast of up to 64%. In such patients presenting with good prognosis tumours, bilateral mastectomy should be discussed with the patient by her surgeon.

The risk of ovarian cancer is dependent on the family history and gene involved. Both high-risk (63% lifetime risk at 70 years) and low-risk (<40%) families exist. Preliminary data suggest that prophylactic salpingo-oophorectomy does reduce the risk of ovarian cancer.

Assessment, investigation and staging of breast cancer

Methods of assessing breast conditions, including breast cancer, are based on triple assessment: clinical history and examination, imaging and pathological assessment.

Imaging of symptomatic breast disease

In patients with symptomatic disease two-view mammography should be performed: craniocaudal and oblique views (Figure 17.13) supplemented by compression/paddle or magnification views. The radiological classification of breast appearances is listed in Table 17.1. Mammography is not recommended under the age of 40 years unless there is a strong clinical suspicion of carcinoma. Ultrasound examination may provide additional information to mammography (Figure 17.3), and can be useful to visualize focal breast disease in women under 40 years in whom the breast is radiologically dense and lesions may be more difficult to detect. Thus, mammography alone may not exclude

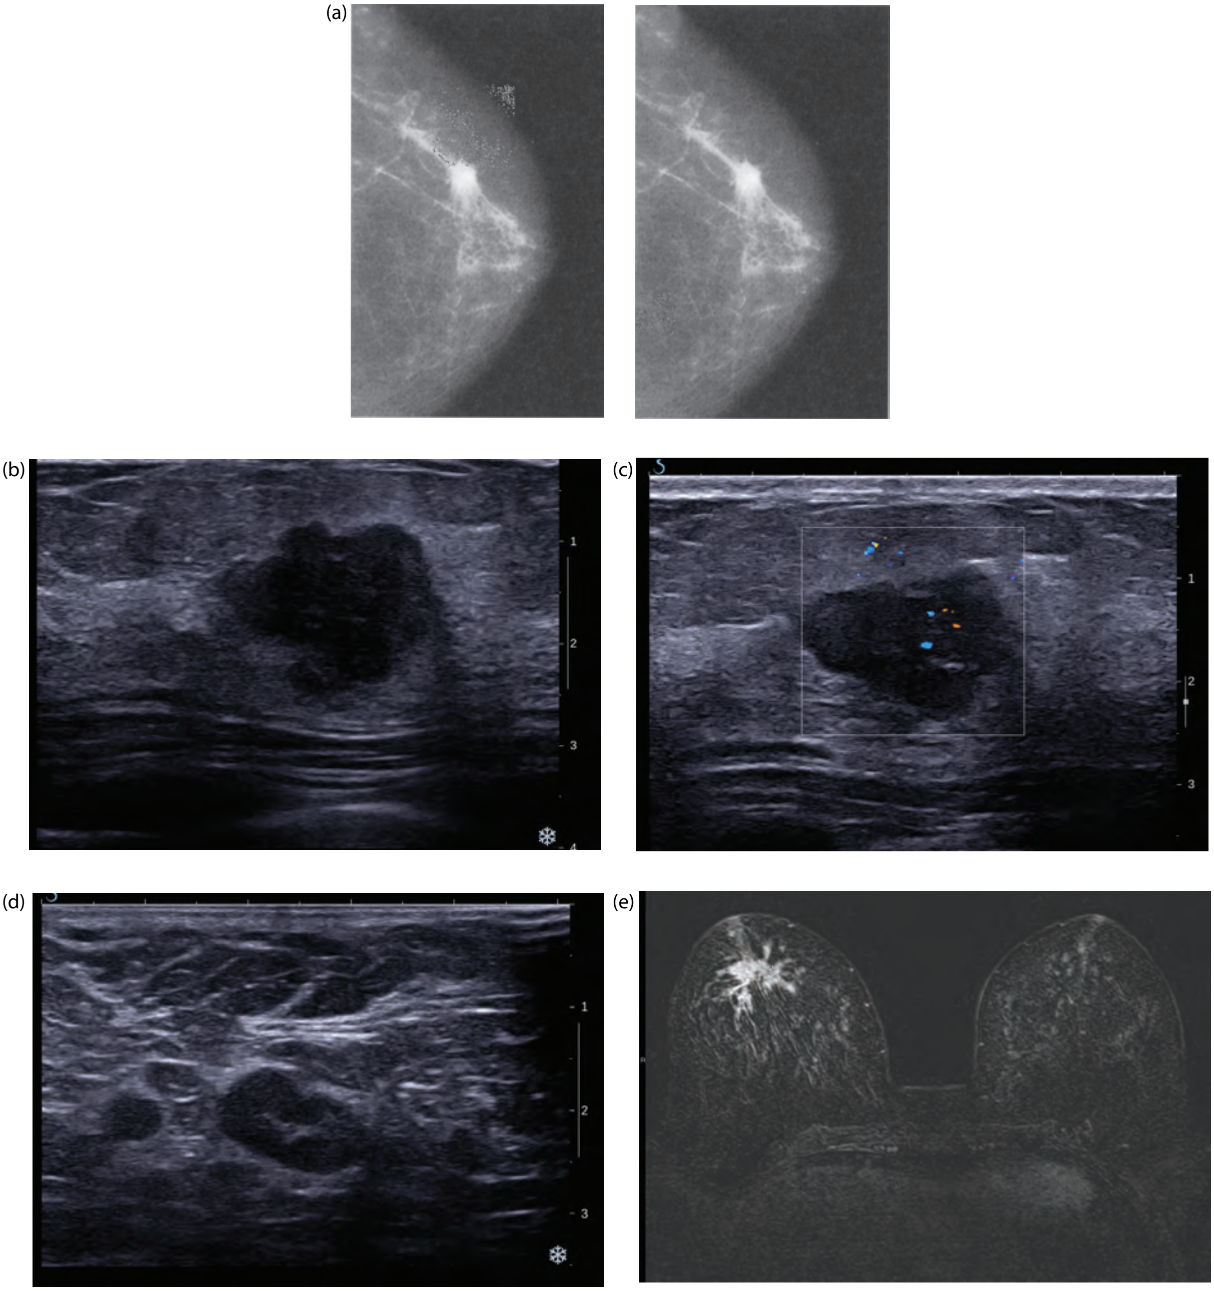

Figure 17.13 Images of breast cancer: (a) mammograms of a screen-detected breast cancer showing a spiculated mass. (b) Ultrasound image showing an ill-defined, inhomogeneous, irregular mass. (c) Colour Doppler image of a breast cancer showing central neovascularity. (d) Ultrasound of the axilla showing a node with a thickened cortex due to axillary metastasis. (e) MRI of invasive cancer.

Table 17.1 Classification of radiological appearances

Mammograms		Breast type		Ultrasound	
R1	Normal	N1	Good visualization; no masses/calcification/deformities	U1	Normal/diffuse benign
R2	Benign	P1		U2	Single cyst
R3	Indeterminate	P2		U3	Solid benign
R4	Probably malignant	PDY	Dense; cannot rule out masses	U4	Suspicious of malignancy
R5	Malignant	DY		U5	Malignant
				U6	Multiple cysts

breast cancer, particularly in younger women. Ultrasound is superior to mammography in characterizing breast masses. It is the primary imaging tool in women who are young, pregnant, lactating or have suspected infection. Ultrasound is also useful in the preoperative assessment of the axilla in breast cancer patients. Ultrasound has improved in recent years with additional techniques such as power Doppler and elastography.

Stereotactic (mammographic) or ultrasound-guided core biopsy should be performed on impalpable lesions that are suspicious or equivocal on radiological review. This may provide sufficient information to allow a benign lesion to be left *in situ*, but, if clinical doubt persists or the patient requests, needle localization biopsy of the impalpable lesion with specimen radiographs is necessary to allow histological examination of the appropriate portion of the biopsy specimen. Palpable lesions are also best biopsied under ultrasound control.

Other imaging modalities

MRI has a number of well-defined indications:

- sizing lobular cancers prior to wide local excision or mastectomy
- sizing breast cancer when conventional assessments are difficult or conflicting
- indentifying the primary tumour in women with metastatic adenocarcinoma in the axillary nodes and normal mammography, breast ultrasound and clinical breast examination
- identifying intracapsular rupture of silicone implants
- assessment of response in women receiving neoadjuvant chemotherapy
- excluding invasive cancer in women with mammographically detected lesions not amenable to image-guided biopsy.

Positron emission tomography/CT, breast CT and breast-specific gamma imaging are promising imaging modalities but their place in routine clinical practice is yet to be defined.

Histological diagnosis of breast cancer

Core biopsy of a focal breast abnormality using a 14 G needle with a 22 mm throw is the best method of obtaining a histological diagnosis of most breast lesions. The reported samples are classified as B_1 (normal tissue), B_2 (benign), B_3 (lesion of uncertain malignant potential), B_4 (suspicious of cancer), B_{5a} (DCIS) or B_{5b} (invasive cancer).

B_3 lesions are subdivided on basis of epithelial atypia. Lesions without atypia have low upgrade rates at surgery so vacuum removal is an option. Lesions with atypia have higher upgrade rates and require surgical excision. Lesions yielding a B_4 result are often repeated to try to make a definitive diagnosis of malignancy. Immunohistochemistry to give ER, PgR and HER2 status can be performed on the core samples giving a B_{5b} result. Provisional grade and typing of invasive cancers and DCIS can be performed on core biopsy samples. Preoperative diagnosis rates for DCIS using core biopsy are not high, so many units now use 11 G vacuum biopsy devices, which are associated with higher diagnosis rates of DCIS and lower upgrade rates of ADH to DCIS and DCIS to invasion than core biopsy.

Staging of breast cancer

Clinical staging of breast cancer

Patients are staged clinically according to the Union for International Cancer Control TNM classification (Table 17.2). Although clinical assessment of tumour size is not completely accurate, and ultrasound, mammogram or MRI can be more accurate, there is reasonable correlation between clinical tumour size and final pathological assessment. All patients with a breast mass should have a careful clinical examination and the mass may be measured with callipers. The presence or absence of any signs of local advancement (inflammation, peau d'orange, ulceration, satellite nodules, direct chest wall involvement, fixed axillary nodes) should be noted and recorded. Clinical examination is an unreliable guide as to whether there is involvement of the axillary nodes by metastatic breast cancer. Ultrasound of the axilla and biopsy of abnormal nodes is able to give a preoperative diagnosis of nodal involvement in about 40% of cases.

In early, operable breast cancer (T1–2, N0–1), there is no current evidence to support routine screening for metastatic disease in asymptomatic women. Such patients should normally only have investigations to confirm general fitness, which may include a chest radiograph, ECG, full blood count, urea, electrolytes and liver function tests. Patients with symptoms suggestive of metastases require appropriate investigation. The incidence of asymptomatic metastases increases as the T (Figure 17.14) and N stage of the locoregional cancer increases. If it will affect treatment, patients with more advanced but operable disease (T3, N1–2) may require staging to exclude distant metastases. Screening for metastatic disease is best performed with chest, abdominal and pelvic CT scan. Such investigations aim to identify bone, visceral and soft-tissue metastases. If metastases are detected, the tumour markers CEA and CA15-3 may be elevated and can be useful for monitoring disease progression in certain patients.

Pathological staging of breast cancer

The pathology staging of breast cancer follows similar principles to clinical staging, but requires tissue to stage the tumour size

Table 17.2 Tumour (T)–node (N)–metastasis (M) staging

T Primary tumour		
TX		Primary tumour cannot be assessed
T0		No evidence of primary tumour
Tis		Carcinoma *in situ*: intraductal carcinoma, or lobular carcinoma *in situ*, or Paget's disease[a] of the nipple with no tumour
T1		Tumour 2 cm or less in greatest dimension
	T1mic	Microinvasion[b] 0.1 cm or less in greatest dimension
	T1a	More than 0.1 cm but not more than 0.5 cm in greatest dimension
	T1b	More than 0.5 cm but not more than 1 cm in greatest dimension
	T1c	More than 1 cm but not more than 2 cm in greatest dimension
T2		Tumour more than 2 cm but not more than 5 cm in greatest dimension
T3		Tumour more than 5 cm in greatest dimension
T4		Tumour of any size with direct extension to chest wall[c] or skin
	T4a	Extension to chest wall
	T4b	Oedema (including peau d'orange), or ulceration of the skin of the breast, or satellite skin nodules confined to the same breast
	T4c	Both 4a and 4b, above
	T4d	Inflammatory carcinoma[d]
N Regional lymph nodes		
NX		Regional lymph nodes cannot be assessed (e.g. previously removed)
N0		No regional lymph node metastasis
N1		Metastasis to movable ipsilateral node(s)
N2		Metastasis to ipsilateral axillary node(s) fixed to one another or to other structures
N3		Metastasis to ipsilateral internal mammary lymph node(s)
M Distant metastasis		
MX		Distant metastasis cannot be assessed
M0		No distant metastasis
M1		Distant metastasis

[a] Paget's disease associated with a tumour is classified according to the size of the tumour.

[b] Microinvasion is the extension of cancer cells beyond the basement membrane into the adjacent tissues with no focus more than 0.1 cm in greatest dimension. When there are multiple foci of microinvasion, the size of only the largest focus is used to classify the microinvasion. (Do not use the sum of all the individual foci.) The presence of multiple foci of microinvasion should be noted, as it is with multiple larger invasive carcinomas.

[c] Chest wall includes ribs, intercostal muscles and serratus anterior muscle but not pectoral muscle.

[d] Inflammatory carcinoma of the breast is characterized by diffuse, brawny induration of the skin with an erysipeloid edge, usually with no underlying mass. If the skin biopsy is negative and there is no localized measurable primary cancer, the T category is pTX when pathologically staging a clinical inflammatory carcinoma (T4d). Dimpling of the skin, nipple retraction or other skin changes, except those in T4b and T4d, may occur in T1, T2 or T3 without affecting the classification.

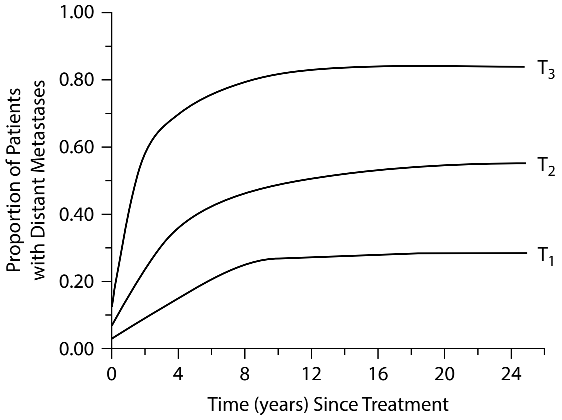

Figure 17.14 Tumour size in relation to proportion of patients with metastases following initial treatment for breast cancer.

and whether there is involvement of regional lymph nodes. The TNM stage is then adapted to pTpN and, when pathology material is available from a metastasis, pM. For lymph nodes the presence of micrometastases or isolated tumour cells may also be noted but are currently considered to be pN0.

Pathology

Prognostic factors

In the management of breast cancer, prognostic factors aid the selection of treatment for individual patients. Tumour size (measured histological larger size means worse prognosis), axillary node metastasis (Figure 17.15) (on pathology, not clinical, grounds, survival is directly correlated with the number of lymph nodes involved – women with >10 nodes do particularly badly), high histological grade, lymphatic and/or vascular invasion and the presence of distant metastasis are all important prognostic factors.

Prognostic indices

Combined with tumour grade, histological tumour size and pathological node status have been used to construct the Nottingham Prognostic Index (NPI), where NPI = (tumour size in cm × 0.2) + lymph node stage (1, no nodes; 2, one to three nodes positive; 3, four or more nodes involved) + grade (1, 2 or 3). Originally forming three prognostic groups (good, moderate, poor) the NPI is now used to place patients in one of five prognostic groups (Blamey, 1996) (Table 17.3).

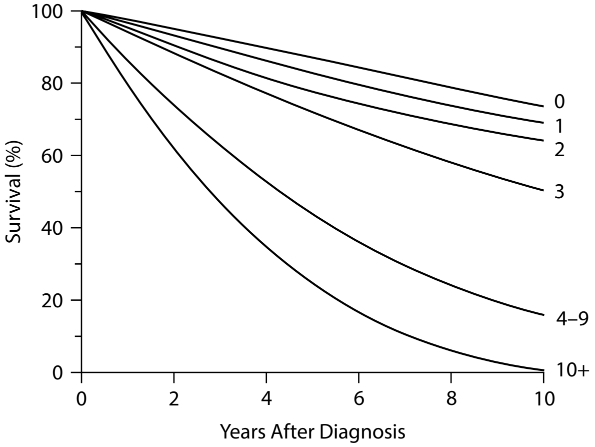

Figure 17.15 Axillary node involvement (number of nodes on pathology review) compared with survival following the diagnosis of breast cancer.

Table 17.3 Nottingham Prognostic Index (NPI) groups

Prognostic group	NPI	10 year survival (%)
Excellent	≤2.4	94
Good	≤3.4	83
Moderate I	≤4.4	70
Moderate II	<5.4	51
Poor	>5.4	19

Computational techniques have been used to develop the Adjuvant! online program, which incorporates additional information (such as the patient's age and ER status) and can estimate the likely benefit to a patient of receiving endocrine and/or chemotherapy. More recently, the PREDICT prognostication model has been used to predict breast cancer survival following surgery for breast cancer, based on UK cancer registry data, and can also take into account the mode of detection of the cancer.

High-risk subtypes of breast cancer

Locally advanced breast tumours

These are defined as primary tumours >5 cm in size (or fixed to skin or chest wall) or, less often, patients with bulky or fixed axillary lymph nodes. These patients would thus be staged as T3–4, N0–2, M0. As previously mentioned, there is a significant risk of these patients having detectable metastatic disease, and they should be formally staged by CT even if asymptomatic, to confirm the absence of overt metastases.

Some of these patients ('small' T3 tumours, 'localized' T4 tumours) will be operable but, for most patients, their initial management will be non-surgical. The diagnosis should be confirmed by core biopsy and the receptor status measured.

Inflammatory breast cancer

This aggressive locally advanced breast cancer presents clinically as an inflamed and tender breast; the patient may well have been initially treated with antibiotics. The diagnosis should be confirmed by core biopsy, although this may need more than one attempt, since the inflammatory reaction within the breast may make it difficult to obtain definitive histology. Inflammatory breast cancer is associated with high morbidity and mortality and has a 5-year survival of 50%, with only 30% of patients disease free at 10 years.

These tumours do not respond well to endocrine management and, because of their rapid growth, should be treated with initial chemotherapy and then subsequent surgery/radiotherapy to achieve the best local control, disease-free survival and overall survival.

Overview of breast cancer management

It is well established that breast cancer is a spectrum of diseases associated with different clinical behaviours and treatment should be tailored appropriately. Therefore, management of patients with breast cancer may involve surgery, radiotherapy, systemic therapy (hormonal and/or chemotherapy) or a combination of these. Since there remain uncertainties in the management of breast cancer, consenting patients should be entered into appropriate clinical trials when possible. Many patients want to be, and benefit from being, fully informed of the possible treatment options, and involved in the decisions about their treatment. The availability of a breast care nurse and discussion within a multidisciplinary team is helpful in this respect.

Management options by stage

These are as follows:

- All patients with T1–3, N0 or 1, M0 should be considered for surgical resection of the primary tumour and evaluation/resection of the ipsilateral axillary nodes; however, surgery may follow the administration of systemic therapy (neoadjuvant therapy) in select patients.
- Some patients with larger T2 (>2 cm) or T3, N0 or 1, M0 tumours may be considered for primary systemic therapy (neoadjuvant endocrine, chemotherapy or biologically targeted therapy) prior to surgery. This neoadjuvant approach may improve rates of breast conservation and can be informative about the individual tumour response to therapy.
- Most T4 tumours are initially inoperable but may become operable after a course of primary systemic therapy or radiotherapy.
- Very small numbers of patients (usually elderly) with potentially operable breast cancer are not anaesthetically fit for a surgical procedure; if ER positive, primary endocrine therapy may be beneficial.
- Patients with established distant metastatic disease should be managed palliatively but actively. Core biopsy of metastasis, used to confirm the diagnosis, will also allow ER and HER2 assessment.

Most patients will complete their initial treatment and then enter survivorship follow-up.

Operable breast cancer

Surgery to the breast

There are three established surgical procedures for invasive breast cancers:

1. wide local excision
2. quadrantectomy or segmentectomy
3. mastectomy.

Both wide local excision and segmentectomy would normally be followed by radiotherapy. The combination of wide local excision or segmentectomy and radiotherapy is often called breast conservation. Randomized controlled clinical trials have shown that in tumours up to 4 cm in size treatment by mastectomy or breast conservation (surgery plus radiotherapy) results in no significant difference in overall survival. Local recurrence rates are similar with a non-significant relative reduction in favour of mastectomy. Patients undergoing conservation have similar psychological morbidity to those undergoing mastectomy, but have greater freedom of dress and better body image than women who have had mastectomy.

Conservation surgery

Wide local excision is excision of a tumour with a margin of clearance of both invasive and *in situ* disease. Wide local excision (sometimes referred to as lumpectomy) should be performed with due respect to the skin lines of the breast and the likely cosmetic result (Figure 17.16); for invasive disease, an axillary procedure (see below) may be conducted under the same anaesthetic. Lateral margins (histopathological) should be 1 mm or more clear of disease. There are no direct comparisons between wide local excision (1 cm macroscopic clearance) and segmental excision (1 cm macroscopic clearance but the excision incorporating tissue from the nipple right out to the periphery of the breast) or quadrantectomy (similar excision to segmental excision but with 2–3 cm macroscopic margin clearance). The most important factor related to cosmetic outcome is the volume of tissue excised relative to the volume of the breast and therefore quadrantectomies if not followed by reconstruction (e.g. a latissimus dorsi miniflap) produce less good cosmetic results than wide local excision or segmental excision.

A central tumour is not a contraindication to conservation although it may necessitate removal of the nipple and areola, which may compromise cosmesis for some patients. Similarly, oncoplastic remodelling of the breast at the time of resection can reduce the shape and volume of deformities.

Oncoplastic remodelling can range from the judicious apposition of tissues with undermining of the skin through swung flaps of breast tissue (including skin if necessary) to reduction mammoplasty approaches. The contralateral breast may require symmetrization procedures, which may be achieved under the same operation or left to a later date.

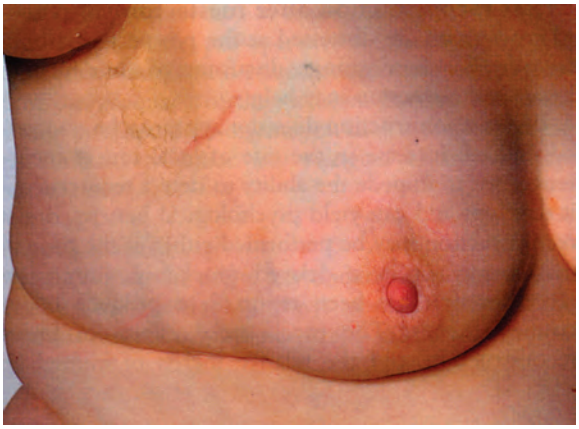

Figure 17.16 Breast conservation: surgical scars following wide local excision of a breast cancer from the 12 o'clock position and axillary node sampling.

Mastectomy

The decision whether to recommend mastectomy or breast conservation will depend on the factors listed in Box 17.6.

Mastectomy is indicated for operable breast cancer which is either large or at multiple sites, when radiotherapy is to be avoided, or by patient preference. A (now standard) modified radical mastectomy removes the skin overlying the cancer, nipple areolar complex and all breast tissue including the axillary tail, but leaves the pectoral muscle intact (removed in a radical mastectomy) and may avoid the need for radiotherapy in many cases. Patients with high-grade tumours, pathology size >5 cm, lymphatic permeation or multiple axillary node involvement have a significantly higher risk of locoregional recurrence that can be reduced by supplementing mastectomy with postoperative radiotherapy. When mastectomy is carried out, axillary clearance is usually performed.

Mastectomy may be complicated postoperatively by haematoma or seroma formation beneath the skin flaps (and hence most surgeons leave in a vacuum drain beneath the skin flaps), wound infection (which should complicate <2% of operations) or, rarely, flap necrosis.

Breast reconstruction after mastectomy

Many women are distressed at the prospect of a mastectomy. For these women, discussion of breast reconstruction may help.

Breast reconstruction does not appear to be associated with an increase in the rate of local cancer recurrence nor does it impede the ability to detect recurrence if it develops, and it can yield psychological benefit. Breast reconstruction may be performed either at the time of mastectomy or as a delayed procedure. Immediate reconstruction has been reported to

BOX 17.6 Factors influencing choice of breast surgery

- The ratio of the size of the tumour to the size of the breast:
  - smaller tumours in larger breasts are more suitable for breast conservation than larger tumours in smaller breasts: a cut-off of 4 cm tumour diameter is often quoted
- The pathological features of the tumour (if known):
  - extensive *in situ* component
  - histological grade II or III
  - lymphatic/vascular invasion
- There is an increased risk of local recurrence if disease (invasive or DCIS) is <1 mm from the margins of excision or present at multiple sites
- Age of patient:
  - Patients aged <35 years are at increased risk of local recurrence
- The patient's own preference
- Fitness for surgery and/or radiotherapy.

produce better cosmetic results. The psychosocial effects of breast reconstruction, and the relative merits of immediate and delayed surgery, have not been adequately studied.

The choice of operation for an individual patient depends on several factors including tumour site, breast size, the adequacy of skin flaps and whether radiotherapy is planned or has been previously used.

Methods comprise:

- An implant filled with silicone or saline that can be placed subcutaneously or subpectorally. Despite some adverse publicity there is no evidence that silicone prostheses are associated with significant systemic problems. Soya oil implants have now been withdrawn worldwide leaving saline-filled implants as the only alternative.
- Use of a tissue expander, placed in either the subpectoral or subcutaneous plane, which can be expanded to provide a matched size with a contralateral side and then partially deflated to allow ptosis or replaced with a silicone or saline implant with repositioning as necessary (Figure 17.17). Tissue expansion is not recommended following radiotherapy owing to the fibrotic process induced by radiation.
- Myocutaneous flaps. (1) A latissimus dorsi (LD) flap together with overlying skin based on the neurovascular supply to the LD may be used to replace a defect after mastectomy but often requires a prosthesis deep to the muscle to ensure adequate bulk and ptosis on the reconstructed side (Figure 17.18). LD miniflaps, in which skin is not taken, can be used to replace bulk following quadrantectomy and may be harvested using laparoscopic equipment and techniques. (2) Transverse rectus abdominis myocutaneous (TRAM) flap may be performed either as a pedicle flap based on the superior epigastric artery or as a free flap based on the deep inferior epigastric artery with a microvascular anastomosis between the inferior epigastric and the subscapular vessels or internal mammary artery. This provides a good bulk of tissue of similar consistency to normal breast and, together with contralateral surgery and nipple reconstruction or tattooing, can give outstanding results (Figure 17.19). The deep inferior epigastric flap (DIEP) uses perforating vessels from the epigastric artery and, although this involves microvascular anastomosis (usually to the internal mammary vessels), results in less abdominal wall defect. Other free autologous flaps include the gracilis or gluteal vessel based flaps.

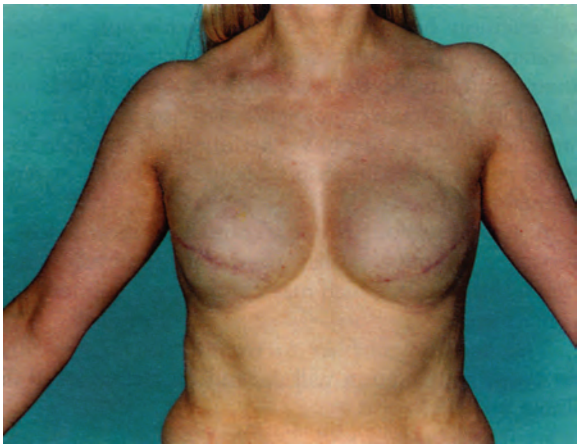

Figure 17.17 Patient who has undergone bilateral mastectomy, bilateral tissue expansion and most recently replacement of the expanders with silicone prostheses.

Surgery to the opposite breast, mastopexy or reduction mammoplasty, may be required to achieve symmetry. Techniques for reconstruction of the nipple/areola complex have been described. Alternatively, acceptable nipple prostheses may be made by taking a mould from the existing nipple or nipple tattooing.

Complications of breast reconstruction include infection of the prosthesis, necrosis of skin or flap tissue (ranging from minor fat necrosis to necrosis of the whole flap in <5% of patients)

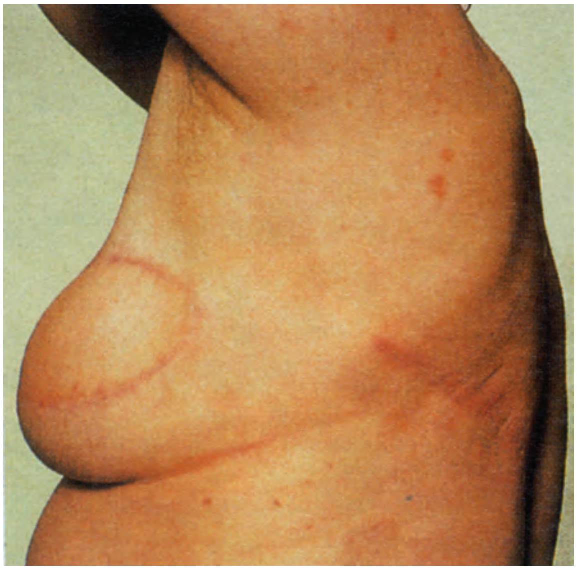

Figure 17.18 Lateral view of latissimus dorsi reconstruction showing the posterior scar and the skin/muscle reconstruction (with silicone implant) demonstrating good ptosis of the breast.

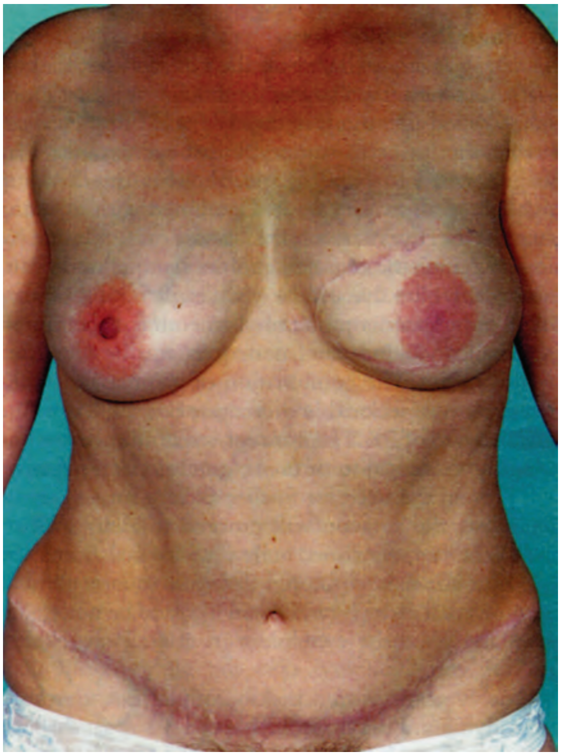

Figure 17.19 Left transverse rectus abdominis myocutaneous free flap reconstruction plus nipple tattooing. Note abdominal donorsite scar.

and puncture or leakage of implants (10% at 10 years); fibrotic capsule formation around the implant (requiring capsulotomy or capsulectomy) is now less common (<10% at 1 year) owing to the use of textured implants, but cosmetically unsatisfactory results can still occur.

Who should perform breast reconstruction? Should it be the same surgeon who performs the mastectomy? There are advantages and disadvantages to the same surgeon performing both operations. Certainly, the surgeon performing the reconstruction should be fully trained in all the appropriate techniques and, in most units, will be a plastic surgeon. Patients who are being prepared for a mastectomy should be informed of the option of reconstruction and, if appropriate, should discuss the options with a surgeon trained in reconstructive techniques, prior to their surgery.

Impalpable tumours

Mammographic screening is increasingly detecting lesions which are radiologically suspicious of malignancy but impalpable. While stereotactic core or vacuum biopsy may provide satisfactory diagnostic material, excision of an impalpable lesion may be required for diagnosis, and excision of histologically proven cancer for therapeutic breast conservation requires localization of the radiologically detected lesion. Excision of a needle-localized radiological abnormality (Figure 17.20) may thus be considered diagnostic (if lesser procedures have failed to establish the diagnosis) when the procedure will simply excise the area targeted, or a therapeutic procedure to excise the radiologically abnormal area with a 10 mm rim of normal tissue while at the same operation axillary sentinel node biopsy may be performed. The diagnostic biopsy of a benign lesion should weigh <30 g, the intention being to minimize breast disruption by the diagnostic procedure.

Localization can be performed under either ultrasound or stereotactic guidance and then guiding one or more fine wires to the localized lesion. A check film is taken to allow the surgeon to place an appropriate incision and excise the abnormal area (Figure 17.20a).

Specimen radiology of the excised lesion while the patient remains anaesthetized (local anaesthesia or general anaesthesia may be used for this procedure) ensures that the correct area of tissue has been removed by comparison with preoperative mammography (Figure 17.20b), and subsequent histological examination is required to confirm the adequacy of the excision. Excised specimens should be marked for orientation so that the pathologist can indicate whether any margins of excision are inadequate.

Paget's disease

Depending on the site of any underlying primary, either wide local excision (with/without radiotherapy) or mastectomy (if the lesion is distinct from the Paget's disease) is satisfactory.

Ductal carcinoma *in situ*

Localized areas of DCIS should be completely excised with a wide margin (minimum 2 mm) on pathology review.

In patients with extensive DCIS (>4 cm) (Figure 17.21) or disease affecting more than one quadrant, a mastectomy should usually be performed and results in 98% 5 year survival. Surgical staging of the axilla is not required for DCIS alone.

Following adequate local excision of DCIS, patients should be considered for radiotherapy to the breast. While a 1 cm margin of normal tissue around DCIS may be sufficient to gain local control, there is a reduction in recurrence or the development of invasive cancer in those given radiotherapy following wide local

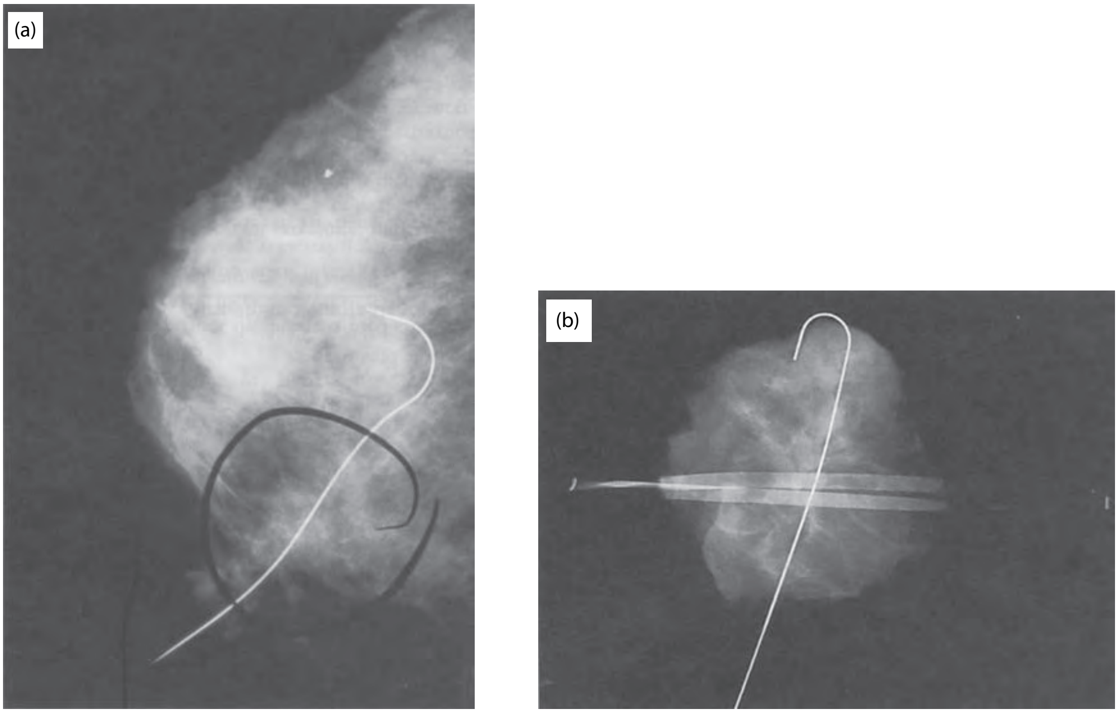

Figure 17.20 Needle localization for impalpable screen-detected cancer: (a) mammogram with localizing wire in place; (b) excision biopsy confirmatory film.

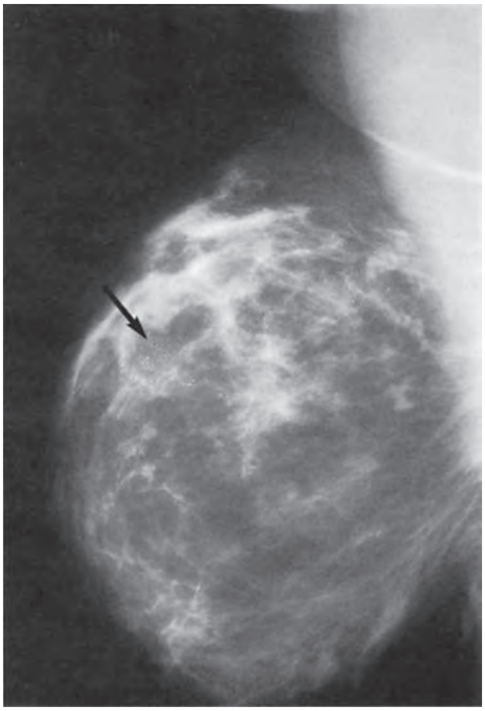

Figure 17.21 Ductal carcinoma *in situ* on a screening mammogram showing pleomorphic branching calcifications.

excision of high-grade DCIS. The role of systemic endocrine treatment may be to reduce development of contralateral DCIS.

Axillary surgery is not usually recommended in patients with DCIS alone; however, patients with large areas of high-grade DCIS have a 50% chance of occult invasion on excision. In these circumstances, sentinel node biopsy may be appropriate.

Lobular carcinoma *in situ*

Women with LCIS diagnosed on core biopsy require surgical diagnostic biopsy to exclude the presence of DCIS or invasive cancer. Women with LCIS diagnosed or confirmed at surgery require mammographic screening because of their increased risk of future breast cancer.

Surgery to the axilla

Lymphatic drainage from the breast is predominantly to the axilla, although metastatic breast cancer may spread via internal mammary, intercostal or interpectoral nodes.

One of the most important prognostic indicators is whether there has been spread of cancer to the axillary lymph nodes (Figure 17.15), and hence it is used as one of the major determinants of appropriate systemic adjuvant therapy. Axillary surgery should be performed in all patients with invasive operable breast cancer. Axillary nodes lie inferior to the axillary vein and are classified in relation to the pectoralis minor muscle, with level I lateral to, level II posterior to and level III medial to pectoralis minor.

Although present in only 23% of screen-detected cancers, some 40% of symptomatic cancers have axillary metastases.

For larger tumours (T3 and above) a complete level I, II and III axillary clearance is the treatment of choice.

Table 17.4 Recommended management of axillary nodes for operable breast cancer

Impalpable cancer or <4 cm, clinically node negative	Sentinel node biopsy
Proven axillary metastases	Level I, II and III clearance

Since only 5% of node metastases are ‘skip metastases’, missing the lower level I nodes but involving level II or III, for small cancers there is emerging consensus as to the best way to manage the axilla (Table 17.4).

The following procedures are practised.

To stage the axilla

Sentinel node biopsy

Based on the concept that there is a first or sentinel axillary node draining breast cancer, radiolabelled albumin is injected adjacent to the cancer up to 24 hours prior to surgery; breast scintigraphy may be performed to confirm that the label has travelled and highlighted an axillary node. Combined with injecting patent blue dye around the cancer at the time of surgery, lymphatic channels and the sentinel node containing the blue dye can be visually identified (Figure 17.22) and a gamma probe used to confirm the hottest (sentinel) node. A second node may commonly be identified by this means. The combination of gamma and visual detection is superior to either alone but still has a false-negative rate of 5%. Immediate histological examination of the sentinel node, if negative, will prevent the need for further axillary surgery. If positive, by cytology, frozen section or polymerase chain reaction at the time of surgery or on subsequent immunohistochemistry, the surgeon will proceed to immediate or subsequent, axillary clearance.

To treat the axilla

Axillary node clearance – a block dissection of the axillary contents – comprises the tissue bounded by the axillary vein (superiorly), LD, serratus anterior and pectoralis major, and the apex is situated at the point where the axillary vein passes over the first rib.

Level I is up to the lateral border of pectoralis minor; level II is up to the medial border of pectoralis minor; and level III is up to

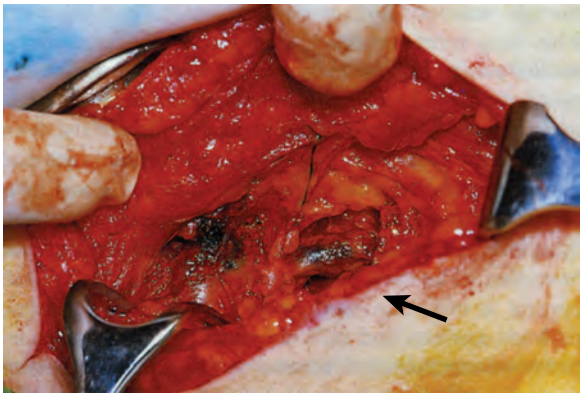

Figure 17.22 Sentinel node biopsy: blue dye staining lymphatics and two sentinel nodes. The lower node contained a high radiolabel signal and had a small focus of metastatic breast cancer.

the apex of the axilla. Care is taken to preserve the neurovascular supply to serratus, latissimus and pectoralis major and cutaneous nerves and not to dissect superior to the axillary vein.

Complications of axillary clearance include seroma formation (50%), infection (5%), cutaneous nerve damage, shoulder stiffness (5%) and pain. Long-term complications include upper limb lymphoedema (up to 15%), neural damage or restricted shoulder movement (10%).

There is no advantage of axillary clearance over axillary radiation in terms of survival at 10 years, nor does either have an advantage in terms of regional control of disease.

Only level III dissection fully stages the axilla and treats nodal disease. Further treatment of the axilla (radiotherapy or surgical re-excision) may be required for patients who have had a level I or II dissection to achieve local disease control if involved nodes are identified histologically, but risks lymphoedema. Further treatment after level III dissection is only considered if the nodes cannot be adequately cleared or if there is extranodal spread of the tumour. Clearance and radiotherapy increases the risk of lymphoedema of the upper limb to some 40%.

Only 5% of women with breast cancer have internal mammary node metastases, usually from medially placed cancers, but 90% of these women also have axillary metastases, so most surgeons do not perform internal mammary node biopsy.

Rarely, breast cancer may present with axillary nodes but no clinically evident breast primary. While mammography and MRI may identify an occult lesion in two-thirds of these patients, in the remainder level III axillary clearance with observation (clinical and radiological) of the breast may be the treatment of choice.

Adjuvant radiotherapy

Radiotherapy has been used after surgery for breast cancer for decades. Indeed the move from radical mastectomy was facilitated by trials showing that simple mastectomy and radiotherapy produced results equivalent to radical mastectomy, with less loss of function. A generation later, trials showed that, for patients with small operable tumours, wide local excision and postoperative radiotherapy were equivalent in terms of survival and local control to conventional mastectomy. Postoperative radiotherapy is now used following mastectomy (selectively) or breast conservation for operable breast cancer.

Postmastectomy radiotherapy

Radiotherapy and local control

Radiotherapy given after mastectomy will reduce the risk of isolated local recurrence by approximately two-thirds. The absolute benefit will depend on the risk of recurrence: thus, if the risk of recurrence without radiotherapy is 39%, this will be reduced to 13% with radiotherapy, an absolute benefit of 39% − 13% = 26%. Conversely, a risk of recurrence of 3% would be reduced to 1%, an absolute benefit of 2%. The former would certainly be clinically useful, whereas, for the latter, the toxicities of radiotherapy would probably outweigh the (modest) benefit.

Radiotherapy after mastectomy is thus generally recommended only for those patients judged to be at a particular risk of recurrence, i.e. large primary tumour size (>5 cm), more than three involved nodes, high histological grade, lymphatic and/or vascular invasion and involved (usually deep) margins. The risk of local recurrence is a summation of these factors, although there is no convenient formula to quantify them.

Systemic adjuvant therapy (see page 398) does reduce the risk of local recurrence, but radiotherapy confers additional benefit and the relative reduction in local recurrence is independent of any systemic therapy. Thus, the decision as to whether to recommend postmastectomy radiotherapy depends on the perceived risk of recurrence, bearing in mind the pathological factors considered above and the systemic therapy to be offered.

Extent of radiotherapy

For the reasons mentioned above, radiotherapy will normally certainly include the chest wall. Whether the axilla is included depends on the type and results of axillary surgery. If the axilla has been formally assessed as negative by sentinel node biopsy then axillary radiotherapy will not improve local control within the axilla. Conversely, a positive sample should be followed by either level III axillary clearance or axillary radiotherapy. A surgical clearance of the axilla should both stage and treat the axilla. Radiotherapy following axillary clearance will substantially increase the risk of morbidity without any increase in local control. The only exceptions are when a clearance is known to have left residual disease and/or there is extensive extracapsular spread – these patients are at high risk of local recurrence with its associated morbidity, which must be balanced against the morbidity of treatment.

The supraclavicular fossa and internal mammary chain of nodes have been irradiated as part of standard therapy in some centres, but without clear evidence of benefit. Isolated internal mammary chain recurrence is rare and supraclavicular recurrence is a manifestation of metastatic relapse.

Radiotherapy after breast conservation

All studies have shown that radiotherapy to the breast following limited breast surgery reduces the risk of local recurrence. Table 17.5 shows the recurrence rate for three trials in which different surgical procedures were used. Although these are not direct comparisons, the data suggest that, when more extensive surgery (quandrantectomy or sector resection) is used, the local recurrence

Table 17.5 Comparison of effect of radiotherapy and the extent of breast surgery on recurrence rate

Type of surgery	**Wide local excision**	**Sector resection**	**Quadrantectomy**
Name of trial	NSABP	Uppsala–Orebro	Milan
No. of patients	1450	381	579
No radiotherapy	39%	7.6%	10%
Radiotherapy	10%	2.9%	0%
Duration	8 years	3 years	3 years

NSABP, National Surgical Adjuvant Breast and Bowel Project.

rate without radiotherapy is less (albeit at the cost of an impaired cosmetic result). Nevertheless, even with more extensive surgery, radiotherapy significantly reduces the local recurrence rate.

If the patient has systemic adjuvant therapy as well as surgery, radiotherapy further reduces the risk of local recurrence; the magnitude of the effect is very similar to that seen after mastectomy. Trials have not identified a group of patients in whom radiotherapy does not reduce the risk of recurrence and hence in whom it could be safely omitted. Nevertheless, the absolute benefit of radiotherapy for (especially older) patients with small, grade 1, node-negative breast cancers is small and there are ongoing trials quantifying this risk. Thus, radiotherapy is of potential benefit to all patients undergoing breast conservation and should only be omitted if the clinician feels, after discussion with the patient, that the morbidity of radiotherapy does not justify the excess recurrence risk for that patient.

Most recurrences after breast-conserving surgery occur in the tumour bed and hence some studies have looked at whether radiotherapy to the tumour bed alone may be adequate in terms of local control. This has consisted of a single dose of intraoperative radiotherapy given at the time of surgery (the TARGIT trial) or fractionated brachytherapy given later (ELIOT trial).

Effect on survival

Although the importance of local treatment (surgery, radiotherapy) on local control has long been recognized, the concept of breast cancer as a systemic disease at presentation used to discount the importance of local therapy in terms of survival. An overview of trials of radiotherapy (after both breast-conserving surgery and mastectomy) has shown that an improvement in local control at 5 years translates into an improvement in 15 year mortality – approximately for every four local recurrences avoided, there is an avoidance of one breast cancer death at 15 years. There is a similar but smaller effect on 15 year overall mortality. Longer follow-up (>15 years) has also shown a modest but real excess in overall mortality with an excess of deaths from heart disease and lung cancer in irradiated patients. These trials were inevitably started decades ago (1960s and 1970s), when radiotherapy techniques were very different, so one would expect (and hope) that modern techniques that limit the amount of heart and lung irradiated would be safer. There is thus good evidence that improving local control can affect survival, presumably by the recurrence acting as the focus for metastatic reseeding. The practical implications are that local control is important and needs meticulous technique by both surgeon and radiotherapist to minimize morbidity, maximize local control and hence improve survival.

Dosage and complications

Radiotherapy was traditionally given to the breast/chest wall and lymphatics as a dose of 50 Gy in 25 daily fractions over 5 weeks, but recent trials have shown that equivalent rates of local control and cosmesis can be obtained by giving 40–42 Gy in 15 or 16 fractions over 3 weeks, as exemplified by the START trial. Further reductions in the number of fractions ('hypofractionation') are the subject of ongoing studies.

Since local recurrences occur in the tumour bed, it has been common practice to give a higher dose (a 'boost') to the tumour bed. A large EORTC trial showed that this improved local control but that this was at the expense of some impairment in cosmesis. The benefit of the boost was mainly in patients at higher risk of recurrence (mainly younger patients, i.e. under 50), and hence a policy of tailoring the boost to the risk of recurrence is widely practised.

Patients can expect a degree of skin erythema and fatigue during and shortly after radiotherapy to the breast. Supraclavicular radiotherapy may cause transient oesophagitis. In the long term, a small number of patients develop breast oedema and/or fibrosis. As mentioned earlier, radiotherapy to the axilla can cause lymphoedema, especially if given after axillary clearance.

Systemic therapy for breast cancer

Breast cancer was the first cancer to be treated systemically when Beatson reported the benefits of oophorectomy for young patients with advanced breast cancer in 1896. Most patients will receive some form of systemic therapy, whether this be adjuvant or palliative in intent.

Adjuvant systemic therapy

For many patients, invasive breast cancer is a systemic disease at presentation, albeit the metastases are not detectable and only become apparent during the ensuing years. The rationale of systemic adjuvant therapy given after surgery is to treat and hopefully eradicate the occult distant metastases and hence improve survival. There have been numerous trials of adjuvant therapy and the results of these have contributed to the regular overviews of the Early Breast Cancer Trialists' Collaborative Group (EBCTCG). These confirm that adjuvant endocrine, cytotoxic and biological therapy can improve both recurrence-free and overall survival in a subset of patients with clinically localized disease. The principles and magnitude of the benefits of adjuvant therapy can be illustrated by considering the results of trials of ovarian ablation. For premenopausal women not receiving chemotherapy, ovarian ablation reduces the odds of death by 24%, but Figure 17.23 shows, first, that there is a slightly greater effect on recurrence-free survival than on overall survival, and, second, that the absolute reduction varies according to the risk of relapse. In other words, node-positive women have a higher absolute benefit because they are at a higher risk of relapse.

In effect there are three groups of women, as summarized in Table 17.6 (percentage defined at 10 years).

Women in group A have significant occult metastatic disease that is either resistant to or not eradicated by the systemic therapy. They may gain some prolongation of disease-free survival but they will not gain any survival advantage.

Those in group B have occult distant metastases that are eradicated by systemic therapy and hence achieve a personal cure; they are thus the true beneficiaries of systemic adjuvant therapy (and represent the difference between the curves in Figure 17.23).

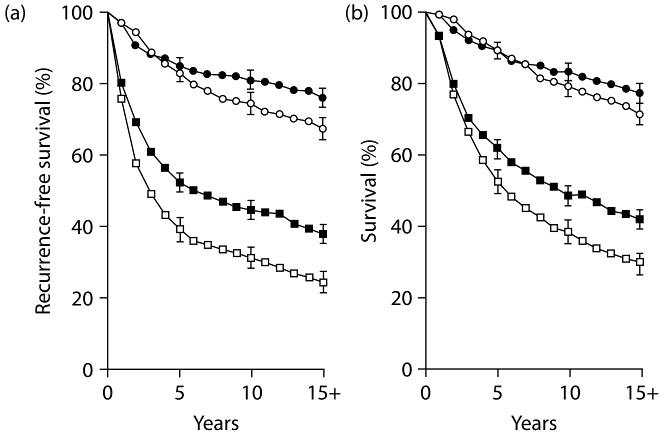

Figure 17.23 Effects of ovarian ablation alone in breast cancer.
(a) Recurrence-free survival for node-negative women <50 years (upper pair of curves), demonstrating improved survival for women who had ovarian ablation (top line) versus controls (second line); for node-positive women <50 years (lower pair of curves), better survival for patients who received ovarian ablation (third line down) versus control (bottom line). (b) Overall survival for node-positive women <50 years (upper pair of curves), demonstrating improved survival for women who had ovarian ablation (top line) versus controls (second line); for node-positive women <50 years (lower pair of curves), better survival for patients who received ovarian ablation (third line down) versus control (bottom line).

Table 17.6 Relative benefit of ovarian ablation on survival (see text)

Group	A	B	C	Total
Node negative	24%	6%	70%	100%
Node positive	58%	13%	29%	100%
Occult metastases	Resistant	Sensitive	None	

Those in group C had no metastases at presentation and do not benefit from systemic therapy since they would have survived anyway.

Table 17.6 also summarizes the relative size of the groups for both node-positive and -negative patients. Adjuvant systemic therapy can significantly improve the outlook for patients with breast cancer and has contributed to the recent improvement in survival. Nevertheless, most patients will not derive personal benefit from it and it is important to balance the morbidity of treatment (for all) against the benefit (for a minority).

Although a survival benefit has rarely been demonstrated with the administration of therapy prior to surgical resection, neoadjuvant therapy should be strongly considered in a subset of patients with localized breast cancer. In these cases, the diagnosis should be confirmed by a core biopsy, since a positive fine needle aspirate does not discriminate between invasive and *in situ* disease.

Specifically, candidates for neoadjuvant therapy include patients with locally advanced breast cancer, patients with triple receptor-negative breast cancer >1–2 cm in size or with positive lymph nodes on initial evaluation, young patients with tumours >2 cm in size regardless of receptor or nodal status, or patients with large tumours who are interested in breast-conserving surgery. The administration of neoadjuvant therapy has no worse outcome than the administration of adjuvant therapy; however, several benefits can be derived from preoperative systemic therapy. First, by decreasing the size of the primary tumour, tumours may be 'downstaged' from inoperable to operable in select patients. Second, although most patients (~80%) will have either a complete (CR) or partial response in the primary tumour, because the effects of treatment are directly observed, therapy can be altered in cases of disease progression, which results in less patient exposure to the toxicity of ineffective drugs. Additionally, a subset of patients will develop a complete pathological response (pCR) to neoadjuvant therapy, which has been associated with an extremely good prognosis. Finally, the use of neoadjuvant therapy has become a powerful tool in drug development as it offers the opportunity to obtain tissue before and after therapy to correlate tumour response with molecular parameters of drug response.

Choice of systemic therapy

The choice of appropriate adjuvant (and neoadjuvant) therapy will be determined by the:

- receptor status of the tumour
- patient's menopausal status
- patient's risk of recurrence (based mainly on age, nodal status, tumour size and tumour grade).

The selection of systemic therapy requires individual discussion of clinical and pathology findings, which may be helped by using the NPI, Adjuvant! Online or similar programs, and molecular testing as an aid to decision-making (see page 385).

Endocrine therapy

In most women, defining menopausal status is usually straightforward. Particular caution should, however, be exercised in premenopausal women whose periods stop after adjuvant chemotherapy. Their periods can return some considerable time after chemotherapy and hence such women should not be treated with aromatase inhibitors.

Ovarian ablation

Ovarian ablation reduces the odds of recurrence by 25% and of death by 24% (a similar order of improvement to that achieved by polychemotherapy), but is only of benefit to premenopausal women. Many of the trials of ovarian ablation were carried out before hormone receptor status was measured, but more recent studies suggest that the benefit is clearly confined to women with hormone receptor-positive tumours. Ovarian ablation can be performed either laparoscopically, by a short course (usually four fractions) of low-dose radiotherapy to the pelvis ('radiation menopause'), or medically using a gonadotrophin analogue (usually given as a monthly subcutaneous injection into the abdominal wall). The optimal duration of 'medical oophorectomy' has not been established, but has generally been 2–5 years and has become the favoured method because of its reversibility. All methods seem to work, although there are few comparative data. The main side effects of all approaches are those of a menopause – flushes, sweats, mood changes – but are often worse than a physiological menopause, because of the precipitative nature of the menopause.

Selective oestrogen response modulators

Selective oestrogen response modulators (SERMs) structurally resemble oestrogens and bind to ERs, which decreases proliferation and induces tumour regression in ER-positive breast cancer cells. The most commonly prescribed SERM is tamoxifen, a drug which has demonstrated clinical benefit for the treatment of hormone receptor-positive breast cancer in both the adjuvant and metastatic settings. Although tamoxifen acts as an 'antioestrogen' in cancer cells, it is an oestrogen agonist in normal tissue. For example, in postmenopausal women, tamoxifen gives some protection against osteoporosis and reduces blood cholesterol. Additionally, tamoxifen is associated with a small, but significant, increased risk of venous thrombotic disease and endometrial hyperplasia, which can progress to endometrial cancer.

In the adjuvant setting, 5 years of tamoxifen was associated with a 41% reduction in the risk of recurrence and 34% reduction in the risk of death from breast cancer in women with ER-positive breast cancer. This effect was greater than that seen with 2 years of adjuvant tamoxifen. Ten years of adjuvant tamoxifen is better than 5 years at reducing the risk of breast cancer recurrence, although the effect is seen only beyond 10 years, thus establishing 10 years of tamoxifen therapy as the standard of care for the adjuvant treatment of hormone receptor-positive breast cancer in premenopausal women.

Tamoxifen is reasonably well tolerated, but up to 40% of women can experience side effects such as hot flushes, weight gain, gastrointestinal upset, loss of libido and vaginal dryness or discharge. For some women, the severity of these side effects may be enough for them to cease taking tamoxifen.

Aromatase inhibitors

For postmenopausal women, oestrogen is produced by aromatization of androgenic precursors. Inhibition of aromatase, the enzyme that converts androgenic substrates into oestrogens, has been a target for drug development for over two decades; however, early inhibitors were associated with significant toxicity and incomplete suppression of oestrogen synthesis. Third-generation aromatase inhibitors, such as anastrozole, letrozole and exemestane, were noted to have improved efficacy with acceptable toxicity and are commonly used to treat postmenopausal women with either localized or advanced hormone receptor-positive breast cancer.

In the adjuvant setting, aromatase inhibitors have also demonstrated improved efficacy compared with tamoxifen in risk reduction for breast cancer recurrence. The Arimidex, Tamoxifen, Alone or in Combination (ATAC) trial was a randomized double-blind adjuvant therapy trial conducted in postmenopausal women with surgically treated, hormone receptor-positive (or unknown) breast cancer. Patients were randomized to receive either oral anastrozole 1 mg daily or oral tamoxifen 20 mg daily, or the combination. Interim analysis of the combination arm demonstrated no improvement compared with tamoxifen alone and accrual to this arm was halted. Single agent anastrozole significantly improved disease-free survival and time to recurrence compared with single agent tamoxifen. Patients receiving anastrozole also developed fewer contralateral breast primary tumours than those taking tamoxifen.

These results have been validated by additional studies with letrozole or exemestane as primary adjuvant therapy or following tamoxifen in a cross-over design. To date, it is not clearly established whether initial therapy with an aromatase inhibitor is preferred to therapy with tamoxifen followed by an aromatase inhibitor. Currently, the use of adjuvant therapy with aromatase inhibitors is limited to postmenopausal patients; however, data from ongoing clinical trials such as the SOFT or TEXT trials are maturing and will determine the benefit of ovarian ablation and aromatase inhibition as adjuvant therapy in premenopausal women with hormone receptor-positive breast cancer.

Neoadjuvant endocrine therapy has also been used for the treatment of postmenopausal women with operable hormone receptor-positive breast cancer and, in at least one small randomized phase II study in postmenopausal hormone receptor-positive breast cancer, treatment with the aromatase inhibitor exemestane demonstrated similar response rates to doxorubicin and paclitaxel. Several randomized trials have demonstrated improved response rates for neoadjuvant therapy with aromatase inhibitors compared with tamoxifen. There appears to be similar efficacy among the aromatase inhibitors used for neoadjuvant therapy.

Cytotoxic therapy

Because of toxicity and the risk of long-term morbidity, the use of chemotherapy is a complex decision in the treatment of breast cancer. In the adjuvant and neoadjuvant settings, the use of chemotherapy depends upon the risk of recurrence and the receptor status of the tumour.

Many chemotherapy drugs have activity against breast cancer. Anthracyclines exert their effects by inhibiting topoisomerase II and increasing DNA fragmentation. Taxanes, epothilones, vinca alkaloids and analogues of halichondrin B exert their cytotoxicity by affecting microtubular dynamics and blocking the progression of mitosis. Nucleoside analogues, such as 5-fluorouracil, capecitabine and gemcitabine, induce apoptosis by affecting DNA replication. Alkylating agents (e.g. cyclophosphamide) and platinum salts cross-link DNA strands and induce apoptosis. Common toxicities associated with chemotherapy drugs used to treat breast cancer include myelosuppression, alopecia, nausea/vomiting, neuropathy and, in the case of anthracyclines, cardiomyopathy, which can cause congestive heart failure. Neutropenic sepsis is an uncommon, but serious (and occasionaly fatal), complication of chemotherapy administration and warrants immediate intervention with broad-spectrum antibiotics, including coverage for Gram-negative pathogens. Chemotherapy can also induce cessation of menses, which may be permanent; thus, premenopausal patients should always be warned of the risk of an early menopause and loss of fertility. Not all premenopausal patients experience menopause, however, so these patients should be counselled to avoid conception, since all chemotherapy drugs can be damaging to the fetus if administered during the first trimester of pregnancy.

The EBCTCG (2012) overview confirms that adjuvant polychemotherapy using an anthracycline-containing combination, such as FEC (5-fluorouracil, epirubicin, cyclophosphamide) or an anthracycline/taxane combination, produces an approximately one-third reduction in breast cancer mortality. This proportional risk reduction is little affected by nodal status, hormone receptor status, tumour grade or size, age or the use of adjuvant tamoxifen. The absolute benefit however depends on the risk of relapse without chemotherapy. The absolute benefit of adjuvant chemotherapy is greater for node-positive women than those who are node negative because their risk of relapse is higher. Chemotherapy seems to be of benefit to patients with both ER-positive and -negative tumours.

In the adjuvant and neoadjuvant settings, a combination of drugs is more effective than one alone, and a prolonged course of multiple doses more effective than a single dose for increasing disease-free recurrence and overall survival (Table 17.7). Early adjuvant chemotherapy trials in patients with lymph node-positive disease established a regimen of cyclophosphamide, methotrexate and 5-fluorouracil (CMF) as the standard of care. Subsequent studies have incorporated an anthracycline (usually doxorubicin or epirubicin), and the overview shows that these drugs can produce a further reduction in the odds of recurrence or death (compared with CMF) of about 11–12%, which translates to an absolute survival gain of about 2–3%. Some of these studies also demonstrated similar relative risk reductions in patients with lymph node-negative breast cancer. The addition of taxanes to adjuvant anthracycline-based regimens resulted in an additional improvement in disease-free survival of ~14% and overall survival of ~13%. To date, no adjuvant trials have demonstrated improvement in survival with chemotherapy agents added to anthracycline/taxane-based regimens or the use of high-dose chemotherapy with stem cell transplantation.

Randomized controlled trials have also been conducted to evaluate the benefit of neoadjuvant compared with adjuvant chemotherapy in patients with operable breast cancer. These studies demonstrated improvements in the numbers of patients able to undergo breast-conserving surgery; however, no difference was seen in disease-free or overall survival. pCR rates can be achieved in 12–80% of women treated with neoadjuvant chemotherapy (depending on tumour subtype and drugs used) and these patients have a better prognosis with improved overall survival than those whose tumours do not respond completely to therapy.

Biological therapies

HER2 overexpression occurs in approximately 13% of primary invasive breast cancers (and some 25% of metastatic breast cancers) and has been correlated with poor prognosis. Trastuzumab, a recombinant humanized monoclonal antibody against the extracellular domain of HER2, was the first biological therapy effective in breast cancer.

Trastuzumab is considered to be standard of care as adjuvant therapy for patients with HER2-positive localized breast cancer. The National Surgical Adjuvant Breast and Bowel Project (NSABP) B-31 trial and the North Central Cancer Treatment Group N9831 intergroup trial demonstrated that the addition of trastuzumab to standard adjuvant chemotherapy (doxorubicin and cyclophosphamide every 3 weeks for four cycles followed by paclitaxel with/without trastuzumab) improved disease-free survival and overall survival in patients with localized breast cancer. Comparison of the concurrent with the sequential arms in N9831 revealed an improvement in disease-free survival favouring the concurrent arm (hazard ratio 0.75, 95% confidence interval 0.60–0.94, $p = 0.019$); however, no difference in overall survival has been reported to date. Similar results were seen in the Herceptin Adjuvant Breast International Group 01-01 trial. In this study, adjuvant trastuzumab was administered after completion of adjuvant systemic chemotherapy using a 3-weekly administration schedule of trastuzumab for 1 or 2 years. The optimal duration of trastuzumab administration (1 versus 2 years) has yet to be defined.

The Breast Cancer International Research Group 006 compared anthracycline- and non-anthracycline-based chemotherapy regimens in combination with trastuzumab. This study demonstrated improvement in disease-free survival with the addition of trastuzumab to adjuvant chemotherapy and to date there has been no significant difference in disease-

Table 17.7 Pivotal adjuvant chemotherapy trials

Author/trial	Treatment regimens	*N*	Disease-free survival	*P*-value	Overall survival	*P*-value
Bonadonna	CMF × 6 cycles vs no chemotherapy	207 179	29% 22%	NS	25% 16%	NS
NSABP B-15	AC × 4 cycles vs CMF × 6 cycles vs AC × 4 cycles→CMF × 3 cycles	734 732 728	62% 63% 68%	NS NS NS	83% 82%	NS
CALGB 9344	AC × 4 cycles vs AC × 4 cycles→paclitaxel × 4 cycles	1551 1570	65% 70%	0.0023	77% 80%	0.0064
NSABP B-28	AC × 4 cycles vs AC × 4 cycles→paclitaxel × 4 cycles	1529 1531	81% 81%	NS	92% 90%	NS

AC, doxorubicin, cyclophosphamide; CMF, cyclophosphamide, methotrexate, 5-fluorouracil; NS, not significant NSABP, National Surgical Adjuvant Breast and Bowel Project; CALGB, Cancer and Leukemia Group.

free survival in the anthracycline-containing arm compared with the non-anthracycline arm; however, it is important to note that these two arms were not statistically powered to assess equivalence. A Finnish trial that was designed to evaluate the effects of adjuvant docetaxel versus vinorelbine followed by 5-fluorouracil, epirubicin and cyclophosphamide for three cycles included a small subset of 232 patients with HER2-positive disease who also underwent randomization to either chemotherapy alone or in combination with nine treatments of concurrent, weekly trastuzumab. The magnitude of improvement in disease-free survival in this small subset was similar to that seen in trials investigating a more prolonged administration of trastuzumab, bringing into question the optimal duration of trastuzumab therapy. Trials of different durations of trastuzumab are ongoing. Trastuzumab has also demonstrated pCR rates from 12% to 65% when given in combination with neoadjuvant chemotherapy.

In general, single agent trastuzumab is well tolerated and trastuzumab given in combination with chemotherapy does not significantly increase chemotherapy toxicity, with the exception of cardiac toxicity in combination with anthracyclines. In the adjuvant trials, predetermined criteria for holding or stopping trastuzumab were implemented and the rate of congestive heart failure was approximately 4% across the adjuvant trials.

Adjuvant therapy for ductal carcinoma *in situ* and chemoprevention

Tamoxifen has been used as adjuvant therapy for the treatment of DCIS or for prevention of cancer in women at high risk for developing breast cancer. The NSABP B-24 trial randomized 1804 women who had undergone surgical excision of DCIS to receive either tamoxifen or placebo and demonstrated that 5 years of tamoxifen following breast-conserving surgery and radiation therapy for DCIS resulted in an improvement in ipsilateral breast cancer events from 10% to 8.5% (risk reduction 32%) at 15 year follow-up. This benefit was not confirmed in a second European study, which randomized 1701 patients to tamoxifen or placebo and found no difference in breast cancer events between the two arms. The NSABP P-1 study investigated the role of tamoxifen in preventing invasive breast cancer for high-risk women (*n*=13 388). This study was stopped before reaching full accrual as an interim efficacy analysis found that tamoxifen reduced the relative risk of invasive breast cancer events by 43% compared with placebo (absolute risk reduction 1.8%). A second prevention study, IBIS-I, enrolled 7152 women who were randomly assigned to receive tamoxifen or placebo. At a median follow-up of 96 months, the estimated absolute reduction in cumulative incidence of breast cancer was similar to that seen in the P-1 study. Two smaller European studies failed to show statistical benefit; however, a meta-analysis of all four trials demonstrated that tamoxifen significantly reduced the incidence of invasive breast cancer by 38% (1.7% versus 2.6%), but the incidence of serious adverse events such as endometrial cancer or thromboembolic events were also increased by tamoxifen (1.2% versus 0.6%). The STAR trial compared the use of tamoxifen with raloxifen, a SERM that lacks the oestrogen agonist effects of tamoxifen, for the prevention of breast cancer in high-risk women. This study demonstrated a similar risk reduction between the two drugs with fewer thromboembolic and endometrial proliferative/cancer events in women treated with raloxifen. To date, the use of SERMs to prevent breast cancer in high-risk patients and patients with DCIS remains controversial and it is important to note that none of the studies for prevention or treatment of non-invasive breast cancer have demonstrated an improvement in overall survival with the use of SERMs.

Primary medical therapy

Elderly fit patients (>70 years), who constitute 40% of women with potentially operable tumours, have in the past been managed with tamoxifen alone. Although there is no adverse effect on survival, two randomized controlled trials have shown that tamoxifen alone is associated with a higher rate of local recurrence than surgery and adjuvant tamoxifen. Thus, elderly patients with potentially operable tumours able to undergo surgery should be managed in the same way as younger women, rather than by using endocrine therapy as sole therapy. Some elderly women with larger cancers, inoperable disease or who are unfit for anaesthetic with a tumour that expresses ER may respond to neoadjuvant therapy with aromatase inhibitors or tamoxifen to render the tumour operable or gain control of disease for a sustained time without the option of resection. In consideration of which therapy to use, it should be noted that letrozole given for 4–12 months downstages breast cancer more significantly than tamoxifen.

Breast cancer in pregnancy

About 1% of breast cancers occur during pregnancy or lactation, and are thus diagnosed in 1:10 000 pregnancies. The difficulties of detecting a lump in the enlarging breast result in later detection (two-thirds have nodal metastasis). In the first 6 months of pregnancy, mastectomy and clearance form the mainstay of treatment (termination of pregnancy may be considered). In the third trimester, early delivery then conventional surgical or neoadjuvant anthracycline-based therapy may be used. Taxanes should be avoided at all times during pregnancy. Pregnancy after diagnosis/treatment for breast cancer does not appear to reduce survival.

Patients who are unfit for surgery

These will generally be elderly patients and, because of their comorbidity, the principles of their management will be closer to those applicable to metastatic disease than to those applicable to operable breast cancer. In general, the aim of treatment is to control the primary tumour with the least morbidity, maintaining quality of life, so letrozole is usually the most appropriate therapy when the tumour is ER positive on core biopsy.

Radiotherapy alone is not recommended for local control of advanced tumours, although local control rates of 20–40% at 5 years may be obtained in selected cases after using at least 60 Gy conventionally fractionated.

Local and regional recurrence

Local and regional recurrence is defined as recurrence in the treated breast or chest wall, axilla and previously the ipsilateral supraclavicular fossa, although the last is now regarded as a distant relapse.

Relapse in the chest wall, axilla or supraclavicular fossa (Figure 17.24) is usually found clinically – 80% occur within 2 years and most occur within 5 years of initial surgery – and is frequently a harbinger of distant spread. Distant metastases will be found at the time of local relapse in about 20% of patients and about a further 70% will develop distant metastases within 5–10 years following locoregional relapse. Local relapse should be confirmed histologically, by biopsy, since 17% of patients lose (or more rarely gain) ER and PgR positivity or gain (usually) HER2 positivity. Patients with local relapse should be restaged (full blood count, blood biochemistry, CT of chest, abdomen and pelvis), and those with distant metastases managed appropriately.

For patients with apparently isolated local recurrence, the best predictor of prognosis is the disease-free interval (time from initial treatment to local relapse) – the longer the interval the better the prognosis.

Management of local recurrence

Local recurrence may be classified as single spot relapse, multiple spot relapse or a field change.

The aim of treatment is to regain local control – uncontrolled local disease is miserable for the patient and difficult to manage. The management strategy will be determined by the previous treatment, the site of recurrence, its operability and hormone receptor status. The patient should be assessed jointly by the multidisciplinary team and treatment individualized. In general, recurrence in the chest wall or axilla should be removed surgically if feasible, as it usually is for single site or sometimes multiple site recurrence. This may be easier if it is first reduced in extent by systemic therapy (hormone therapy or chemotherapy) and, if not previously used, radiotherapy, which should be employed for field change recurrence. Systemic therapy should be reviewed and may be changed depending on the patient's condition, previous systemic adjuvant therapy and the hormone receptor status of the tumour. Intra-arterial chemotherapy, infusional 5-fluorouracil or photodynamic therapy have all been used to try to achieve local control with limited success. Tissue necrosis with infection may become a significant problem requiring topical metronidazole gel, charcoal dressings or systemic antibiotics. Progression of local disease recurrence often causes troublesome bleeding and may progress to carcinoma *en cuirasse* encircling and constricting the chest wall.

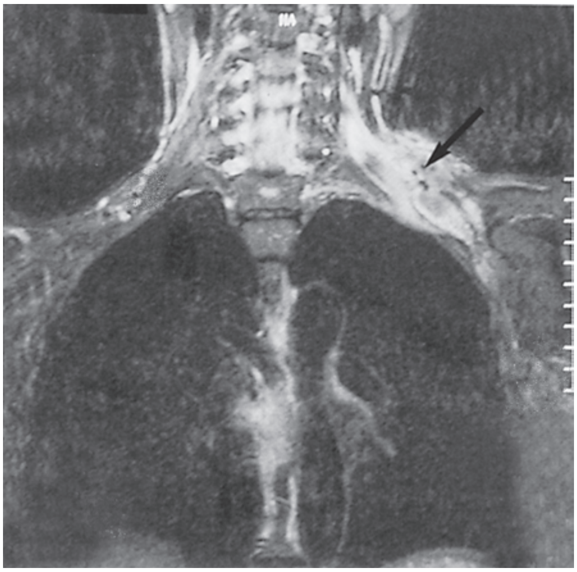

Figure 17.24 MRI showing tumour surrounding and infiltrating the left brachial plexus and right-sided pleural metastases.

Local recurrence in the treated breast

Unlike recurrence after mastectomy, recurrence in the conserved breast occurs at a more constant rate (approximately <1% per year), and is much less commonly associated with distant relapse. It is usually detected clinically and/or mammographically. Further surgery (most commonly mastectomy) is recommended and, after this, the patient may have no further recurrence.

Metastatic disease

Approximately 8% of patients have distant metastases at first presentation, but subsequently most patients with distant metastases will have been previously treated for breast cancer that was apparently localized to the breast and the axillary lymph nodes some time previously.

Patients with metastatic breast cancer are incurable. Treatment is therefore palliative, the aim being to relieve symptoms and maintain the best quality of life. Median survival after the diagnosis of visceral metastatic breast cancer is about 2 years, but there is a 'tail' of patients who survive for 5–10 years. Thus, management varies from the treatment of a patient with a rapidly fatal cancer to the management of what is a chronic, albeit serious, disease.

For the patient with metastatic disease, proper working of the multidisciplinary team is crucial. Her needs will vary over time and she will need access to a wide variety of disciplines. Most patients will be primarily under the care of their family doctor and the practice team, and the secondary sector should aim to support the GP so that the patient has prompt access to the surgeon, oncologist, orthopaedic specialist and palliative care team at the appropriate times.

The presentations of patients with metastases are legion, but among the commonest sites are bone (with pain or fracture; Figure 17.25), pleura (effusion causing dyspnoea; Figure 17.26), liver (lethargy, nausea, anorexia), peritoneal cavity (ascites causing abdominal distension; Figure 17.27), lung (dyspnoea, dry cough), supraclavicular fossa/cervical nodes (Figure 17.24),
